Foreword

The first edition of *Biomarkers in Toxicology*, edited by Ramesh Gupta, was published in 2014. The whole area of biomarkers, not only in toxicology, is rapidly developing, partly because of the availability of highly sophisticated analytical equipment, and so the second edition of this book is greatly welcomed. The second edition contains 12 new chapters, and most of the rest have been updated.

Merriam Webster defines a biomarker as a distinctive biological or biologically derived indicator (as a metabolite) of a process, event, or condition (as, for example, aging, disease, or oil formation). There are other definitions, for example, in Environmental Health Criteria 222 Biomarkers. In Risk Assessment http://www.inchem.org/documents/ehc/ehc/ehc222.htm#1.0 biomarkers are defined thus "A biomarker is any substance, structure or process that can be measured in the body or its products and influence or predict the incidence of outcome or disease." The subject of the present book is biomarkers in toxicology, but it should be remembered that biomarkers include substances used in the detection of numerous diseases, including the autoimmune diseases, which are not generally thought to be toxicological in origin. However, biomarkers are crucial to toxicology and allied disciplines such as epidemiology and risk assessment.

The earliest toxicological biomarkers of exposure date from before precise analytical techniques were available and include the Kayser−Fleischer ring (described 1902/3), usually indicative of copper accumulation in the cornea in cases of Wilson's disease, as well as lead lines in the gums associated with lead toxicity. The cherry red color noted as a (rather unreliable) clinical sign in carbon monoxide poisoning may also be described as a biomarker.

One of the earliest biomarkers relying on biochemical analytical techniques was measurement of cholinesterase activity, initially whole blood cholinesterase and later plasma pseudocholinesterase (butyrylcholinesterase) and red blood cell acetylcholinesterase. Cholinesterase measurements were introduced at defense laboratories after World War II as a screening test for excessive exposure to organophosphate compounds: a 20% depression in activity was considered to mandate cessation of exposure of individuals to organophosphate nerve agents (the basis of the 20% figure is obscure, but seemed protective). Pseudocholinesterase and red blood cell acetylcholinesterase measurements now have numerous uses in worker protection, clinical diagnosis of poisoning, and human and experimental animal studies (including regulatory ones) in relation to the use of organophosphate and other anticholinesterase pesticides. Since World War II biomarkers of toxicity have ballooned in importance and number in worker and consumer protection and clinical and experimental toxicology and are also widely used in regulation of chemicals in animal and, less commonly, human experimental studies. Toxicological biomarkers are also used in allied disciplines, for example, epidemiology, and may be used to estimate loads of exposure in populations being investigated.

In toxicology, biomarkers are often divided into biomarkers of exposure, of effect, and of susceptibility, and all of these are dealt with in this book, which is extremely wide-ranging. The book has an initial introductory part, including discussion of rodent, nonhuman primate, and zebrafish and *Caenorhabditis elegans* models for toxicological testing. There are two new chapters in this part: firstly, *Drosophila melanogaster, Eisenia fetida,* and *Daphnia magna* for toxicity testing and biomarkers and secondly, adverse outcome pathways and biomarkers.

Part II, systems toxicity biomarkers, comprises chapters on biomarkers of toxicity in relation to all important organs and organ systems. There is an additional chapter on reproductive and developmental toxicity biomarkers, and another on ototoxicity biomarkers. Part III, renamed chemical agents, solvents, and gases toxicity biomarkers, deals with biomarkers in relation to the toxicity of specific groups of compounds and comprises chapters on pesticides, as well as polychlorinated biphenyls (PCBs), polybrominated biphenyls (PBBs), brominated flame retardants, polycyclic aromatic hydrocarbons (PAHs), bisphenol A, melamine and cyanuric acid, and metals; there is a very useful chapter on biomarkers of chemical mixture toxicity. Part IV (biotoxins biomarkers) has three chapters on, respectively, freshwater cyanotoxins, mycotoxins, and poisonous plants: biomarkers for diagnosis (of poisoning). Part V covers pharmaceuticals and nutraceuticals, with chapters on drug toxicity biomarkers and nutriphenomic biomarkers together with a new chapter on biomarkers of toxicity for dietary ingredients contained in dietary supplements. Part VI covers nanomaterials and radiation, with two chapters, one on biomarkers of exposure and effect of engineered nanomaterials and the other on biomarkers of exposure and effects of radiation.

Part VII is entitled carcinogens biomonitoring and cancer biomarkers and contains six chapters. These are on biomonitoring exposures to carcinogens, genotoxicity biomarkers, epigenetic biomarkers in toxicology, breast cancer biomarkers, pancreatic and ovarian cancer biomarkers, and prostate cancer biomarkers. Part VIII is called disease biomarkers and deals with biomarkers of Alzheimer's disease, biomarkers of Parkinson's disease, biomarkers for drugs of abuse and neuropsychiatric disorders: models and mechanisms, osteoarthritis biomarkers, pathological biomarkers in toxicology and oral pathology biomarkers. Of these, the chapters on osteoarthritis and oral pathology are new. Part IX is called special topics. This part of the book contains chapters on biomarkers of mitochondrial dysfunction and toxicity, biomarkers of blood-brain barrier dysfunction, biomarkers of oxidative/nitrosative stress and neurotoxicity, cytoskeletal disruption as a biomarker of developmental neurotoxicity, membrane transporters and transporter substrates as biomarkers for drug pharmacokinetics, pharmacodynamics, and toxicity/adverse events, and citrulline: pharmacological perspectives and role as a biomarker in diseases and toxicity. Of these chapters, that on the blood-brain barrier dysfunction is new and is particularly welcome as the blood-brain barrier is very important in protecting the central nervous system against toxicants. The last part of the book is on applications of biomarkers. It contains three new chapters: biomarkers detection for toxicity testing using microarray technology, metabolomics, and proteomics. Also there are chapters on transcriptomic biomarkers, percellome toxicogenomics, biomarkers in computational toxicology, biomarkers in biomonitoring of xenobiotics and biomarkers in toxicology, risk assessment, and environmental chemical regulations.

The 67-chapter book has an outstanding array of authors from the United States, Canada, Denmark, Finland, Greece, India, Italy, Japan, Portugal, Romania, and Spain. Professor Gupta deserves our gratitude for assembling such a distinguished group of experts to produce so comprehensive a book on this rapidly growing and very important field.

Introduction

Ramesh C. Gupta

Toxicology Department, Breathitt Veterinary Center, Murray State University, Hopkinsville, Kentucky, United States

Biomarkers can broadly be defined as indicators or signaling events in biological systems or samples of measurable changes at the molecular, biochemical, cellular, physiological, pathological, or behavioral levels in response to xenobiotics. The Biomarkers Definitions Working Group of the National Institutes of Health (NIH) has defined the biomarker as "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes or pharmacological responses to a therapeutic agent." In the field of toxicology, biomarkers have been classified as markers of exposure, effect, and susceptibility. Measurement of biomarkers reflects the time course of an injury and provides information on the molecular mechanisms of toxicity. These biomarkers provide us the confidence of accurate diagnosis, prognosis, and treatment. The biomarkers of early chemical exposure can occur in concert with biomarkers of early disease detection, and that information aids in avoiding further chemical exposure and in strategic development of a novel treatment, including personalized medicine (i.e., treating the patient, and not the disease). In essence, with the utilization of specific biomarkers, an ounce of prevention can be worth a pound of treatment.

Biomarkers are used in drug development, during preclinical and clinical trials, for efficacy and safety assessment. Biomarkers can reveal valuable information regarding diagnosis, prognosis, and predict treatment efficacy or toxicity; serve as markers of disease progression; and serve as auxiliary endpoints for clinical trials (Stern et al., 2018), with the ultimate goal of delivering safe and effective medicines to patients (Lavezzari and Womack, 2016; Gerlach et al., 2018). In addition, a biomarker in drug development should be ethically acceptable (Hey, 2017). Safety biomarkers can be used to predict, detect, and monitor drug-induced toxicity during both preclinical studies and human clinical trials.

Developing and validating highly sensitive methods for measurement of biomarkers and understanding the resultant data are complex processes that require a great deal of time, effort, and intellectual input. Furthermore, understanding drug metabolism seems essential in some cases, as the metabolite of a drug can be used as a biomarker, and the drug and/or its metabolite has to be patented by the United States Patent Office and by a similar governmental office/agency in other countries. In the past, many drugs were developed with biomarker assays that guided their use, and this trend is likely to continue in the future for drug discovery and development. With the judicious use of biomarkers, as in evidence-based medicine, patients are most likely to benefit from select treatments and least likely to suffer from their adverse effects. On the contrary, utilization of a bad biomarker can be as harmful to a patient as a bad drug. Therefore, biomarkers need to be validated and evaluated by an accredited laboratory, which participates in a proficiency testing program, to provide a high level of confidence to both clinicians and patients.

In the toxicology field, biomarkers should be specific, accurate, sensitive, validated, biologically or clinically relevant, and easy and fast to perform to be useful as predictive tools for toxicity testing and surveillance and for improving quantitative estimates of exposure and dose. Therefore, biomarkers are utilized for biomonitoring data that are useful in a variety of applications, from exposure assessment to risk assessment, management, and regulations (Ganzleben et al., 2017).

In the early 1990s, Dr. Maria Cristina Fossi from the University of Siena, Italy, emphasized the approach for the development and validation of nondestructive biomarkers over destructive biomarkers in the field of toxicology. She described the ideal biomarker as being measurable in readily available tissues or biological products and obtainable in a noninvasive way; related

to exposure and/or degree of harm to the organism; directly related to the mechanism of action of the contaminants; highly sensitive with techniques that require minimal quantities of sample and are easy to perform and cost-effective; and suitable for different species.

The development and validation of new techniques in the laboratory may provide the basis for a valuable field method. But, before a new biomarker's application, some basic information is required, such as dose–response relationships, and biological and environmental factors, which can influence the baseline values of responses. It is important to mention that, when dealing with a biochemical or metabolic biomarker, species differences can be the biggest challenge for any toxicologist.

Biomarkers have applications in all areas of toxicology, especially in the fields of pesticides, metals, mycotoxins, and drugs. In the case of veterinary toxicology, biomarkers of plant toxins deserve equal attention. Farmers, pesticide application workers, and greenhouse workers are exposed to pesticides by direct contact and their family members can be exposed via secondhand exposure. Measurement of residues of pesticides, and their metabolites and metals in urine, serves as the most accurate and reliable biomarkers of exposure in agriculture, industrial, and occupational safety and health settings. Recent evidence suggests that in utero or early life exposure to certain pesticides, metals, and other environmental contaminants may cause neurodegenerative (Alzheimer's, Parkinson's, schizophrenia, Huntington's, ALS, and others) and cardiovascular diseases, diabetes, and cancer later in life. In these diseases and many others, specific and sensitive biomarkers play important roles in early diagnosis, and this can serve as the cornerstone for timely therapeutic intervention.

Mycotoxin-related toxicity, carcinogenesis, and other health ailments are encountered in man and animals around the world. In developing countries, where regulatory guidelines are not strictly followed, adverse health effects (especially reproductive and developmental effects) are devastating. In these scenarios, early biomarkers of exposure play a pivotal role in avoiding further exposure to the contaminated food/feed and thus safeguard human and animal health.

With the current knowledge of system biology, proteomics, metabonomics, toxicogenomics, and various mathematical and computational/chemometric modelings, undetectable biomarkers can be discovered and these biomarkers can predict how tissues respond to toxicants and drugs and/or their metabolites, and how the tissue damage and repair processes compromise the tissue's function. Imaging and chemometric biomarkers are of greater sensitivity and carry more information than conventional biomarkers, as they detect (1) low levels of chemical exposure (exposure biomarker) and (2) an early tissue response (endogenous response biomarker). The priority will always be for the development of a noninvasive approach over an invasive approach, and nondestructive biomarkers over destructive biomarkers, but this may not be possible in all cases.

In 2011, the Joint SOT/EUROTOX Debate proposed that "biomarkers from blood and urine will replace traditional histopathological evaluation to determine adverse responses," identifying and comparing the strengths and limitations of histopathology with serum and urine biomarkers. Unlike histopathological techniques, blood and urine biomarkers are noninvasive, quantifiable, and of translational value. Of course, the complete replacement of histopathological biomarkers with blood and urine may not be possible in the near future, as in some instances histopathological biomarkers will still be used because of recent developments in invaluable molecular pathology techniques.

For the quest of developing the most sensitive and reliable biomarkers, integration of novel and existing biomarkers with a multidisciplinary approach appears fruitful. Furthermore, a multibiomarker approach seems more informative and accurate than a single biomarker approach. By now, microRNAs (miRNAs) have been well recognized as reliable and robust biomarkers for early detection of diseases, birth defects, pathological changes, cancer, and toxicities (Quiat and Olson, 2013; Wang et al., 2013; Bailey and Glaab, 2018). Because they are stable in biofluids, such as blood, there is rapidly growing interest in using miRNAs as diagnostic, prognostic, and predictive biomarkers, and the outlook for the clinical application of miRNA discoveries is promising, especially in molecular medicine. Soon, incorporating pharmacological and toxicological targeting of miRNAs into the development of innovative therapeutic strategies will be routine. Still, more innovative biomarkers need to be developed that will be highly sensitive (biotechnology-based techniques), require minimum quantities of sample, and will promise high-throughput screening.

At the recent meetings of the Society of Toxicology, the EUROTOX, and International Congress of Toxicology, a large number of toxicologists emphasized the importance of biomarkers in health, disease, and toxicity. Accordingly, *Biomarkers in Toxicology*, second edition has been prepared to meet the challenges of today's toxicologists, pharmacologists, environmentalists, and physicians in academia, industry, and government. This reference book is of particular interest to those in governmental agencies, such as NIH, USEPA, USFDA, USDA, NIOSH, OSHA, CDC, REACH, EFSA, etc. This is the most comprehensive biomarkers book to date as it covers every possible aspect of exposure, effects, and susceptibility to chemicals. There are many novel topics

in this volume that are not covered in any previous book. This edition identifies and establishes the most sensitive, accurate, unique, and validated biomarkers that can be used as indicators of exposure and effect(s) of chemicals, and chemical-related long-term diseases, such as cardiovascular, metabolic and neurodegenerative diseases, and cancer. Sixty-seven chapters are organized under eight sections with a user-friendly format, and each chapter is enriched with current literature and references for further reading. This book begins with general concepts of toxicity and safety testing and biomarker development using various animal and animal alternative models, adverse outcome pathways, followed by biomarkers of system/organ toxicity, chemicals, solvents, gases, and biotoxins. There are several chapters on biomarkers of pharmaceuticals, nutraceuticals, petroleum products, chemical mixtures, radiation, engineered nanomaterials, epigenetics, genotoxicity, and carcinogens. In the disease section, chapters cover the biomarkers of Alzheimer's, Parkinson's, neuropsychiatric disorders, osteoarthritis, and some other pathological conditions. Under special topics, chapters are included on mitochondrial dysfunction and toxicity, the blood—brain barrier, oxidative/nitrosative stress, developmental neurotoxicity, miRNAs as indicators of tissue injury, and citrulline in diseases and toxicity. Lastly, a large number of chapters are dedicated to the application of biomarkers in toxicology, including the latest strategies and technologies in the development of biomarkers, biomarkers in drug development, safety evaluation, and toxicity testing and integration of biomarkers in biomonitoring of chemical exposure and risk assessment, especially in the context of industrial, environmental, and occupational medicine and toxicology.

The editor remains indebted to the contributors of this book for their hard work and dedication. These contributors are highly qualified and considered authorities in the fields of toxicology, pharmacology, pathology, biochemistry, and human and veterinary medicine. He expresses his gratitude to Ms. Denise Gupta and Ms. Robin B. Doss for their untiring support in technical assistance and text and reference checking. Finally, the editor would like to thank Ms. Kristi Anderson, Ms. Kattie Washington, Ms. Kathy Padilla, and Mr. Mohana Priyan Rajendran (the editorial staff at Academic Press/Elsevier) for their immense support at every stage of the production of this book.

Rodent Models for Toxicity Testing and Biomarkers

Shayne C. Gad

Principal of Gad Consulting Services, Raleigh, NC, United States

INTRODUCTION

Three rodent species are widely used in toxicology: the rat, the mouse, and the hamster. Two of these, the rat and mouse, are the most widely used in experimental biology and medicine. These have formed the basis for exploring the efficacy of drugs and for the identification and evaluation of toxicities associated with exposure to drugs, industrial and agricultural chemicals, and understanding the mechanisms of their toxicity since toxicology became an identified discipline.

A large (and growing) set of biomarkers are known for use in identifying and determining the relative (and relevant) risks to humans or other target species. These include:

- Body weights
- Clinical pathology (hematology)
- Clinical chemistry
- Organ weights
- Gross histologic changes at necropsy
- Immunogenicity
- Microscopic evaluation of tissues
- Changes in physiologic functions and electrophysiology
- Effects on specific genomic markers

Biomarkers are measurements of test model (animal) parameters that can provide important quantitative data about the biological state of the test model, which are predictive of effects in humans. These biomarkers in toxicology are preferably shared by both test animals and humans and in a manner that the relationship of findings in one species to another is known.

Accordingly, we will proceed to understand the current uses of these three rodent species as predictive models for effects in humans, as well as how they are measured and what their normal ranges are.

As these potential pieces of data are overviewed and considered, it is important to remember that each of these biomarkers is a part of the overall picture as to what the model is predicting as per potential adverse effects in humans. Meaningful safety assessment requires that all the data be incorporated in an integrated safety assessment. Because dose/toxicodynamic relationships will vary with level of exposure of test animals, it is also necessary that multiple (traditionally at least three) "dose" levels be evaluated.

The picture becomes both more complex but also clearer as to relevance as new biomarkers are identified and became understandable. These include proteomics (Amacher, 2010), new clinical chemistry parameters, immune system responses, and real time functional physiologic system measurements by telemetrized instrumentation (Gad, 2013).

Table 2.1 (Gad, 2013) presents the current most relevant associations of biomarkers with renal and liver toxicity, whereas Table 2.2 (adopted from Gad, 2013) presents an overview of the association between classical clinical chemistry parameters and specific target organ toxicities (Table 2.3). Table 2.4 summarizes causes associated with hematological findings in the rat.

Over the last 10 years, diligent efforts under the rubric of the Critical Path Initiative have led to the identification of a more specific set of clinical chemistry biomarkers for key potential target organs.

Heart	Troponins	Zethelius et al. (2008)
Kidney	KIM-1, Albumin, Beta-2-Microglobulin	Hoffmann et al. (2010), Ozer et al. (2010), and Vaidya et al. (2010)
Liver	DILI (Drug Induced Liver Injury)l ALT, BUN, coagulation factor	Shi et al. (2010)

Other recently identified biomarkers for specific targets include:

1. *Mitochondrial Dysfunction*. Increased uptake of calcium (because ATP depletion) by mitochondria activates phospholipases, resulting in accumulation of free fatty acids. These cause changes in the permeability of mitochondrial membranes, such as the *mitochondrial permeability transition*.
2. *Progressive Loss of Phospholipids*. Increased degradation by endogenous phospholipases and inability of the cell to keep up with synthesis of new phospholipids (reacylation, an ATP-dependent process).
3. *Cytoskeletal Abnormalities*. Activated proteases lyse cytoskeletal elements and cell swelling causes detachment of cell membrane from cytoskeleton; stretching of the cell membrane results in increased membrane damage.

TABLE 2.1   Classic Associations in Toxicology

Liver Toxicity	Renal Toxicity
Increased plasma activity of liver marker enzymes, e.g., alanine and aspartate aminotransferases	Increased water consumption and urine volume. Urine parameters may change, e.g., enzymes and cellular debris.
Decreased plasma total protein concentration	Increased plasma concentrations of urea and creatinine. Proteinuria.
Increased coagulation times due to decreased synthesis of coagulation factors	Severe renal toxicity may lead to decreased erythrocyte parameters due to effects on erythrocyte synthesis
Increased liver weight due to enzyme induction or accumulation of lipid or glycogen	Increased kidney weight
Change in color or size at necropsy	Change in color or size at necropsy
Histological findings such as necrosis or centrilobular hypertrophy due to enzyme induction	Histological change, e.g., basophilic tubules or necrosis, papillary necrosis, or glomerular changes.

4. *Reactive Oxygen Species*. Produced within the cell by infiltrating neutrophils and macrophages, especially after restoration of blood flow to an area (reperfusion injury). Cell injury triggers release of a number of inflammatory cytokines and chemokines that amplify the host immune response and attract neutrophils to the site.
5. *Lipid Breakdown Products*. Unesterified free fatty acids, acyl carnitine, and lysophospholipids. These have a detergent effect on membranes and may exchange with membrane phospholipids, causing permeability changes.

THE RAT

Use in Toxicological Research

Ideally, safety testing of products intended for use in humans, or to which humans could be exposed, should be done in humans. The data from humans would apply without reservation to complex human physiology and cellular/biochemical mechanisms and human risk assessment. Unfortunately, humans cannot be used for this purpose. Therefore, the choice of an appropriate species for toxicology studies should be based on a comparison of the pharmacokinetics, target pharmacodynamics, and metabolism of the test compound in different laboratory species and man. In the absence of this data, this choice is often based on practicality and economics. The rat has become a species of choice because of the metabolic similarities, as well as their small size, relatively docile nature, short life span, and short gestation period. The extensive use of the rat in research has led to the development of a large historical database of their nutrition, diseases, and general biology.

Characteristics

Although the rat is a species of choice in toxicology research because of the many physiological similarities and anatomical characteristics, differences exist that must be considered when designing and conducting studies with this animal. Rats are obligate nose breathers; as such an inhaled test material is subject to nasal filtration and absorption. The placenta is considerably more porous in the rat. This difference may increase the chance of fetal exposure to an administered test material or increase the overall level of fetal exposure to an administered test material. The overall distribution of intestinal microflora is different in the rat, which may lead to differences in the metabolism of an orally administered test material. These and other differences in the rat may lead to positive signs of toxicity to a test material that may not be present in a different species. There are

TABLE 2.2 Association of Changes in Biochemical Parameters With Actions at Particular Target Organs (Gad, 2013)

Parameter	Blood	Heart	Lung	Kidney	Liver	Bone	Intestine	Pancreas	Notes
Albumin				↓	↓				Produced by the liver; very significant reductions indicate extensive liver damage
ALP					↑	↑	↑		Elevations usually associated with cholestasis; bone alkaline phosphatase tends to be higher in young animals
ALT (formerly SGPT)					↑				Elevations usually associated with hepatic damage or disease
AST (formerly SGOT)		↑		↑	↑			↑	Present in skeletal muscle and heart and most commonly associated with damage to these
Beta-2-Microglobulin				↑					
Bilirubin (total)	↑				↑				Usually elevated due to cholestasis, due to either obstruction or hepatopathy
BUN				↑	↓				Estimates blood filtering capacity of the kidneys; does not become significantly elevated until the kidney function is reduced 60%–75%
Calcium				↑					Can be life threatening and result in acute death
Cholinesterase				↑	↓				Found in plasma, brain, and RBC
CPK		↑							Most often elevated due to skeletal muscle damage but can also be produced by cardiac muscle damage; can be more sensitive than histopathology
Creatinine				↑					Also estimates blood filtering capacity of kidney as BUN does
Glucose								↑	Alterations other than those associated with stress uncommon and reflect an effect on the pancreatic islets or anorexia
GGT					↑				Elevated in cholestasis; this is a microsomal enzyme, and levels often increase in response to microsomal enzyme induction
HBDH		↑			↑				—
KIM-1				↑					
LDH		↑	↑	↑	↑				Increase usually due to skeletal muscle, cardiac muscle, or liver damage; not very specific
Protein (total)				↓	↓				Absolute alterations usually associated with decreased production (liver) or increased loss (kidney); can see increase in case of muscle wasting (catabolism)
SDH					↑↓				Liver enzyme that can be quite sensitive but is fairly unstable; samples should be processed as soon as possible
Trophonin		↑							

ALP, alkaline phosphatase; *BUN*, blood urea nitrogen; *CPK*, creatinine phosphokinase; *GGT*, gamma glutamyl transferase; *HBDH*, hydroxybutyric dehydrogenase; *LDH*, lactic dehydrogenase; *RBCs*, red blood cells; *SDH*, sorbitol dehydrogenase; *SGOT*, serum glutamic oxaloacetic transaminase (also called AST [aspartate amino transferase]); *SGPT*, serum glutamicpyruvic transaminase (also called ALT [alanine amino transferase]); ↑, increase in chemistry values; ↓, decrease in chemistry values.

TABLE 2.3 Liver Enzymes

"Liver Enzyme"	Nomenclature	Plasma-Tissue Sources	Cellular Location
AST (SGOT)	Aspartate Aminotransferase	Liver, Heart, Skeletal Muscle, Kidney, Brain, RBCs	Mitochondria, Cytoplasm
ALT (SGPT)	Alanine Aminotransferase	Mostly liver, Heart, Skeletal Muscle	Cytoplasm
Alk Phos (AP)	Alkaline Phosphatase	Bile ducts, GI tract, Bone, Placenta	Membranes
GGT	Gamma-glutamyl transferase	Liver, Kidney, Heart	Membranes
GDH	Glutamate Dehydrogenase	Liver, Kidney Skeletal Muscle	Mitochondria
SDH	Sorbitol Dehydrogenase	Mostly liver	Cytoplasm
LDH	Lactate Dehydrogenase	Heart, Skeletal Muscle, RBCs, Lung, Liver, All tissues	Cytoplasm

RBC, red blood cell.

TABLE 2.4 Some Probable Conditions Affecting Hematological Changes (Gad, 2013)

Parameter	Elevation	Depression	Parameter	Elevation	Depression
Red blood cells (RBCs)	**1.** Vascular shock **2.** Excessive diuresis **3.** Chronic hypoxia **4.** Hyperadreno corticism	**1.** Anemias **a.** Blood Loss **b.** Hemolysis **c.** Low RBC production	Platelets		**1.** Bone marrow depression **2.** Immune disorder
Hematocrit	**1.** Increased RBC **2.** Stress **3.** Shock **a.** Trauma **b.** Surgery **4.** Polycythemia	**1.** Anemias **2.** Pregnancy **3.** Excessive hydration	Neutrophils	**1.** Acute bacterial infections **2.** Tissue necrosis **3.** Strenuous exercise **4.** Convulsions **5.** Tachycardia **6.** Acute hemorrhage	
Hemoglobin	**1.** Polycythemia (increased in production of RBC)	**1.** Anemias **2.** Lead Poisonings	Lymphocytes	**1.** Leukemia **2.** Malnutrition **3.** Viral infections

Mean corpuscular hemoglobin	**1.** Reticulocytosis	**1.** Iron deficiency	Eosinophils	**1.** Allergy **2.** Irradiation **3.** Pernicious anemia **4.** Parasitism	
White blood cells	**1.** Bacterial infections **2.** Bone marrow stimulation	**1.** Bone marrow depression **2.** Cancer chemotherapy **3.** Chemical intoxication **4.** Splenic disorders	Basophils	**1.** Lead poisoning	

also differences (though generally less striking) between different strains of rats and sometimes even between the animals supplied by difference sources.

Strain Differences

Breeding rats for specific characteristics has produced some physiological differences between strains of rats. Some of these differences are known to affect how the various strains react to toxicants. Among others, strain specific differences have been found in sensitivity to thiourea (Dieke and Richter, 1945), sensitivity to acetaminophen nephrotoxicity (Newton et al., 1985a,b), the incidence of spontaneous glomerular sclerosis (Bolton et al., 1976), sensitivity to the carcinogenic actions of 7,12-dimethylbenz(a)anthracene (Boyland and Sydnor, 1962), the effects of trimethyltin on operant behavior and hippocampal glial fibrillary acidic protein (GFAP) (MacPhail et al., 2003), differences in renal

carcinogenesis (Hino et al., 2003), differences in cytochrome P4501A1 gene expression caused by 2,3,7,8-tetrachlorodibenzo-p-dioxin in the liver (Jana et al., 1998), susceptibility to 4-nitroquinoline 1-oxide induce carcinoma (Kitano et al., 1992), and differences in the levels of drug-metabolizing enzymes (Page and Vesell, 1969). In recent years, research and breeding programs have been focused on producing inbred and outbred strains focused on specific disease models and susceptibility to the development of certain carcinomas. When choosing a strain for use, it is important to consider these differences.

Of importance for carcinogenicity studies, strain differences have been found in the incidence of spontaneous tumors. Table 2.5 gives the incidence of spontaneous tumors found in commonly used strains in carcinogenicity studies. The historical incidence is important to the analysis of a study in that a high spontaneous rate may mask a small test material–related increase in tumor incidence.

Because of lower spontaneous tumor rates, the Wistar has become the most popular strain in toxicological research.

Normal Physiological Values

General values for selected physiological parameters are given in Tables 2.6 and 2.7. Normal values will vary based on the strain of animal, supplier, feed, and housing conditions. These tables should be used as a point of reference only.

STUDY DESIGNS

The length and design of toxicology studies used to predict human risk are governed by guidelines issued by regulatory bodies such as the US Food and Drug Administration (FDA), the International Conference on Harmonization (ICH), the Environmental Protection Agency (EPA), and their counterparts worldwide. Toxicology studies are divided into a series of three sets of studies that are required for each phase of clinical trials. For initial approval to begin clinical trials, the following studies are required. The length of dosing in the toxicology studies varies depending on the intended length in clinical trials. A test compound intended to be a repeat dose study for up to 28 days in duration initially requires a two phase study in which a maximum tolerated dose (MTD) following a single administration is determined followed by a second phase during which the test compound is administered daily at dose levels based on the MTD for 5–7 days (Table 2.8). Following the completion of the MTD study a 14 or 28 Day Repeat Dose study should be conducted (Table 2.9). These studies assess the effects of a test compound at dosages that do not cause immediate toxic effects.

In support of Phase 2 clinical trials, longer-term subchronic and chronic toxicity studies (Table 2.10) should be conducted. Subchronic and chronic toxicity studies are designed to assess the test compound effects following prolonged periods of exposure. The highest dosage level in each of these studies should produce a toxic effect such that target organs may be identified. The lowest dosage level should provide a margin of safety that exceeds the human clinical dose and ideally allows for the definition of no observable effect level. Alternatively, when effects related to the pharmacological mechanism of the test compound or when observed effects may be related to treatment with the test compound but may not be of toxicologic significance, a no observable adverse effect level (NOAEL) may be determined.

In addition to the subchronic and chronic toxicity studies in support of Phase 2 clinical trials, reproductive

TABLE 2.6   Selected Normative Data

HUSBANDRY	
Room temperature (°C)	18–26
Relative humidity (%)	30–70
Ventilation (air change/h)	10
Light/dark cycle (h)	12–14/12–10
Minimum cage floor size	
Housed individually (cm^2)	350
Breeding with pup (cm^2)	800
Group housed (cm^2 adult)	250

GENERAL	
Life span (years)	2.5–3.0
Surface area (cm^2)	0.03–0.06
Chromosome number (diploid)	42
Water consumption (mL/100 g/day)	10–12
Food consumption (g/day)	20–40
Average body temperature (°C)	37.5

REPRODUCTION	
Puberty (males and females)	50 ± 10 days
Breeding season	All year
Type of estrous cycle	Polyestrous
Length of estrous cycle	4–5 days
Duration of estrous	10–20 h
Mechanism of ovulation	Spontaneous
Time of ovulation	7–10 h after onset of estrous
Time of implantation	Late day 4 or 5[a]
Length of gestation	21–23 days
Litter size	8–16 pups
Birth weight	5–6 g
Eyes open	10–12 days
Weaning age/weight	21 days/40–50 g

CARDIOVASCULAR	
Arterial blood pressure	
Systolic (mmHg)	116–145
Diastolic (mmHg)	76–97
Heart rate (beats/min)	296–388
Cardiac output (mL/min)	10–80
Blood volume (mL/kg)	64

PULMONARY	
Respiration (breaths/min)	100–140
Tidal volume (mL)	1.1–2.5

TABLE 2.6   Selected Normative Data—cont'd

Compliance (mL/cm H$_2$O)	0.3–0.9
Resistance (cm H$_2$O/mL s)	0.1–0.55
Pattern	Obligate nasal

RENAL	
Urine volume	15–30 mL/24 h
Na$^+$ excretion	200 mmol/L/24 h
K$^+$ excretion	150 mmol/L/24 h
Urine osmolarity	2000 mOsm/kg H$_2$O
Urine pH	7.3–8.5
Urine specific gravity	1.01–1.07
Urine creatinine	6 μmol/L/24 h
Glomerular filtration rate	1.0 mL/min/100 g body weight

[a]The estrous cycle length may vary from 4 to 5 days between strains. Time of implantation may vary based upon the length of the estrous cycle and is dependent upon Day 0 or the first day sperm is found in the vagina.
Data from Baker, H.J., Lindsey, J.R., Weisbroth, S.H., 1979. Housing to control research variables. In: Baker, H.J., Lindsey, J.R., Weisbroth, S.H. (Eds.), The Laboratory Rat, vol. 1. Academic Press, New York, pp. 169–192; Hofsteller, J., Svekow, M.A., Hickman, D.L., 2006. Morphophysiology. In: Svekow, M.A., Weisbroth, S.H., Franlin, C.L. Elsevier Academic Press; Sharp, P., LaRegina, M., 1998. The Laboratory Rat. Academic Press, Philadelphia; Van Zutphen, L.F.M., Baumans, V., Beynen, A.C., 1993. Principles of Laboratory Animal Science. Elsevier, Amsterdam.

safety studies may also be required. Reproductive toxicity studies are typically required for a test compound intended to be administered to women of child-bearing age or may affect male reproduction. These studies include an assessment of the potential effects of the test compound on general fertility and reproductive performance (Segment I), developmental toxicity (Segment II), or affect perinatal and postnatal development (Segment III). The highest dose in reproductive studies should be chosen so that administration causes some minimal toxicity. Typically, a dose range finding pilot study in a small number of animals should be conducted prior to initiating the definitive reproductive toxicology studies. Examples of protocols designed to meet the ICH guidelines are presented in Tables 2.9, 2.9A, and 2.10.

In support of Phase 3 clinical trials, two carcinogenicity studies may be required (Table 2.8), one in rats and one in mice. Typically 18 months to 2 years in duration, this type of study is designed to assess the potential of the test compound to induce neoplastic lesions. The highest dosage in a carcinogenicity study should cause minimal toxicity when administered via the intended route for clinical use. The preclinical studies required

in support of the clinical trials are dependent on the intended route and frequency of administration of the test compound and the intended age group to be treated (Tables 2.11−2.14).

ROUTES OF TEST ARTICLE ADMINISTRATION

Oral Routes

Rodents have several unique characteristics to be considered regarding the oral administration of test compounds. One of the most important characteristics is the lack of an emetic response. The lack of this response allows for a higher dose of a potential emetic compound to be administered and evaluated. Many compound and excipients may cause emesis in dogs or other large animal species and may lead to a low level of exposure and erratic blood levels. A second factor to consider is that rodents are nocturnal and eat most of their food at night. When maintained on a 12 h light−dark cycle, rats have been found to consume 75% of their daily food intake during the dark cycle (Wong and Oace, 1981). This should be taken into consideration when designing an oral gavage study and determining when the animal may be dosed. Early in the light cycle,

animals are more likely to have a full stomach and complications associated with dosing may occur if large volumes of test article are administered. In addition, a full stomach may affect gastric emptying and the rate of absorption of an orally administered test compound.

Techniques for oral administration of test compounds include mixing in the diet, via gavage or stomach tube, via capsule, or in drinking water. The most widely used methods of oral administration are the dietary and gavage techniques.

Dietary Versus Gavage Methods

The choice between dietary and gavage dosing techniques is typically based on several factors. A scientific decision can only be made with a knowledge of the pharmacokinetics of the test compound administered by both methods. Other considerations that may be used in making this decision are as follows.

The dietary method can be used if a compound can be mixed with the diet, is stable under storage conditions in the diet, and is palatable to the animal. A major advantage of the dietary method is that it requires less manpower to perform the study. The diet mixing process can be performed weekly or, if stability allows, less often. The mixing and feeding process is less labor-intensive than gavaging rats on a daily basis.

TABLE 2.8 Maximum Tolerated Dose Study in Rats

Phase A	Oral MTD Study	
	Males	Females
Dose Level 1	3	3
Dose Level 2	3	3
Dose Level 3	3	3
Dose Level 4	3	3

Phase B	7-Day Oral Range Finding Study			
	Main Study		Toxicokinetics	
	Males	Females	Males	Females
Control	5	5	—	—
Low dose	5	5	9	9
Mid dose	5	5	9	9
High dose	5	5	9	9

Experimental Design:
In Phase A, the dose level will be increased until the maximum tolerated dose (MTD) is determined. The MTD is a dose that produces neither mortality nor more than a 10% decrement in body weight nor clinical signs of toxicity. In Phase B, animals will be dosed daily for 7 days at fractions of the single dose MTD to estimate a repeat dose MTD.
Dose Route/Frequency:
As requested.
Phase A: Once.
Phase B: Once per day for 7 consecutive days.
Observations: *Twice daily in both phases (mortality/moribundity).*
Detailed Clinical Observations: *Daily in both phases.*
Body Weights: *Daily in both phases.*
Food Consumption: *Daily.*
Clinical Pathology (Phase B only): *Hematology, clinical chemistry, and urinalysis evaluations on all surviving main study animals at termination.*
Necropsy (Phase B only): *Tissues saved for possible future histopathological evaluation.*
Organ Weights (Phase B only): *Adrenals, brain, heart, kidneys, liver, lungs, ovaries with oviducts, pituitary, prostate, salivary glands, seminal vesicles, spleen, thyroid with parathyroid, thymus, testes, uterus.*
Toxicokinetics: *Blood collected on days 1 and 7 (three cohorts consisting of three animals/sex/treatment group bled twice to equal six time points), calculation of C_{max}, T_{max}, AUC_{0-24}, and $T_{1/2}$.*

Several disadvantages also exist in using the dietary method. Methods must be developed and validated to prove homogeneity and stability. This is not as easy a process as with a suspension or solution. The dietary method is also less exact than the gavage method, in that the concentration of compound mixed in the feed is based on predicted feed consumption and body weights. In addition, if the feed is not palatable to the animal, or the test compound makes the animal ill, feed consumption may be reduced thereby reducing exposure to the test compound. In addition, the facility and control animals may be exposed to the test compound through dust or vapors.

TABLE 2.9 14 or 28 Day Repeat Dose Toxicity Study in Rats

	Main Study*		Toxicokinetics	
	Males	Females	Males	Females
Vehicle control	10	10	—	—
Low dose	10	10	9 + 3[a]	9 + 3[a]
Mid dose	10	10	9 + 3[a]	9 + 3[a]
High dose	10	10	9 + 3[a]	9 + 3[a]

Observations: Twice daily (mortality/moribundity).
Detailed Clinical Observation: Weekly.
Functional Observational Battery: Pretest and Day 14 or 25.
Body Weights: Weekly.
Food Consumption: Weekly.
Ophthalmology: All animals prior to test article administration; all surviving main study animals at study termination.
Clinical Pathology: Hematology, clinical chemistry, and urinalysis evaluations on all surviving main study animals at termination.
Toxicokinetics: Blood collected on Days 1 and 14 or 27 (three cohorts consisting of three animals/sex/treatment group bled twice to equal six time points); TK modeling. The use of subsets of all the animals in a test group is called "spare sampling," intended to avoid the need for additional ("Satellite") groups of animals. Note that although six time points are commonly collected, more may be required or taken to adequately characterize a drug's pharmacokinetics.
Necropsy: All main study animals; toxicokinetic animals euthanized and discarded.
Organ Weights: Adrenals, brain, heart, kidneys, liver, lungs, ovaries with oviducts, pituitary, prostate, salivary glands, seminal vesicles, spleen, thyroid with parathyroid, thymus, testes, uterus.
Slide Preparation/Microscopic Pathology: All animals in the vehicle control and high dose groups and all found dead animals: full set of standard tissues; low and mid dose group target organs (to be determined); gross lesions from all animals.
[a]Three additional animals/sex/treatment group included as replacement animals.
* Should also refer to table note "a".

The gavage method may be used when the test compound is not stable in the diet or may not be palatable to the animals. In addition, the gavage method is preferable when evaluating toxicokinetics or pharmacokinetics. As with dietary mixtures, test compound administered via gavage as a solution or suspension should be analyzed for homogeneity, stability, and concentration. Methods for solution or suspension may be easier to develop than those required for dietary mixtures. For Good Laboratory Practices (GLP) studies, evaluation of homogeneity, stability, and concentration should be conducted for every study. If the same methodology and batch size are used for multiple studies, homogeneity may be established once. Stability of the test compound in solution or suspension should be determined under the testing conditions in the proposed vehicle. Typically, stability for toxicology studies is established for between 7 and 14 days. If the test compound is not found to be stable, stability of shorter duration may be established. Lastly, concentration analysis should be established for each dose level and should be periodically evaluated during longer-term studies.

With the gavage method of dosing, a more precise amount of the test compound can be delivered and

	Main Study		Toxicokinetics	
	Males	Females	Males	Females
Vehicle control	10	10		
Low dose	10	10	$9 + 3^a$	$9 + 3^a$
Mid dose	10	10	$9 + 3^a$	$9 + 3^a$
High dose	10	10	$9 + 3^a$	$9 + 3^a$

Observations: Twice daily (mortality/moribundity).
Detailed Clinical Observation: Weekly.
Functional Observational Battery: Pretest and Day 25.
Body Weights: Weekly.
Food consumption: Weekly.
Ophthalmology: All animals prior to test article administration; all surviving main study animals at study termination.
Clinical Pathology: Hematology, clinical chemistry, and urinalysis evaluations on all surviving main study animals at termination.
Immunotoxicology: Immunophenotyping of blood leukocytes by flow cytometry on all surviving main study animals at termination. NK cell assay on blood leukocytes of all surviving main study animals at termination. May include identification of any antidrug antibodies (ADAs).
Toxicokinetics: Blood collected on Days 1 and 27 (three cohorts consisting of three animals/sex/treatment group bled twice to equal six time points).
Necropsy: All main study animals; toxicokinetic animals euthanized and discarded.
Organ Weights: Adrenals, brain, heart, kidneys, liver, lungs, ovaries with oviducts, pituitary, prostate, **salivary** glands, seminal vesicles, spleen, thyroid with parathyroid, thymus, testes, uterus, two lymph nodes (e.g., mesenteric, axillary, popliteal, etc.) including the lymph node draining the route of administration.
Slide Preparation/Microscopic Pathology: All animals in the vehicle control and high dose groups and all found dead animals: full set of standard tissues (add Peyer's patch, extra lymph node); low and mid dose group target organs; gross lesions from all animals.
[a]Three additional animals/sex/treatment groups included as replacement animals; the control animals will not be evaluated for toxicokinetics.

may reduce the amount of test compound required to complete the study. This becomes important when evaluating the effects of a pharmaceutical, as the required dose levels and exposure levels to show safety may be lower than that required for a pesticide or chemical. A disadvantage of the gavage method is that it involves handling of the rat for each dosing. Handling of the rat has been shown to increase corticosterone levels (Barrett and Stockham, 1963) and may affect study results. Additionally, daily intubation may lead to death due to esophageal puncture or inhalation pneumonia.

Dietary Method

When utilizing the dietary method, the test compound is mixed with the diet and administered to the animals either ad libitum or the diet is presented to the animals for a fixed amount of time each day. The dosage received by an animal is regulated by varying the concentration of test compound in the diet based on the predicted food consumption and body weight.

TABLE 2.10 Subchronic and Chronic Toxicity Study in Rats

	Main Study		Toxicokinetics	
	Males	Females	Males	Females
Vehicle control	15	15	—	—
Low dose	15	15	$9+3^a$	$9+3^a$
Mid dose	15	15	$9+3^a$	$9+3^a$
High dose	15	15	$9+3^a$	$9+3^a$

Observations: Twice daily (mortality/moribundity).
Detailed Clinical Observation: Weekly.
Body Weights: Weekly.
Food Consumption: Weekly.
Ophthalmology: All animals prior to test article administration; all surviving main study animals at study termination.
Clinical Pathology: Hematology, clinical chemistry, and urinalysis evaluations on all surviving main study animals at termination.
Toxicokinetics: Blood collected on Days 1 and 90 (three cohorts consisting of three animals/sex/treatment group bled twice to equal six time points); TK modeling.
Necropsy: All main study animals; toxicokinetic animals euthanized and discarded.
Organ Weights: Adrenals, brain, heart, kidneys, liver, lungs, ovaries with oviducts, pituitary, prostate, salivary glands, seminal vesicles, spleen, thyroid with parathyroid, thymus, testes, uterus.
Slide Preparation/Microscopic Pathology: All animals in the vehicle control and high dose groups and all found dead animals: full set of standard tissues; low and mid dose group target organs; gross lesions from all animals.
[a]Three additional animals/sex/treatment group included as replacement animals.

Food consumption and body weight predictions are based on historical laboratory data for early time points in a study. As the study progresses, growth and food consumption curves can be established for each group

TABLE 2.11 Study of Fertility and Early Embryonic Development to Implantation in Rats

	Males	Females
Vehicle control	25	25
Low dose	25	25
Mid dose	25	25
High dose	25	25

Dose Route/Frequency: Males dosed began 28 days before mating and continued until euthanasia. Females dosed began 14 days before mating and continued through Day 7 of gestation (implantation).
Observations: Twice daily (mortality/moribundity).
Clinical Examinations: Observations for clinical signs, body weights, and food consumption measurements recorded during the study period. Beginning at initiation of test article administration, females examined daily to establish estrous cycle.
Uterine Examinations: Performed on dams on Day 13 of gestation. Gravid uterine weight and the weight of the ovaries recorded. Total number of corpora lutea and implantations, location of resorptions, and embryos recorded. Females subjected to necropsy, and reproductive organs and gross lesions fixed for possible microscopic evaluation.
Evaluation of Males: Following disposition of females, the males were euthanized and subjected to a necropsy. The testes and epididymides weighed, and analysis of sperm parameters (concentration, motility, and morphology) performed. Reproductive organs and gross lesions fixed for possible microscopic evaluation.
Statistical Analysis: Standard.

TABLE 2.12 Embryo-Fetal Development in Rats

	Time Mated Females
Vehicle control	25
Low dose	25
Mid dose	25
High dose	25

Dose Route/Frequency: Dosing initiated on Day 6 of gestation and continued to include Day 17 of gestation.
Observations: Twice daily (mortality/moribundity).
Clinical Examinations: Daily Gestation Days 6 through 20.
Body weights/Food Consumption: Gestation Days 0, 6, 9, 12, 15, 18, and 20.
Cesarean Section/Necropsy: Litters will be delivered by cesarean section on Day 20 of gestation. Gravid uterine weight will be recorded. Total number of corpora lutea, implantations, early and late resorptions, live and dead fetuses, and sex and individual body weights of fetuses will be recorded. External abnormalities of fetuses will be recorded. Approximately one-half of the fetuses will be processed for visceral abnormalities, and the remaining fetuses will be processed for skeletal abnormalities. Dams will be subjected to a necropsy and gross lesions and target organs (if known) will be saved.

and group mean data can be used to predict future food consumption. Different concentrations of the test compound and diet should be made for each sex.

Test compounds and diets are mixed in two steps: (1) the compound and about 10% of the total amount of diet are blended in a premix, then (2) the premix and the remainders of the diet are mixed. The total amount of diet

Study Desgin: Group as per Table 2.14.
Observations: Twice daily (mortality/moribundity).
Detailed Clinical Observations: Once weekly.
Body Weights: Weekly for first 13 weeks, monthly thereafter.
Food Consumption: Weekly for first 13 weeks, monthly thereafter.
Ophthalmology: All animals pretest and all survivors prior to terminal sacrifice.
Clinical Pathology:
Main Study: Hematology at termination.
6-Month Satellite: Hematology, clinical chemistry, and urinalysis evaluations on all surviving satellite animals at termination.
Necropsy: All animals.
Slide Preparation/Microscopic Pathology: All animals, full set of standard tissues, all masses, and all lesions.
Statistical Analysis: Standard.

to be mixed is first weighed out, the 10% is separated into the premix. To make the premix, the entire test compound and an aliquot of the diet (from the 10%) are put into a mortar. These ingredients are ground with a pestle

TABLE 2.13 Pre- and Postnatal Development, Including Maternal Function in Rats

	P Generation (F0)		F1 Generation	
	Males	**Females**	**Males**	**Females**
Vehicle control	NA	25	25	25
Low dose	NA	25	25	25
Mid dose	NA	25	25	25
High dose	NA	25	25	25

Number in Study: P Generation—100 females, F1 Generation—100 males, 100 females.
Dose Route/frequency: Once daily to P animals from Gestation Day (GD) 6 to Postnatal Day (PND) 21. F1 animals not dosed.
Observations: Twice daily (mortality/moribundity).
Clinical Observations: P females—daily during treatment/F1 adults—weekly.
Body Weights:
P females—GD 0, 6, 10, 14, 17, and 20, PND 0, 7, 10, 14, and 21.
F1 males—Weekly through termination.
F1 females—Weekly until evidence of copulation detected, then GD 0, 7, 10, and 13.
Food Consumption: P females—On corresponding body weight days during gestation/lactation.
Vaginal Smears: All F1 females during a 21-day cohabitation period until evidence of copulation is detected.
Litter Evaluations: All F1 offspring, count, body weight, sex, clinical observations on PND 0, 4, 7, 14, 21; behavioral and developmental evaluation of four males and four females from each litter for static righting, pinna detachment, cliff aversion, eye opening, air drop righting reflex, neuropharmacological evaluation, auditory response. One male and one female (selected for the next generation) tested for sexual maturation (vaginal opening, preputial separation), motor activity/emotionality, and passive avoidance.
Cesarean Section: On GD 13, F1 females for location of viable and nonviable embryos, early and late resorptions, number of total implantations, and corpora lutea.
Sperm Evaluation: May be conducted on F1 males if evidence of reduced fertility is noted (additional cost).
Necropsy: Gross lesions/target organs fixed for possible microscopic evaluation (additional cost).
All P females at PND 22 as well as all F1 weanlings not selected for F1 generation.
All F1 females at GD 13.
All F1 males after termination of F1 cesarean sections.

until the mixture appears homogeneous. The mixture and the remainder of the premix are then layered in a small capacity mixer and mixed for 5—10 min. The time for this mixing process can be varied if analysis shows the total mixture is not homogeneous. For the final mix, the premix and the remainder of the diet are layered in a large capacity mixer. The mixing time will vary with the type of blender and can be varied if the analysis shows the total mixture is not homogeneous.

Several types of blenders are available for the mixing process; these include open-bowl "kitchen" mixers, V or PK blenders, and Turbula mixers. Metal parts should be ground to eliminate electrostatic forces. In addition, alternative methods of dietary administration such as microencapsulation may be used for volatile, reactive, or unpalatable chemicals.

Gavage Method

In the gavage procedure, the test compound is administered by passing a feeding tube or gavage needle attached to a syringe down the esophagus into the stomach.

Test Article Preparation

If not already a liquid, the test compound is prepared for administration by adding it to the appropriate vehicle. The choice of vehicle will depend on the characteristics of the compound and whether it is to be administered as a suspension or a solution. In addition, consideration must be given to the effects of the vehicle on the rat (Gad and Chengelis, 1998). Common vehicles used include water and food grade oils such as corn oil. Suspensions are made when aqueous vehicles are desired and the test compound is not soluble. Suspending agents such as methylcellulose are added to increase the viscosity and hold the compound in suspension. Other agents such as Tween 80, ethanol, polyethyleneglycol 400 (PEG 400), and others may be used as wetting or stabilizing agents.

Equipment

Soft catheters made of silastic or polyethylene (e.g., infant feeding tubes), stainless steel gavage needles with smooth ball-shaped tips, or polyethylene gavage needles with ball-shaped tips are commonly used. All are commercially available and are relatively inexpensive. Although the soft catheter minimizes the chance of esophageal trauma, liquid can leak past the catheter and back up the esophagus and be aspirated. The ball-shaped tips of the stainless steel gavage needles reduce the chances of tracheal injections; however, if an animal struggles while the needle is in the esophagus, the rigid needle increases the chances of perforating the esophagus. The polyethylene gavage needle incorporates the best of both the soft catheter and the stainless steel needle, but because of the flexible nature of the needle, the risk for tracheal injection is increased.

Conybeare and Leslie (1980) found that deaths in gavage studies were a result of aspiration of small amounts of irritant solutions or acidic, hypertonic solutions. They also found that the use of a ball-tip 4 mm in diameter helped to eliminate deaths related to dosing. With gentle handling, the animals will be acclimated to the techniques used and dosing will become easier.

Aspiration and tracheal administration of test compound as well as esophageal trauma have been associated with gavage dosing and may lead to difficulty in interpretation of the study. The catheter and the needles all have risks inherent in their use; therefore, care should be taken when using these tools and animal technicians should be properly trained. The choice of the appropriate catheter or needle should be left up to the technician and should be whatever the technician has been trained and is most comfortable with.

Technique

The description below is appropriate for either a gavage needle or catheter; for simplicity, only the needle will be mentioned in the description. Prior to picking up the animal, the syringe should be attached to the needle and filled with the appropriate amount of test compound to be delivered. Any air bubbles should be eliminated and the needle wiped clean of residual test compound. This is done so that the animal does not taste the test compound and residual test compound is not aspirated as the needle is passed down the esophagus. If the dosing liquid is distasteful, the animal may struggle after repeated dosing and increase the chances of being injured.

To position the animals for gavage, it should be grasped by the skin of the back and neck ensuring that the head, neck, and back are in a straight line. Alternatively, the animals can be grasped about the shoulders, with the index finger and thumb on either side of the head. The objective is to firmly hold the animals to be able to control any struggling if it occurs and to also prevent the animal from being able to bite the technician. For even more control, the animal may be placed on a table or brought up against the operator's chest.

Once the animal is in position, the needle can be inserted into the mouth of the animal, moved over the tongue, and down into the esophagus. The length of the needle should be inserted into the animal. A slight rotation of the needle may help with insertion into the esophagus. If the needle is inserted into the trachea, the animal may struggle. The syringe should be grasped lightly such that, if the animal does struggle, the chances of an esophageal tear are minimized. If the animal continues to struggle, the needle should be withdrawn to allow the animal to calm down, and then dosing should

be attempted again. Alternatively, if a catheter is used, as the tube is placed into the mouth, it should be placed to the side between the molars. This is done because the tube may by bitten or transected if passed too close to the front teeth.

With the needle in place, the test compound should be slowly expelled into the animal. If administered to rapidly, reflux may occur and the test compound may back up into the esophagus, resulting in an inaccurate dose being given and possible aspiration of the test compound. Once the dose has been delivered, the needle should be withdrawn and the animal observed for any signs of distress or respiratory difficulty. An experienced technician should be able to dose between five and seven animals per minute without causing discomfort to the animals and with minimal dosing-related deaths.

Gavage liquids are commonly administered at a volume of 5–10 mL/kg body weight. The volume should be enough to be delivered accurately, but not so much that it will adversely affect the animal. The maximum volume should be no more than 20 mL/kg. If using volumes greater than 10 mL/kg, it may be advisable to fast the animals for several hours prior to dosing. This will ensure that the stomach is empty prior to dosing and able to handle the larger volume. This option should be considered carefully, as fasting can affect the rate of absorption and clearance from the stomach. In addition, the choice of housing and bedding should be considered when dosing with large volume as rats have the tendency to eat the bedding, which may hinder gavage dosing. In addition, the volume chosen can have an effect on the results of the study and volumes greater the 10 mL/kg should only be used when issues of solubility and exposure exist. Ferguson (1962) found that a change in dose volume of from 5% to 1% of body weight could reduce mortality rate from approximately 95%–5%, respectively, at equivalent doses.

Neonatal Administration

Neonatal intragastric injections can be made orally with thin silicone tubing (Gibson and Becker, 1967; Smith and Kelleher, 1973) or by intragastric injection with a 27-gauge needle through the abdominal wall (Worth et al., 1963; Bader and Klinger, 1974). The oral method using silicone tubing is performed in a similar manner to the previously described method in adult rats. The intragastric injection through the abdominal wall is performed by first locating the stomach in the upper left quadrant of the abdomen and then carefully inserting the needle through the abdominal wall into the stomach taking care that the animal does not move. The syringe should be gently aspirated to ensure proper placement and then the injection completed and the needle withdrawn.

Capsule

To eliminate the possibility of dosing errors and to deal with compounds that cannot be delivered through conventional means, methods have been developed for the administration of capsules into the esophagus of the rat. The test compound may be prefabricated into a small capsule or the test article may be weighed and placed into commercially available capsules. An individual capsule is then placed into a specially designed cup in the end of a gavage needle, and the needle is then inserted into the esophagus of the rat. The capsule is then pushed out of the cup into the esophagus using either air or a rod inside the needle. The needle is then withdrawn and the capsule moves down into the stomach by peristaltic action. Only a small amount of test compound can be administered as a single dose using this method, but multiple capsules can be administered sequentially in the same dosing session.

Water

As an alternative to dietary administration, compounds that are water soluble, palatable to the rat, and stable in water may be administered via the drinking water. This method offers similar advantages as adding a test compound to the diet. Additionally, compounds will be more easily mixed and analyses will be more easily developed than when a compound is in the diet. However, spillage of water makes measurement of the actual dose received difficult.

Intravenous Route

One of the most common methods of administration of test compound is via intravenous (iv) injection or infusion. The iv route is often the route of choice for compounds that have poor bioavailability via the oral route or have a short half-life. Several issues must be considered when administering a test compound intravenously. The compound must be soluble in an acceptable iv vehicle or excipient, must be able to be administered as a solution, and should be sterile or sterile filtered prior to administration. In addition, when designing a study, the pharmacokinetic profile of the test compound administered intravenously should be considered. Study activities such as clinical observations and functional observational battery should be planned around the expected time of greatest plasma concentration.

A variety of veins may be used for iv injections (Diehl et al., 2001). These include the lateral tail (caudal), jugular, femoral, saphenous, lateral marginal, dorsal metatarsal, sublingual, and dorsal penile vein. Although most of these are superficial, and easily available for injection, several require the use of anesthesia or more than one technician and may be of limited use in repeat

dose studies. Although anesthesia may be acceptable for acute studies or surgical model, its repeated use may have an effect on the toxicity of a test compound.

Lateral Tail Vein

The lateral tail veins are currently the most widely used for iv injections in the rat. The veins are easily visible, especially in young animals and injections can be performed by one person without the use of anesthesia. The technician performing the function should be well trained and care should be taken to ensure that the lateral veins are being accessed and not the dorsal or ventral artery of the vein.

Bolus Injection

The animal should be placed in an appropriate restrainer. This typically consists of a solid tube in which the animal is placed into headfirst and has a stop that is placed behind the animal with a hole that allows the tail to hang out the back. The restraint tube is designed to be secure enough that the animal cannot move, back out, or turn, but can still breathe comfortably. Once secure, the tail should be cleaned and the vein may be dilated with heat. This may be accomplished by placing the tail in warm water (40−45°C), placed under a heat lamp, or wrapped with warm gauze. Care must be taken to avoid using excessive heat as tissue damage may result. Minasian (1980) describes a tourniquet made from a plastic syringe and thread. If used, this should not be left on for an extended period of time.

When performing an injection, the end of the tail should be held firmly and taut with the thumb and index finger of one hand. A 23-gauge needle attached to an appropriately sized syringe should be held with the bevel up at a shallow angle parallel to the vein. The skin of the tail is then pierced and the needle advanced until resistance is no longer felt. The plunger of the syringe should then be aspirated to ensure proper placement of the needle. The use of a needle with a clear or transparent hub will facilitate confirmation of correct placement. Blood backflow into the needle confirms entry into the vein. Alternatively, a butterfly needle with an extension line may be used. The butterfly needle with an extension set precludes the need to hold the tail, needle, and syringe. When using this type of setup, the butterfly needle is attached to an extension set and syringe that is filled with the test compound. The tail may be taped to the table, and the butterfly needle is then inserted into the vein and placement is verified by aspiration on the syringe. Once confirmed, the butterfly needle may also be taped in place. This prevents the needle from pulling out of the vein during dosing. This type of setup can be very useful when administering large volumes of test article as a slow bolus over several minutes or when the test compound may be irritating or mildly caustic.

Taping the animal's tail in place prevents the animal from pulling the tail out of the fingers of the technician.

If repeated dosing is to be performed, the initial venipunctures should be performed as close to the tip of the tail as possible. During the injection, if the needle comes out of the vein, a bleb will form under the skin. The needle should be repositioned immediately to prevent infiltration of the solution around the vein. Infiltration of an irritating solution can cause necrosis and make future injections difficult or impossible. Injection of 2 mL/100 g body weight can be accomplished without stress to the rat. Barrow (1968) found that injections of volumes over this amount produced respiratory difficulty and pulmonary edema.

Tail Vein Infusions

Tail vein infusions are convenient because catheter placement can be accomplished without anesthesia. A 23-gauge or smaller needle connected to an extension set is inserted into the tail. The needle and extension set is then secured to the tail with tape. The extension set is attached to a syringe that is placed on a pump and the test compound can be infused. The tail may be taped to a wooden stick or tongue depressor to further protect the needle from being dislodged. Over the needle, catheters are also commercially available and offer the advantage that the needle is removed once the catheter is placed in the vein and may help to prevent further penetration of the vein wall and subsequent perivascular dosing (Rhodes and Patterson, 1979). Advantages that this technique has over permanent indwelling catheters are that the catheter is removed following dosing and will not become occluded and the animal doses not have to undergo anesthesia and a surgical procedure to place the catheter. Permanent catheters have a tendency over time to develop a fibrin flap or become clotted, thus losing patency. A major disadvantage is that the animals have to be restrained during the infusion, which may causes stress and alter the results of the study. When using this technique, the duration of the infusion should be limited so that the length of time the animal is restrained is limited.

An alternative technique using the lateral tail vein involves placing a catheter in the vein and wrapping the tail in a similar manner as previously described, then a lightweight protective cover attached to a tether system is placed around the tail to hold the catheter or needle in place.

Jugular Vein

Although this route has been used for bolus injections, it is most widely used as a site for cannulation from indwelling catheters. The indwelling catheter requires surgical implantation under anesthesia.

Bolus Injection

Although injections can be made by exposing the jugular vein by incision, this method is not acceptable for repeated dosing. The jugular vein can be accessed for test compound administration without exposing the vein. The animal can either be anesthetized or restrained on the back. The head is positioned to either the left or the right for access to the respective jugular vein. A 23-gauge needle fitted to a syringe with the bevel up is inserted in a cephalocaudal direction into the angle made by the neck and shoulder. The needle should enter the vein anterior to the point at which it passes between the pectoralis muscle and the clavicle. When about one-half the length of the needle has penetrated the skin, the bevel should be in the lumen of the vessel. Insertion of the needle through the muscle stabilizes the needle and minimizes bleeding. Caution should be used when using this technique as it is considered to be a "blind stick" into the vessel, and damage to the vessel may occur. Repeated access of the vessel is not recommended.

Infusion

For the purpose of continuous infusion of the test compound over extended periods of time or for repeated short-term infusions, implanted catheters in the jugular vein may be used. For implantation of a jugular catheter, the animal is first anesthetized and placed in dorsal recumbency, and the surgical site is prepared. A midline incision is then made in the neck, and a section of the jugular vein is dissected free. Manipulation of the vein should be limited to prevent vasospasm. A cephalic ligature is then tied and the vein elevated. A small incision is then made in the vein, and the catheter is passed into the vein and tied in place. The other end of the catheter is then tunneled subcutaneously (sc) to between the scapula where the catheter is exteriorized. The catheter should be filled with an anticoagulant solution such as heparin when not in use. When correctly positioned, the tip of the cannula will be at the junction of both vena cava. If placing catheters into young animals, enough of the catheter should be inserted to allow for growth of the animal. Care should be taken that the catheter is not inserted too far as the tip may be pushed into the right ventricle of the heart. Improper placement of the catheter may lead to administration of the test compound directly into the heart, which can cause complications.

Similar to the jugular vein, administration of test article via the femoral vein requires an implanted catheter. For implantation of a femoral catheter, the animal is first anesthetized and placed in dorsal recumbency, and the surgical site is prepared. A midline incision is then made in the inguinal area and a section of the femoral vein is dissected free. Manipulation of the vein should be limited to prevent vasospasm. A ligature is then tied and the vein elevated. A small incision is then made in the vein and the catheter is passed into the vein and tied in place. The other end of the catheter is then tunneled sc to between the scapula where the catheter is exteriorized. The catheter should be filled with an anticoagulant solution such as heparin when not in use. When correctly positioned, the tip of the cannula will be position in the vena cava. For longer-term infusions, the femoral vein catheter may be preferable as patency is easier to maintain and the risk of damage to the heart from the catheter is avoided.

Several commercial vendors offer surgical support services and for an additional fee will implant either jugular or femoral catheters. These vendors will typically have a specific methodology for implant, but will accept requests for modifications such as catheter type, exteriorization site, etc. The typical catheter implanted may be manufactured from polyethylene, polypropylene, or silastic. In recent years, manufacturers have developed catheters impregnated or ionically bound with heparin. These materials may help to prolong the life of the catheter.

The useful lifetime for jugular and femoral catheters is quite variable; the lumen of the cannula may eventually become obstructed by a blood clot or fibrous mass. The position of the tip of the catheter is important. Clot formation is less likely to occur if the tip of the catheter is placed in the venous stream rather than in the jugular vein (Popovic and Popovic, 1960). It is recommended for repeated short-term infusions, and when test article is not being infused, a slow infusion of saline will help to prolong the life of the catheter.

Prior to use, the patency of the catheter should be checked by removing the anticoagulant lock, check for blood draw back, and then flushing with saline or Lactated Ringers solution. Alternatively, patency can be checked by injecting 3−6 mg of pentobarbital solution (0.05−0.10 mL of a 60 mg/mL solution) into the catheter (Weeks, 1972). If the catheter is patent, the rat will lose its righting reflex and become ataxic within 10−15 s of injection. The rat will recover in 10−15 min.

Rats will destroy the catheter if it is left unprotected or in easy reach of the forepaws. By exteriorizing the catheter between the scapula, the rat will not be able to chew on the catheter. For the purpose of continuous infusion, several manufacturers have developed tether systems and catheter sheaths made of metal that prevent the animal from chewing on the catheter. These systems typically consist of a jacket with an attached tether through which the catheter is passed. The catheter then attaches to a swivel that prevents the catheter from becoming kinked. The swivel then attaches to a second catheter that can be attached to a syringe or

pump for administration of the test compound (Guo and Zhou, 2003). When performing long-term infusion studies, the effects of the catheter and harness should be considered. Infections, septicemia, a variety of visceral lesions, endothelial lesions, and increased platelet consumption have been observed in cannulated animals (Hysell and Abrams, 1967; Meuleman et al., 1980; Vilageliu et al., 1981). Decreased or erratic weight gains and decreased liver and thymus weights have been observed in tethered animals. These changes may be attributed to the stress involved in chronic tethering of the animals.

An alternative to an exteriorized catheter is to attach a sc port to the catheter that can be accessed via a transcutaneous needle stick. This type of setup helps to prevent infections that can occur with transcutaneous catheters. One of the pitfalls of this sc port is that the port may only be accessed a finite number of time. In addition, care has to be taken to ensure the port and catheter are properly flushed of all test compound and blood as clots can easily form. Administration of small volumes of test compound may be accomplished using a sc implanted osmotic pump. This type of pump is connected to the catheter after being filled with the test compound and implanted in a sc pocket. This allows for continuous administration of small amounts of compound without the need for a jacket and tether system.

Saphenous, Lateral Marginal, and Metatarsal Veins

These veins in the leg and foot are easily visualized and can be injected without anesthesia; however, assistance is required. Shaving the area over the saphenous or lateral marginal vein makes visualization easier. During injection it is necessary for one technician to restrain the animal and occlude the vessel to cause it to dilate. Wiping the skin over the vein with 70% alcohol or with gauze soaked in hot water will help to dilate the vessel and increase the possibility of success. The second technician then performs the injection, in which a 26—27-gauge needle should be used.

Dorsal Penis Vein

When administering test article via the dorsal penis vein, it is preferable to use anesthesia. Lightly anesthetizing the animals with an inhaled anesthetic such as isoflurane or CO_2/O_2 will prevent the animal from struggling and increase the possibility of a successful injection. This procedure requires two technicians to perform the injection. One technician holds the animal by the skin on the back and the feet and tail. The vertebral column is then hyperextended. The second technician then grasps the tip of the penis between the thumb and forefinger, and injects the test solution into the dorsal vein using a 26—30-gauge needle.

Sublingual Vein

Although the method of sublingual vein injection has the disadvantage of requiring anesthesia, it only requires one technician. Ideally, the animal should be anesthetized with an inhaled anesthetic such as isoflurane or CO_2/O_2, but injectable anesthesia may also be used. The animal should be placed in dorsal recumbency with the head toward the operator. The test compound may be administered by holding the tongue between the thumb and forefinger; using a 26—30-gauge needle, the vein is entered at a very shallow angle and the injection is performed. After completion of the injection, the bleeding can be stopped using direct pressure. Once the bleeding has stopped, a small cotton-wool pledget should be placed over the vein and the tongue placed back in the mouth. The animal will spit the cotton out on regaining consciousness.

Intraperitoneal Route

Test compounds injected into the peritoneal cavity will be absorbed into the portal circulation and transported to the liver. As a result, the compound will be subjected to the metabolic activity of the liver prior to being circulated to the remainder of the animal. Based on the level of blood flow and circulatory surface area in the peritoneal cavity, compounds injected intraperitoneally (ip) will be absorbed quickly.

Intraperitoneal administration of test compounds in the rat can be performed by one person. The animal should be picked up by the scruff of the neck and back and held firmly in dorsal recumbency. This position will allow for proper access to the peritoneal cavity. The belly of the animal should be visually divided into quadrants and a needle (<21 gauge) should be inserted anteriorly into one of the lower quadrants just lateral to the midline. Aspiration of the syringe prior to injection will help the investigator to determine if the needle is positioned appropriately.

Intramuscular Route

Intramuscular (im) injection of compounds will result in the rapid absorption into general circulation due to the abundant supply of blood vessels. However, the speed of absorption will not be as fast as with an ip injection. Acceptable sites in the rat are the quadriceps, the thigh, and the triceps. This procedure can be done with one or two technicians. The selected muscle mass should be stabilized with the thumb and forefinger of one hand while restraining the animal and guiding the needle into the muscle with the other hand. A 21-gauge or smaller needle should be used. The needle should be lightly aspirated to ensure the tip of the needle

is not in a blood vessel and then the compound is slowly injected. A slow injection with a minimal volume will help to minimize pain. Approximately 1 mL/kg of solution can be injected per site. If larger volumes are required, multiple injection sites should be used.

Subcutaneous Route

Absorption following sc injection is typically slower than following im injection. This may be advantageous if a relatively sustained period of absorption is desired. Another advantage of the sc route versus the im route is that a much large volume of test compound can be administered. Five to ten milliliter can be easily injected with little to no discomfort to the animals. This can be beneficial for test compounds that have limited solubility. Suitable sites for injection are the ventral body, the flank, and shoulders. To perform the injection, the skin is grasped between the thumb and forefinger and raised to make a tent. The needle (<20 gauge) is inserted through the skin to make the injection. Injection sites can be varied for multiple-dose studies where the solution is a potential irritant.

To minimize the stress of manipulation and to provide a means for continuous infusion, a perforated cannula or catheter can be implanted transcutaneously. The cannula can then be secured using a tether system similar to that used for iv infusions. Using this system, the test compound can be infused continuously. Mucha (1980) injected sodium pentobarbital directly into the cannula and showed it was absorbed much more rapidly than following injection. An alternate method of infusion of small volumes over an extended period of time is through the use of an osmotic minipump. The pump is filled with the test compound and implanted sc under anesthesia. These pumps are commercially available and offer the advantage of a continuous infusion at a constant rate without the animals being encumbered with the infusion apparatus. This method would work only when the solutions are stable at body temperature for the duration of the infusion period. In recent years several types of absorbable microspheres have been developed that can act as carriers for the test compound.

Topical Route

The rat has not traditionally been used as a model in skin irritation or sensitization studies. However, the rat has been used in systemic toxicity studies where the skin is used as a portal of entry for whole body exposure or in skin painting studies where the carcinogenic potential is being assessed. In a comparison of absolute absorption rates of several compounds, Bartek et al. (1972) found dermal absorption rates in the rat tended to be slightly lower than in the rabbit, and higher than in the monkey, swine, and human.

Exposure in dermal studies is usually to the anterior dorsal portion of the back. The skin should be shaved weekly or 24 h prior to skin painting. Care should be taken to ensure that the skin is not damaged during shaving, as this can increase the rate of absorption of the test compound. The test area for application should be clearly marked; for repeat dose studies, the area of this site is often 10% of the body area. Usually 0.25—1.0 mL of the test solution is applied in skin painting studies. The amount of a cream or ointment applied will vary with the test compound and desired total dose administered. Dosing is typically performed every day.

The actual dose in a dermal toxicity study is determined by the amount of compound absorbed, therefore factors that influence absorption should be considered. Several design features in a topical study may affect absorption; abraded skin will tend to absorb faster than intact skin; test compound may adhere to or build up at the site of exposure and may impede absorption (and test compound may be chemically changed owing to exposure to air or light); the test compound may be licked or scratched from the site; and the test compound may be ingested by the animal.

Several techniques have been developed to avoid removal or ingestion of the test compound. For acute studies, Rice and Ketterer (1977) described a cable-type restrainer attached to a stainless steel plate. Loops just behind the front and just in front of the hind legs hold the animal immobile. Other methods may be used to reduce stress to the animals and allow the animal mobility. One method is the use of an "Elizabethan" collar. This is a 4—5-cm wide strip of plastic or metal that fits around the neck of the animal. This prevents the animal from being able to turn its head to gain access to its back. Consideration should be given to the use of this method as the collar also may prevent the animal from being able to properly eat from a feed jar. A second method is to wrap the animal with gauze and then with plastic wrap. Care should be taken when wrapping the animal to ensure that the wrap is not too tight. This type of covered exposure may affect the absorption of the test compound. Other types of harness, collars, and acrylic chambers may be used, and the appropriate technique should be chosen based on the intended length of exposure and the efficacy with which the technique can be performed by the technicians.

Rectal Route

The rectal route is not a routinely used method of administration in toxicology. However, administration

by this route is sometimes required to support drugs given rectally by suppository. For dosing, the animal is held by the base of the tail and a stainless steel, and ball-tipped gavage needle (5 cm) or vinyl tube (6 cm) attached to a syringe is inserted into the rectum. Care must be taken not to damage the rectum when inserting the needle. The syringe should be held lightly: the weight of the needle and syringe propel the needle. The animal can either be awake or anesthetized. If animals are awake, excretion of the unabsorbed test compound may occur. Methods to control excretion have included ligation of the rectum (Nishihata et al., 1984) or various types of septums that are tied or glued in place (DeBoer et al., 1980; Iwamoto and Watanabe, 1985). Anesthetized animals can be placed on an inclined board to retard expulsion.

An important factor in rectally dosing the rat is that the depth of deposition of the test compound will affect the rate of absorption and should be standardized. Drugs subject to extensive first-pass metabolism, such as propranolol and lidocaine, have been found to be much more bioavailable when injected close to the anus rather than in the upper areas of the rectum (DeBoer et al., 1980; Iwamoto and Watanabe, 1985). The reason for this difference in bioavailability appears to be that the venous return in the upper rectal area is through the upper rectal vein that feeds back into the portal circulation and then into the liver. The venous return in the lower rectum is through the lower hemorrhoidal veins and is not connected to the portal system, but goes directly to the inferior vena cava (Iwamoto and Watanabe, 1985).

Intranasal Route

With the increasing number of drugs being delivered nasally, methods have been developed to support this route. For administration in unanesthetized animals, the appropriate volume of test material is drawn into the tip of a pipette or other appropriate dosing implement. The tip of the dosing implement is placed directly over but not into the nostril to be dosed, and the test material is instilled into the nostril. The animal will aspirate the test material into the nasal passage. This can be repeated for the opposite nostril, or the opposite nostril can be used as a control treatment. In the event that the animal sneezes or the test compound is otherwise expelled, the nostril should be retreated.

Inhalation Route

Owing to the complexities and equipment involved in generating, maintaining, and measuring appropriate atmospheres, the inhalation study is one of the most technically difficult to perform. This section is not written to provide a complete discussion of the skills necessary to perform an inhalation study, but will deal with the general considerations about the three major steps in exposing rats by the inhalation route: generation of the test atmosphere, exposure of the test animals, and measurement and characterization of the test atmosphere.

Intratracheal Administration

An alternative to inhalation administration is to instill the test compound into the trachea of the animal. Techniques have been developed to instill the test compound into the trachea safely and repeatedly. To perform the procedure, the animal must first be anesthetized, preferably with a gas anesthesia such as isoflurane. Once anesthetized, a speculum is inserted into the mouth and passed into the trachea. A syringe and needle with a 5-cm piece of tubing is used to instill the test compound. The tubing is then passed over the speculum and the test compound is administered. Volumes should be limited to 2 mL or less of test compound.

REGIMEN

There are a number of factors that can be manipulated to maximize both administered and absorbed levels of a drug, as well as increasing both tolerance and target tissue specificity. Most of these are beyond the scope of this volume (Gad and Spainhour, 2017), but regimens (how often and at what intervals a test article is administered) are fundamental tools of the experimental animal researcher. Once, twice (bid), or three (tid) times a day are readily available approaches. Likewise, for parenteral routes, an administration can be done quickly (bolus) or over a period of time (infusion).

END POINT MEASUREMENT TECHNIQUES

Observations and Physical Examinations

Rats are routinely monitored during toxicology studies as an assessment of their general health and to define the effects of the test article. In acute and subchronic studies, animals may be observed frequently in an effort to define short-term pharmacologic changes induced by the test compound, which may become apparent at peak blood levels. Specifically, in acute toxicology studies clinical observations will help to establish a MTD. In chronic studies, these observations are critical in tracking tumor development and for determining

animals in extremis, which should be euthanized for humane reasons and to prevent autolysis and tissue loss. Arnold et al. (1977) provide a useful description of a clinical assessment program for chronic studies.

Daily observations are performed first thing in the morning and last thing before leaving in the afternoon to assess the health of the animals and identify animals that may be in extremis. In this observation, behavioral status, respiratory signs, skin, eyes, and excretory products are noted. Care should be taken to disturb the animal as little as possible, as this may induce stress and affect the animal's behavior. The animal should be picked up and examined more closely if abnormalities are detected. Special attention should be paid to the amount of feces present, because a decrease in fecal output may be the first signs of a watering system malfunction. In acute studies or where pharmacological effects are expected, animals may be examined continuously or at peak plasma levels.

A more thorough physical examination should be done weekly. Each animal is taken from its cage and placed on an examination table where respiration, behavior, general appearance, and locomotion are observed. The technician should then pick up the animal, examine its body orifices, skin, and coat, and perform a palpation of the trunk and limbs to check for tumors. The detection and tracking of the size and fate of masses (potential tumors) is essential for carcinogenicity studies.

Animals that have experienced severe weight loss over the previous week, a progressive decline in weight over several weeks, or other severe clinical signs should be observed more frequently and marked for possible euthanasia. Body and feeder weights can be measured as part of the physical examination or as a separate function. Performance of these operations as a part of physical examinations will minimize animal handling and potential stress. If the operations are combined, it is important that the physical examinations be done completely and not rushed.

Neurobehavioral Examination

Neurobehavioral examinations are included in toxicology studies to assess the behavioral and neurological effects of test compounds. These examinations, which may be done as part of acute or repeat dose toxicity studies or studies specifically designed to assess only neurobehavioral effects, typically involve screens consisting of an abbreviated functional observational battery and some measure of locomotor activity (Annau, 1986). The EPA has written guidelines on the design and conduct of these studies (OECD, 1997, 2008). To meet EPA guidelines, the screen is performed prior to

the start of treatment, then periodically during the course of treatment. It may be performed as a separate study, on satellite groups of animals in conjunction with the main study, or on animals in the main portion of the toxicology study. The ICH in 2002 adapted guidelines requiring neurobehavioral assessment of all new pharmaceuticals prior to initiation of Phase I clinical trials. To meet ICH guidelines, a more formal functional observational battery should be conducted and may be conducted on main study animals or may be conducted as a separate study. Where initial screens indicate the possibility of a test compound−related change, a more specialized series of tests may be performed to assess the nature of the effect and the extent of the central nervous system involvement. These secondary tests evaluate motor and sensory function as well as cognitive ability. Examples of secondary tests include sensory-evoked potential experiments and schedule-controlled behavior studies. Descriptions of these secondary tests can be found in Annau (1986).

Functional Observational Battery

The typical observational battery (FOB) includes observation of home-cage and open-field activity as well as measurements of reflexive, physiological, and neuromuscular function (Gad, 1982; Moser et al., 1988; Moser and Ross, 1996) as outlined in Table 2.15. Observations and measurements that have become standard for an FOB evaluation are in Table 2.16. The order of measurement should be consistent, progressing from the least interactive to the most interactive measurements. Home-cage observations are made first. Assessments of posture, clonic movements, tonic movements, and palpebral closure (if the animal's eyes can be seen) are taken prior to removing the animal from its cage. However, it may be necessary to pull the cage from the cage bank or remove the cage cover to see the animal's eyes. The animals are then transferred to the open field. During the transfer, certain physical observations are made. The technician removes the animal from the cage. The technician holds the animal and notes increased or decreased body tone as well as such observations as bite marks, soiled fur appearance, missing toe nails, emaciation (shallow stomach, prominent spinal vertebrae), or death. In addition, observations of lacrimation, palpebral closure, piloerection, exophthalmus, and salivation are also made. The animal is then placed in the open-field apparatus for a set period of time. Measurements of rearing, urination, and defecation are made immediately at the end of the assessment period. Assessment of clonic movements, tonic movements, gait, mobility score, arousal, respiration, stereotypic behavior, and bizarre behavior may be made

TABLE 2.15 Functional Observational Battery in Rats

	Number of Animals	
	Males	**Females**
Control	10	10
Low dose	10	10
Mid dose	10	10
High dose	10	10

Dosing: The test article will be administered by the required route.

Functional Observational Battery: FOB evaluations will be conducted prior to dosing, at the estimated time of peak effect, and 24 h postdose. The evaluations are as follows:

Home Cage Observations:

Assessments of posture, clonic movements, tonic movements, and palpebral closure (if the animal's eyes can be seen) are taken prior to removing the animal from its cage.

Handling Observations:

Observations of ease of removal, handling reactivity, lacrimation, palpebral closure, piloerection, and salivation are made on removal of the animal from the home cage.

Open Field Observations:

The animal is placed in the center of an open-field testing box (measuring $20'' \times 20'' \times 8''$). Clean absorbent paper may be used to cover the bottom of the box if required by protocol. Using a stopwatch, the animal's stay in the box is timed for 3 min. Measurements of rearing, urination, and defecation are made immediately at the end of the 3 min. Assessment of clonic movements, tonic movements, gait, mobility score, arousal, vocalization, respiration, stereotypic behavior, and bizarre behavior may be made immediately after the 3 min have ended or the technician may continue to observe the animal for a longer period of time to allow for more accurate assessment.

Sensorimotor Observations:

The approach response, touch response, click response, and tail-pinch response (stimulus reactivity tests) are performed while the animal is in the open-field apparatus, after the 3 min time period is over and all other measurements have been recorded. The animal is removed from the open field apparatus for the pupil response, righting reflex, thermal response, hind limb splay, and grip strength measurements.

Physiological Evaluations:

The animal's body weight and rectal temperature is measured and recorded.

Clinical Examination: Following each FOB assessment (additional observations will be conducted prior to dosing for locomotor activity, if requested).

immediately after the time period has ended or the technician may continue to observe the animal for a longer period to allow for more accurate assessment. When the open-field assessment has been completed, the animal is removed from the open-field apparatus for the approach response, touch response, click response, tail pinch response, pupil response, righting reflex, thermal response, hind limb splay, and grip strength measurements. After completion of the manipulative assessments, the physiological evaluations are completed.

Procedures used during the performance of an FOB must be standardized because some observations made have a subjective component. If at all possible, a single observer should be used throughout a single study. If not possible, a single observer should conduct all assessments of an animal. In addition, technicians should be blinded to the treatment conditions for each animal.

Locomotor Activity

Methods used for recording motor activity include direct observation and automated techniques such as photocell devices and mechanical measurements (MacPhail et al., 1989). In direct observations, the observer can make quantitative measurements of the frequency, duration, or sequencing of various motor components of behavior or qualitative records on the presence or absence of certain components of activity. Photocell devices record the number of times an animal interrupts a beam in specially designed chambers. In mechanical chambers, the animal's movements result in a vertical or horizontal displacement of the chamber; records are kept of the chamber's movements. There are advantages and disadvantages of each technique. In direct observation, record can be made of behavior, such as convulsions, which may not be observed when using the photocell or mechanical methods. A disadvantage of the direct observation method is that the animal may be influenced by the presence of the observer. Advantages to the photocell and mechanical methods are that the data are captured electronically, the observer does not have to be present, and the computer system can graphically present the data in the form of lines crossed or a map of the activity.

To make activity determinations, an animal or group of animals is put into an observation or recording chamber and activity is recorded for a specific period of time. Because activity will normally decline over the course of the session, the length of the observation period is important. The EPA guideline specifies that activity should approach asymptotic levels by the last 20% of the session. Haggerty (1989) used a 15-min recording session, accumulating data over three 5-min intervals. Because a large number of environmental conditions can affect motor activity, e.g., sound level, cage design, lighting, temperature, and humidity, or odors, it is important to minimize variations in the test environment.

Cardiovascular Parameters

Examinations of the cardiovascular system may be scheduled into toxicology studies or performed when the cardiovascular system is a suspected target of the test compound. The ICH has adapted guidelines requiring cardiovascular safety assessment of all new pharmaceuticals prior to initiation of Phase I clinical trials. This guideline recommends that this assessment be conducted in a nonrodent species, but cardiovascular assessment can be performed for screening purposes or as additional support data.

TABLE 2.16   Functional Observation Battery

Home Cage	Open Field	Manipulative	Physiological and Neuromuscular
Posture	Rearing	Ease of Removal From Cage	Body Weight
Clonic Movements	Urination	Handling Reactivity	Body Temperature
Tonic Movements	Defecation	Lacrimation	Hind limb extensor strength
Palpebral Closure	Clonic Movements	Palpebral Closure	Grip Strength
	Tonic Movements	Piloerection	Hind limb Splay
	Gait	Exophthalmus	
	Mobility	Salivation	
	Ataxia	Approach Response	
	Arousal	Touch Response	
	Vocalizations	Click Response	
	Respiration	Tail Pinch Response	
	Stereotypical	Pupil Response	
	Bizarre Behavior	Eye blink response	
		Forelimb extension	
		Hind limb extension	
		Righting reflex	
		Thermal Response

Electrocardiography

Although the dog has traditionally been the species of choice in toxicology studies of effects of ECG (also called EKG), research with the rat has progressed and increased over the years. Detweiler (1981) and Detweiler et al. (1981) provide an excellent review of the use of electrocardiography in toxicology studies in the rat. This section will present a general discussion on the aspects of the recording methods and interpretation of the ECG in the rat.

Recording Methods

Restraint

One of the disadvantages of traditional methods of studying ECGs in rats is that it is difficult to keep the animals still while recording. It is important that the animal remain in a constant position during the procedure using skin leads to avoid muscular artifact in the ECG. Various forms of restraint have been tested, each of which requires acclimation to the procedure prior to evaluation. These methods included restraining the rat in a supine position using rubber gloves (Hundley et al., 1945), pinning the animal to a board, boards with clamps, and plastic tubes with slits on either side, which allow for placement of the electrodes (Zbinden et al., 1980; Spear, 1982). Various forms of anesthesia have also been evaluated.

No conclusion has been reached about the best method of restraint. The basic concerns are that manual methods and physical restraint require acclimation to allow the animal to become accustomed to the procedure, and tracings can be reasonably free of muscular artifact. Also, varying pressures of clamps or handling during the restraint may affect the results. The use of anesthesia has been shown to produce changes in the ECG and the possibility of drug interactions between the anesthetic and the test compound may occur.

Position

The most common positions are the prone or ventral recumbency position when animals are awake and the supine or dorsal recumbency position when anesthetized. Beinfield and Lehr (1956) compared the positions and concluded that the prone position produced an increased R wave and it avoided unfavorable cardiac rotation and an undesirable variation in the projection of the special QRS loop.

Tethered

Robineau (1988) developed an electrode system that can be implanted sc a few days prior to recording. The device has a disconnect that is exteriorized between the scapula. The advantage of this system is that a cable can be connected to the plug and the ECG can be taken in unrestrained rats. The disadvantage of this method is that it should only be used for short-term studies as the implant provides a source for infection in the animal.

Leads

Most investigators use Einthoven's bipolar limb lead system, lead I (right and left foreleg), lead II (right foreleg and left hind leg), and lead III (left foreleg and left hind leg), with and without the augmented unipolar limb leads aVR (right foreleg), aVL (left foreleg), and aVF (one of the hind legs). Because foreleg position can alter the scalar ECG wave amplitudes, investigators must standardize foreleg positions during recording. When implanting telemetry leads, the leads are placed on the right clavical and the most caudal rib on the left side in a modified lead II configuration.

In the past, various types of leads have been used to connect the ECG wires. These included the use of hypodermic needles inserted under the skin, small gauge insulated copper wires wrapped around the shaved distal portion of the limbs, or alligator clips. In addition, platinum-tipped pin electrodes are commercially available, which provide a good quality signal with limited discomfort to the animal.

Telemetry

For the last 10 years, techniques have been developed for monitoring cardiovascular parameters via telemetry in the rat (Kuwahara et al., 1994; Kramer et al., 1995; Ichimaru and Kuwaki, 1998); they have been developed, improved, and used increasingly. Totally implantable battery-operated systems that can monitor several physiological parameters including ECG have been developed. The implants are available with ECG leads that can be positioned in the Lead II configuration for monitoring ECG continuously for extended periods of time in a freely moving animal. As the leads are attached sc to the musculature, the signal is of a higher quality than skin leads. Also, the animal is not affected by the observer, as the animal can be monitored remotely. One of the disadvantages is that these implants are only designed to monitor a single lead.

ECG Waveform

The major points to notice about the rat ECG are that the conventional waves of the mammalian ECG (P, QRS, and T) are all identifiable in the rat ECG, there is no isoelectric line during the electrocardiographic complex,

and there is no ST segment. The duration of the standard intervals evaluated in the ECG of the rat are as follows: P, 10–20; PR Interval 35–50; QRS complex 12–25, and QT interval 38–80 ms (Detweiler, 1981). The duration of the intervals is related to the heart rate; as the heart rate increases, the intervals shorten and as the heart rate slows, the intervals prolong. These intervals can also be affected by administration of test compounds and are the basis for the requirement to assess the effects of a test compound on cardiac function. Specifically, prolongation of the QT interval has been correlated with a phenomenon call Torsade de Pointe or sudden cardiac death. Several classes of compounds, such as antihistamine and Ca^{2+} channel blockers have been shown to prolong the QT interval (Gras and Llenas, 1999). Each wave of the ECG represents either a depolarization or repolarization of the atria and ventricles of the heart. For example, the P wave is an electrical representation of the depolarization of the right atria and the T wave is an electrical representation of the repolarization of the left ventricle. Spear (1982) provides a more in-depth discussion of the waveforms and the electrophysiology of the heart. Several computerized systems that are capable of recognizing the independent waveforms and measuring the intervals have been developed. Caution should be taken when using these systems as they are typically programmed to recognize a normal ECG, and the presence of arrhythmias may be missed or interval may not be measured correctly.

Heart Rate

The heart rate can be calculated from standard limb lead ECGs by measuring the distance between the two peaks of the R wave. This distance is then divided by the chart speed (i.e., 50 mm/s) to calculate the RR Interval in seconds. This is then divided into 60 s to calculate the heart rate in beats per minute. Using the formulas below, the heart rate of an RR Interval of 10 mm is measured on a chart printed at 50 mm/s = 300 beats/min.

RR Interval (mm/beat)/Chart Speed (mm/s) = RR interval (s/beat)

(60 s/min)/RR interval (s/beat) = Heart Rate (Beats/min)

Many environmental factors can affect the heart rate of the rat, such as excessive manipulation, technicians the animal is not familiar with, new environments, etc. Therefore, when evaluating ECG using a restrained method, it is important to acclimate the animal to the test procedures prior to starting. Detweiler (1981), in a review of the literature, found that published heart rates for rats varied between 250 and 750 beats/min. Awake, restrained adult rats had heart rates from 330 to

600 beats/min and well-acclimated restrained adult animals had heart rates from 250 to 350 beats/min. Heart rate in unrestrained telemetrized animals has been reported to be between 225 and 350 beats/min (Guiol et al., 1992; Zbinden, 1981).

Blood Pressure

During the conduct of a toxicology study it may be necessary to monitor blood pressure. This can be done using either indirect or direct methods. Caution should be taken when using indirect methods as the values obtained may be variable. The direct method involves the implantation of an arterial cannula for measurement of blood pressure. This method is more reliable, but it has a limited period during which the cannula may remain patent. It is recommended that for definitive assessment of the hemodynamic effects of a test compound, a nonrodent species such as a dog or a nonhuman primate be used.

Indirect Measurement

Indirect methods of blood pressure measurement detect systolic blood pressures by the occlusion of arterial inflow of blood and the subsequent detection of the pressure at which the first arterial pulsation occurs. The two places where indirect measurements can be made on the rat are the tail and the hindpaw.

Tail Cuff Method

The tail cuff method monitors pressures in the ventral caudal artery. In this method, the animal is put into a restrainer that allows for free access to the tail. An inflatable cuff is then placed around the base of the tail and the pressure is increased until flow stops. The pressure is then slowly released until flow resumes. The cuff pressure at the time when flow resumes is the systolic blood pressure. Various methods have been used to determine when this occurs.

Because the caudal pulse is rather weak, preheating of the animals in boxes at temperatures of $30-42°C$ for periods up to 10 min may be necessary to dilate the caudal artery. This technique should be used with caution, as previously discussed changes in body temperature can have widespread effects on the animal and may produce unexpected test compound effects.

The placement and width of the tail cuff is important. There is a gradient in pressure along the caudal artery, which amounts to 4.5 mmHg/cm. For this reason, the cuff should be placed close to the base of the tail and this should be standardized. If multiple reading will be done over time, marking the placement of the cuff with an indelible marker will help to standardize placement. In addition, variation in the width of the rubber

tubing can be a source of error. Bunag (1973) found that the most accurate readings were given by a 15-mm cuff; shorter cuffs gave falsely elevated readings and longer cuffs gave low readings.

Hindpaw Method

Measurement of blood pressure in the hindpaw does not measure the pressure in a specific vessel. In this method, the animal is placed in a restrainer, as in the tail cuff method. A pressure cuff is placed around the ankle to occlude blood flow and blood pressure is measured as the cuff pressure is released and blood flow returns. As in the tail cuff method, several techniques have been used to determine the return of blood flow. These include visual observation (Griffith, 1934), photoelectric cell (Kersten et al., 1947), and oximeter (Korol and McShane, 1963). The advantage of the photoelectric and oximeter methods is that they do not require preheating to dilate the vessels of the hindpaw. The oximeter method measures mean arterial pressure rather than systolic pressure. None of the indirect measurements are able to evaluate the complete hemodynamic cycle. They evaluate only systolic or mean arterial pressure, but not systolic, diastolic and mean arterial pressure together.

Direct Measurement

The direct measurement techniques involve the cannulation of an artery with the blood pressure being determined with a manometer or transducer connected to the free end of the cannula. This is true for types of direct measurement including telemetry. Surgery and cannula placement utilize similar techniques as those previously described for placement of a venous catheter. In short, the artery is isolated and a small incision is made in the femoral artery. The catheter is then inserted into the hole and passed into the abdominal aorta. The carotid artery may also be used for this procedure, but care should be taken not to insert too far as the catheter may be passed into the left ventricle of the heart. If this occurs, the blood pressure waveform will change in appearance. The left ventricular waveform has a similar systolic pressure as an arterial blood pressure waveform. But the diastolic pressure is much different. If the catheter has been placed in the left ventricle, the diastolic pressure will be 0 mmHg or slightly negative. If this occurs the catheter should be backed out into the aortic arch.

Where chronic use is desired, cannulas are typically run sc and exteriorized between the scapula or at the back of the head. A carotid artery catheter can be expected to remain patent for $3-5$ weeks (Ross, 1977; Andrews et al., 1978), whereas an abdominal aorta

catheter may remain patent for several months. Care should be taken when using arterial catheters for long periods as fibrin deposits can build up on the catheter or clots may form in the catheters. The risk exists that these deposits or clots could be expelled during the flushing of the catheter or during normal movement of the animal. These clots or deposit once free may occlude other vessels downstream and in the case of a carotid catheter may cause a stroke to occur.

Blood Collection Techniques

Blood samples are routinely collected in safety studies to determine: (1) direct test compound effects on the blood or bone marrow, (2) effects on other organs as indicated by the contents of the blood, for instance, leakage enzymes such as aspartate aminotransferase (AST), and (3) blood levels of the test compound or its metabolites. A variety of techniques have been described for the collection of blood from the rat. The choice of a specific technique may depend on factors such as: (1) the volume to be collected, (2) if the animal is to survive the procedure, (3) the frequency with which samples will need to be collected, (4) whether anesthetics can be used, (5) likelihood of the animal surviving the procedure, and (6) the impact of organ damage resulting from the procedure. An adult rat has a blood volume of about 50 mL/kg; approximately 10% of the total blood volume can be collected from the rat in a single draw without adversely affecting hematology parameters. For longer-term studies, 10 mL/kg per 2 weeks is a reliable guideline for volume of blood drawn. If these volumes are exceeded, hematocrit and red cell mass may be reduced on evaluation (Diehl et al., 2001).

Technique, anesthetic used for blood draws, and treatment of the animals (i.e., fasted or not fasted) should be standardized throughout a study if repeated samples are being taken. The technique, anesthetic, and handling of the animal may produce effects on the hematology or clinical chemistry parameters to be evaluated.

Retro-Orbital Plexus

The retro-orbital plexus is a commonly used site for periodic sampling during the course of a study. This method has been shown to be a reliable method for the repeated collection of blood samples. Collection from this site should always be conducted under anesthesia to reduce pain and stress to the animal. Light anesthesia with a mixture of carbon dioxide and oxygen will minimize struggling of the animal and will help to ensure a quick collection with little injury to the animal.

Blood is collected using a microcapillary tube or the fine end of a Pasteur pipet. The tube is inserted into the orbit of the eye at an anterior angle formed by the lids and the nictitating membrane. A slight thrust past the eyeball will make the tube enter the slightly resistant horny membrane of the sinus. The tube may be rotated slightly as it is inserted. Once the sinus has been punctured, blood will fill the tube. Once the tube is filled, the blood may be allowed to drip out of the end of the tube into an appropriate collection tube. If the flow stops, the tube may be pulled out or advanced slightly to reestablish flow.

In the hands of an experienced technician, there is minimal risk to the animal. Studies have shown that repeated collection of blood from the retro-orbital sinus can produce histological and behavioral changes that may require an animal to be removed from study (McGee and Maronpot, 1979; van Heck, 1998). Several serious side effects of this collection method have been documented. These include retro-orbital hemorrhage, corneal ulceration, keratitis, pannus formation, damage to the optic nerve, and fracture of the orbital bones. When designing the study, the method of blood collection should be taken into consideration. If an important end point of the study is ophthalmological examinations, this method should not be used. In addition, anesthetization of the animals may affect other study end points.

Tail

A tail vein bleed offers a visible target and is of minimal risk to the animal. Blood will flow faster if the tail has been warmed causing vasodilation. This may be accomplished by dipping the tail in warm water (40–45°C), placing the animal in a warming cabinet for 5–10 min, or warming the tail with a heat lamp. This method does not require that the animal to be anesthetized, but the animal should be restrained such that the tail is held immobile. Several methods may be employed to collect blood from the tail. These include clipping the end of the tail off, vein puncture, or artery puncture.

Tail Clip

For this method, the animal may be lightly anesthetized or placed in a restraint tube. To collect blood, 2–3 mm of the distal part of the tail is amputated with sharp scissors or a scalpel blade. Blood of 3–4 mL can be collected in 20–30 s from a 200–250 g rat. When collection has been completed, the cut surface may be cauterized with a hot spatula or glass rod. This method produces a reliable volume of blood, but it should not be used for repeated sampling over extended periods of time.

Venipuncture

Animals should be restrained in a holder that allows complete access to the tail. The tail should then be cleaned and pressure may be applied to the base of the tail causing the vein to dilate. The vein should be punctured using a 21-gauge needle, and the blood can either be slowly withdrawn into a syringe through the needle or the needle may be removed and the tail allowed to bleed freely. The use of a butterfly needle may help facilitate the collection of blood as it is less likely to be dislodged if the tail moves. Collection of blood from the tail vein typically yields samples of between 0.5 and 1.0 mL. On completion of sample collection the needle should be withdrawn and pressure is applied to the tail to stop the bleeding (Frank et al., 1991).

Arterial Puncture

This method is conducted in a similar manner to a venipuncture in that the animal is placed in an appropriate restraint tube and the tail is cleaned. A 21-gauge needle is then inserted into the artery in the midventral surface of the tail close to the distal end. The blood is then withdrawn into a syringe or allowed to flow freely into a collection tube. The animal's blood pressure will ensure whether the blood continues to flow until pressure is applied to the wound.

Cardiac Puncture

This method should always be performed under general anesthesia and should not be used as a survival collection technique. This technique offers a rapid method for collection of a large volume of blood from the rat. It is possible to collect between 5 and 7 mL from a 300−350 g rat using this technique, and it is possible to exsanguinate the animal using this method.

To collect blood using this method the animal should be anesthetized with a combination of carbon dioxide and oxygen or carbon dioxide alone. The animal is then placed in dorsal recumbency and the heart is located. The heart may be located by placing the index finger over the fourth and fifth left ribs and the thumb on the right side of the thorax. The collection needle (25−26 gauge, 1−2-cm long) should be inserted at a 45-degree angle into the heart. Once the needle is introduced, the syringe should be aspirated slightly to produce a vacuum. The needle is then advanced until blood is obtained.

Abdominal Aorta and Vena Cava

Collection from the abdominal aorta offers a convenient way to exsanguinate an animal and obtain a maximal amount of blood (Popovic and Popovic, 1960). To perform the procedure, the animal is anesthetized and the aorta exposed by dissection. A section of the aorta distal to the diaphragm is then exposed and the proximal end is clamped. The aorta is then cut and the distal end placed in a collection tube and the clamp is released. This method will allow for collection of a maximal amount of blood in a short period of time. This method should only be used as a terminal procedure. Alternatively, the aorta may be accessed using a needle or a butterfly needle and samples may then be collected into a syringe.

Winsett et al. (1985) described a method of repeated sampling from the vena cava of conscious rats. An assistant holds that animal while the operator grasps the animal just below the last rib. The needle is inserted 1 cm to the right of the spinous process of the first lumbar vertebra at a 45 degrees angle until the needle touches the bone. The needle is slightly withdrawn and then advanced at a slightly shallower angle to miss the bone and access the vena cava. The maneuver of first identifying the bone is essential to the procedure. This procedure may be used for repeated collection, but care should be taken to ensure the animal does not struggle during the collection. If the animal struggles, the needle may lacerate the vena cava causing the death of the animal.

Jugular Vein

The jugular vein provides a means for chronic blood sampling that is of low risk to the animals' health. This method does not require the use of anesthesia and can be accomplished through the proper restraint and positioning of the animal.

The unanesthetized method requires two technicians to perform the collection. The animal is placed on a restraint board in dorsal recumbency. The forelimbs are tied down to the board and one technician holds the hind limbs of the animal. The second technician grasps the animals head and turns it down and away from the desired collection site, right or left jugular. The needle (21 gauge) is then inserted into the middle of the triangle formed by the neck, shoulder, and clavicle, parallel to the body. As the needle is inserted, the syringe is aspirated until blood is observed in the syringe. The collection is then completed and the site is held off for approximately 30 s. It is important that the technician holding the hind limbs of the animal continually observe the respiratory rate of the animal. If the head is turned too far or is held in the wrong position for too long, the animal may go into respiratory distress. This method may be used for repeated collections with a high level of success.

Alternatively, the animal may be anesthetized and the jugular vein may be surgically exposed. The animal should be prepared using standard aseptic technique and the ventral neck should be shaved. The jugular vein may be exposed by incision of the skin and

dissection of the sc tissues. A needle (20 gauge) may then be inserted into the vein through the pectoral muscle, directing the needle toward the head. Inserting the needle through the muscle will help to stabilize the needle during the collection. Once the needle is in place, the blood should flow freely with little to no aspiration. Care should be taken when aspirating the syringe as too much pressure will cause the vein to collapse. Once the collection is complete, the incision can be closed with a wound clip. This method may be used as an alternative if the animal does not require serial bleeds or as a method to replace a terminal bleed. If the procedure is used for a terminal bleed, strict aseptic technique is not necessary.

Proximal Saphenous and Metatarsal Vein

A small amount of blood (0.1−0.2 mL) can be collected from an animal at minimal risk to their health utilizing the proximal saphenous and metatarsal veins. No anesthesia is required.

Proximal Saphenous Vein

The inner aspect of the thigh of the hind limb should be shaved free of hair. While one technician holds the animal and compresses the inguinal area to dilate the vein, a second technician creates a longitudinal nick in the vein with a 20-gauge needle or a hematocrit lancet. The blood can then be collected into heparinized capillary tubes. This method works well for repeated sampling of small amounts of blood but would not be appropriate for blood volumes required for evaluation of clinical pathology parameters.

Metatarsal Vein

This procedure can be conducted with or without an assistant. The animal is restrained and a nick is made in the vessel with a needle. The blood can then be collected into a capillary tube or through the needle into a syringe.

Sublingual Vein

When using the sublingual vein for blood sampling, the animal should be anesthetized and then cradled in the palm of the hand. By holding the animal's head between the thumb and index fingers, the head can be stretched back and the skin of the face pulled backward. This will force the mouth open and the tongue against the palate. The right or left vein should be cut with iris scissors and the animal held such that blood drips into the collection tube. The bleeding can then be stopped by applying pressure with a gauze pad or cotton-tipped applicator.

Decapitation

Decapitation should only be performed by trained technicians with the appropriate equipment. There are several commercially available small animal guillotines that should be used to perform this technique. This technique is appropriate when a maximal blood volume is desired and contamination of the sample is not considered to be an issue. To perform this method, the head is first removed and the animal is held over the collection vessel and arterial and venous blood is allowed to drain from the body.

Cannulation

Although the blood collection methods described above will provide sufficient volumes and quality of sample for the majority of toxicology studies, specific protocols may require blood to be sampled from animals that have been subjected to a minimum of handling or from specific sites within the body of the animal. Cannulation of a specific artery or vein will typically meet this requirement, though in rodents, the usable life span of the cannula is limited by the length of time the cannula remains patent. Yoburn et al. (1984) compared jugular, carotid, and femoral cannulas for long-term sampling of blood. They found the femoral artery cannula was preferable in terms of patency and postsurgical weight loss. Collection from a cannula is the same regardless of implant site. The cannula is typically exteriorized between the animal's scapula and a stylet is inserted into the end of the cannula. For the purpose of collection, the stylet is removed and a needle is inserted into the cannula with a syringe attached. The heparin lock is then drawn out of the cannula until blood is observed in the syringe. The syringe is then removed from the needle and a new syringe is used to collect the sample. The collection syringe is then removed from the needle and replaced with a syringe filled with the desired solution for locking the cannula, typically a heparin dextrose solution. Once the cannula is flushed and locked with the heparin solution, the stylet is replaced. Using the appropriate technique for flushing and locking the cannula is the key to maintaining the patency of the cannula.

Jugular Vein

The cannulation procedure is the same as previously described for infusion techniques. The cannula has been found to remain patent for a variable period of time, and the length of time the cannula remains patent is directly related to the skill of the technician collecting the samples. It is important to remember that a cannula placed in the venous system can easily develop clots in the cannula if not flushed and locked properly. Various methods of anchoring the cannula to the rats back or head have been developed for ease of sampling or as a connection point for continuous infusion. Each of these methods has been developed such that the exteriorized

cannula is positioned so that the animal cannot gain access to it.

Inferior Vena Cava

The inferior vena cava appears to provide a site for long-lived cannulas. The cannula can be surgically placed either directly into the vena cava through an abdominal surgery or can be advanced into the vena cava from the femoral vein. Either way, the cannula has been shown to remain patent for months (Kaufman, 1980). In either implantation, the cannula is then tunneled sc and exteriorized between the scapula in the same manner as the jugular vein cannula.

Abdominal Aorta

The most common method for placing a cannula in the abdominal aorta is via the femoral artery. The cannula is inserted into the femoral artery and advanced to the level of the just above the kidneys. The opposite end of the cannula is then tunneled to and exteriorized between the scapula. This is a minor surgical procedure in which the animal recovers easily. Similar methods are employed when collecting blood from the arterial catheter as those used for the venous catheter. Caution should be taken when removing the stylet from the cannula, as a cannula in the arterial system is under pressure. If not properly prepared, the animal could quickly lose a large amount of blood. It is recommended that the technician place a clamp on the cannula prior to removal of the stylet. Once the blood collection is complete, the cannula should be thoroughly flushed with saline prior to locking the cannula. The tip of an arterial cannula is positioned such that it is against the flow of blood. Because of this, clots and fibrin deposits develop easily on the end of the cannula limiting the usable life.

Subcutaneous Ports

An exteriorized cannula is a source of contamination, infection, and is subject to destruction by the animal or other animals if group housed. Several types of sc ports have been developed for implantation along with the cannula. These ports are designed such that test materials may be injected or infused through them or blood may be collected from the port. In most cases, the port is implanted sc on the dorsal side of the animal. As with exteriorized cannula, the skill of the technician accessing, collecting samples, flushing, and locking the port directly affects the usable life of the port.

Urine Collection

Urine is generally collected in toxicology studies to assess kidney function. The most common method used for urine collection is a commercially available stainless steel cage. The cage is designed such that the urine and feces are separated by a cone-shaped device. The urine drains off the collecting walls into a tube and the feces fall into an inverted cone. Food and water are made available in such a way that the urine will not be contaminated. Although this type of cage produces urine of acceptable quality for normal urinalysis, the sample may be contaminated with hair or feces. Other methods for urine collection in the rat include cystocentesis, which involves a needle stick into the bladder, and cannulation of the bladder.

Necropsy

The necropsy is the link between antemortem findings and histological observation. It is an essential portion of the toxicology study, and because a necropsy will involve the processing of a large number of animals, it is important that the procedure is well planned (Black, 1986). At a prenecropsy meeting involving the pathologist, prosectors, and the study director, necropsy responsibilities can be discussed. Additionally, the study director can summarize clinical findings and potential target organs. The prosectors should be familiar with the protocol and amendments for the study involving the animals being necropsied. The protocol should clearly state which tissues are to be collected and weighed and how the tissues should be preserved. During the necropsy, devices such as checklists or prelabeled compartmentalized trays should be present to ensure that all required organs are taken and weighed. In recent years commercially available computer software has been developed to assist in the collection and weighing of tissues at necropsy. This is an electronic copy of the checklist, but it also provides a method for recording observations in a consistent manner. Copies of the last clinical observations should be present at the necropsy, so the prosectors are alerted to lesions that may be present and require special attention. Palpation records are particularly important at carcinogenicity study necropsies to ensure that all masses detected at the last examination are confirmed and collected.

The necropsy will involve a check of animal identification and sex, an external examination of the animal, an in situ examination of all tissues and organs (prior to dissection, and the collecting and weighing of the required tissues).

SUMMARY

In summary, there are several advantages to the use of the rat in toxicology studies. Because of its widespread use in many fields of biology, there is a large historical

database of information about the anatomy and needs of the species. This knowledge, along with information about the species' metabolism and response to toxicants, has shown the rat to be a generally good model for the prediction of the human response to toxicants. Rats have a life span of 24–30 months, which is convenient for chronic toxicity and carcinogenicity studies where animals need to be exposed for the majority of their lifetime. The short gestation time and large litter size make the rat a good model for reproductive studies. The development of specific pathogen-free rats and improvement in husbandry has eliminated most of the disease outbreaks that may have introduced variability into a study. The lack of an emetic response allows for the testing of higher dosages of compound that may cause vomiting in other species. The small size of the rat is useful in that a large number can be housed economically. The size is also useful in that smaller amounts of test compound are required to gain maximal exposure.

The relatively small size of the rat is also one of its major disadvantages. The amount of blood that can be taken from the animal is limited, thus limiting the number of parameters that can be investigated or the number of toxicokinetic samples that can be collected from a single animal. This problem can be overcome by adding additional animals in interim sacrifice groups or by collecting toxicokinetic samples from cohorts of animals at different times. In most cases it is recommended that toxicokinetic samples be collected from satellite animals and not from the main study animals being used for evaluation of toxicity. However, an increased number of animals means increased work in the conduct of the study. The small size and relatively active nature of the rats makes some procedures, such as iv dosing or collection of electrocardiograms, difficult. These issues have been overcome with the use of suitable restrainers or in some cases, anesthesia. The rat has been used successfully in toxicology research for close to a century and will continue to be used for the foreseeable future.

The Mouse

Use in Toxicological Research

As discussed earlier, the choice of a species for toxicity testing is based on consideration of a range of variables. Ideally, if toxicity testing is intended to provide information on the safety of a test article in or by humans, the species chosen for testing should be most similar to humans in the way it handles the test article pharmacodynamically. Substantial differences in absorption, distribution, metabolism, or elimination between test species and the target species, e.g., humans, will reduce the predictive value of the test results.

From a practical standpoint, often the pharmacokinetics is unknown in humans or the variety of available test species at the time of species selection. For this reason, testing is usually conducted in at least two species. Generally, one of those species is usually a rodent and one a nonrodent.

Mice have many advantages as test animals for toxicity testing. They are small, relatively economical to obtain, house, and care for, and they are generally easy to handle. Mice are generally more economical than rats in these respects. Although mice may attempt to escape or bite handlers, with regular, gentle handling they are easily managed. Other advantages of the species include a short gestation period and a short natural life span. These characteristics allow studies that include evaluation of reproductive performance or exposure to a test article for periods approaching the expected life span (e.g., evaluation of carcinogenic potential) to be conducted in a practical time frame. High quality, healthy mice are available from reliable commercial suppliers. Many genetically well-defined highly inbred, specifically or randomly outbred strains are available. Mice have been used in biomedical research for hundreds of years, and because of this, many technical procedures have been developed for use with the species, and a vast body of historical data is available for most strains. This historical database includes information on optimal nutritional and housing requirements in addition to data such as the expected background incidence of various diseases and types of tumors in untreated animals, and is continuously being added to (Blackwell et al., 1995). An additional advantage for mice, particularly when testing highly humanized biological products, is that transgenic mice that have the gene encoding the specific human pharmacodynamic drug receptor can now be readily developed.

There are also disadvantages to using mice, and most are related to the small size of the animal and the limits that this imposes. The smaller size and higher metabolic rate compared with the rat renders the species less hearty than rats. Deviations in environmental conditions such as an air conditioning failure or failure in an automatic watering system typically have more severe effects on the smaller species such as mice than the same deviations have on rats. Owing to their high level of natural activity, most strains of mice will not become as docile or easy to handle as rats that have received equivalent handling. Small size often precludes or renders more difficult a number of procedures that are commonly conducted in toxicity testing, such as the collection of large samples or repeated samples of blood and urine, electrocardiographic evaluation, and some necropsy evaluations. The FDA provides Human Equivalent Dose interspecies conversion factors for converting most animal model NOAELs or such to a human

equivalent. The conversion factor for the mouse is 12.1, meaning an observed NOAEL in a mouse of 12.1 mg/kg/day would be converted to 1.00 mg/kg/day for conservative human administration. This relatively high value imposes a de facto penalty on using mice as one of the species in a safety assessment.

This section will provide brief summaries of some of the normal physiological values and salient features of the species and some of the specific strains that may be useful in selecting an appropriate species and strain for toxicity testing.

Normal Physiological Values

Selected normal physiological values for mice are shown in Tables 2.17 and 2.18. Median survival of a number of groups of Charles River CD-I outbred mice is shown in Table 2.19.

These normal values will vary depending on the strain of mouse, supplier, condition at arrival, type of feed, environmental and housing conditions, and, in some cases, time of year. These data should be considered as a reference but will not necessarily represent experience in any particular laboratory.

Species Differences

Mice are similar to other common laboratory animal species and to humans in many ways, yet the differences should not be underestimated and must be understood. Mice have a high metabolic rate compared to other species. This fact alone may result in increased or decreased toxicity of a test article, depending on the specific mechanism of intoxication. In many cases, high metabolic rate may be associated with rapid absorption, distribution, metabolism, and elimination of a test article. It may also lead to higher systemic C_{max} levels of toxicants such as reactive oxygen species. Mice are obligate nose breathers and have more convoluted nasal passages than humans. This may result in an excess of respirable test article deposited in the nasal passages, resulting in either increased or decreased relative toxicity, depending on the most critical site of absorption. The small size of the mouse compared to other common laboratory species offers a significant advantage if the test article is expensive or in short supply. As an approximation, a mouse weighs about 10% as much as a rat, about 5% as much as a guinea pig, about 1% as much as a rabbit, and less than 1% as much as a dog or primate. Material requirements to administer equivalent dose levels are usually proportional to body weight, so the test article savings associated with the mouse are evident. The small size of a mouse results in high surface area to body mass ratio, which in turn causes the mouse to be relatively intolerant of thermal and water balance

TABLE 2.17 Normal Physiological Values General and Reproductive

GENERAL	
Life span	
Average	1–3 years
Maximum reported	4 years
Adult weight	
Male	20–40 g
Female	18–40 g
Surface area	0.03–0.06 cm^2
Chromosome number (diploid)	40
Food consumption	4–5 g/day
Water consumption	5–8 mL/day ad libitum
Body temperature	36.5°C
Oxygen consumption	1.69 mL/g/h
REPRODUCTIVE	
Age, sexual maturity	
Male	50 days (20–35 g)
Female	18–40 g
Breeding season	Continuous, cyclic
Estrus cycle	4–5 days
Gestation period	
Average	19 days
Range	17–21 days
Litter size	
Average	12
Range	1–23
Birth weight	1.5 g
Age begin dry food	10 days
Age at weaning	16–21 days (10–12 g)

Data derived from Fox, J.G., Bennett, S.W., 2015. Biology and diseases of mice. In: Fox, J.G., Anderson, L., Otto, G., Prichett-Corning, K., Wary, M. (Eds.), Laboratory Animal Medicine. Academic Press, New York, pp. 31–89.

stresses. The kidneys of a mouse have about twice the glomerular filtering surface per gram of body weight as a rat, and owing to the specific architecture of the murine kidney, they are capable of producing urine that is about four times as concentrated as the highest attainable human concentrations (Fox and Bennett, 2015). These characteristics of renal architecture and function may be important to the toxicity of some test articles. Mice differ from most species by the formation of a persistent vaginal plug after mating. The presence of a vaginal plug is easily detected, is considered evidence

TABLE 2.18 Normal Physiological Values Cardiovascular and Respiratory

CARDIOVASCULAR	
Heart rate	
Average	600/min
Range	320−800/min
Blood pressure	
Systolic	113−160 mmHg
Diastolic	102−110 mmHg
Blood volume	
Plasma	45 mL/kg
Whole	78 mL/kg
Hematocrit	41.5%
RBC life span	20−30 days
RBC diameter	6.6 microns
Plasma pH	7.2−7.4
RESPIRATORY	
Rate	
Average	163/min
Range	320−800/min

of mating, and is a useful characteristic during the conduct of reproductive studies.

It is also frequently the case in pharmaceutical research and development that the nonclinical efficacy model for a new drug is in the mouse, making it the natural choice for rodent evaluation of the drug.

Strain Differences

In addition to differences between mice and other species, there are important differences among different strains of mice. The appropriate choice of a strain of mice for a particular toxicity study should consider the specific objectives of the study and the specific characteristics of candidate strains that might assist or hinder in achieving those study objectives.

One difference among strains is in the normal body weights of various strains at different ages. These differences are summarized for selected strains available from the Charles River Breeding Laboratories in Table 2.20. Outbred strains tend to be larger at maturity than inbred strains, with the CD-I strain reaching the highest mean weights at 56 days of age of those strains in Table 2.20. The CF1 strain has been reported to be highly resistant to mouse typhoid and to be relatively resistant to salmonellosis (Hill, 1981). Nude or athymic strains of mice are more sensitive to tumor development than heterozygous strains. These sensitive strains develop the same types of tumors as those seen in more conventional strains, but the incidences are higher and the latency periods shorter. There is a wide spectrum of susceptibility to spontaneous lung tumors in various strains of mice, and evidence suggests that there is a high correlation between spontaneous incidence and chemical inducibility in those various strains (Shimkin and Stoner, 1975).

The inbred strain A mouse appears to be the most susceptible to lung tumors and forms the basis of a

lung tumor bioassay, with tumors inducible within 8 weeks or less of treatment. Susceptibility of various strains to the initiation and/or promotion of skin tumors has also been shown to differ greatly (Chouroulinkov et al., 1988; Steinel and Baker, 1988). The incidences of selected spontaneously occurring neoplastic lesions in CD-I (outbred) and B60171 (hybrid) strains are compared in Table 2.21.

The number of strain-related differences in susceptibility to various test articles and environmental conditions exceeds the scope of this chapter, but additional information is available (Nebert et al., 1982).

STUDY DESIGNS

Most toxicity and teratology studies conducted in mice are designed to provide information on potential human toxicity. Test substances are typically administered by the expected route of human exposure. A pharmaceutical product that is intended for oral administration (tablet, capsule, solution, or suspension) or a food additive would generally be administered by the oral route. Oral administration to mice is usually accomplished by administration of a solution or suspension by oral gavage, by mixture of the test substance with the diet, or less commonly added to the drinking water.

The specific design of toxicity studies should be tailored to the objective to be achieved and to any specific characteristics of the test substance. Many features of study design will be predicated on guidelines and practices of regulatory agencies such as the FDA or EPA in the United States or their counterparts in other countries to which the results of the study are submitted

in support of a safety claim. Recommendations for study length (duration of dosing) fall in this category.

Toxicity studies are usually conducted in order of increasing duration of dosing, beginning with acute toxicity studies. When this regimen is followed, each study provides progressively more useful information for the selection of doses for the next, longer study.

Acute Toxicity Studies

Acute toxicity studies are conducted to evaluate the effects of a single substance. Usually each animal receives a single dose of the test substance in this study design. On rare occasion, repeated doses may be administered, but in any event, all doses are administered within 24 h or less. Historically, a primary objective of acute toxicity testing was to determine an LD_{50} dose, or that dose which would be lethal to 50% of the animals treated. To achieve this objective, groups of mice, often numbering 10 or more per sex, are treated with a single dose of the test substance. Depending on the rate of survival in the initial group(s), additional groups are added to the study at higher and/or lower doses such that most animals that receive the highest doses die and most that receive the lowest doses survive. Survival is assessed at some predetermined interval after dosing, usually 7 or 14 days, but occasionally as early as 24 h. The resultant dose−response data can be analyzed by a statistical method such as probit analysis (Finney, 1971) to provide an estimate of the median lethal dose (LD_{50}) and some measure of the precision of that estimate, such as the 95% fiducial limits. There are very few scientifically valid reasons to include determination of the LD_{50} as a significant objective of acute toxicity testing, and most regulatory agencies have dropped their requirements for a specific value for the LD_{50}, and animal welfare considerations preclude the use of the large numbers of animals previously required.

A more contemporary design for acute toxicity testing attempts to derive a maximum amount of information from a minimum number of animals. Study objectives include determination of the most important clinical signs attributable to high doses of the test substance, time of onset and remission of those signs, possible determination of a minimum lethal dosage, and in the event of lethality, the sequence and timing of effects leading to death or recovery. These objectives are achieved by means of a comprehensive schedule of animal observations following dosing. These objectives can usually be achieved by treating from one to three groups of three to five mice/sex/group at different doses.

Traditionally, acute toxicity testing of potential new pharmaceutical products is conducted in at least three species, with one being a nonrodent, and by at least two routes of administration, one of which is the intended clinical route. Mice are the most frequently selected rodent species for acute toxicity testing. The choice of routes of administration depends on the intended clinical route and on how much is already known about the oral bioavailability of the test substance. If the intended clinical route is oral, acute testing by oral gavage with a solution or suspension is of primary importance. If other clinical routes are anticipated (e.g., iv or dermal), they represent good secondary routes for acute testing. Ordinarily, at least one parenteral route is used for acute testing, and that route may be intravenous (IV) if the product is soluble in a fairly innocuous vehicle (e.g., water or saline) or ip as a suspension if the product is insoluble in an aqueous (or other innocuous) vehicle. If the intended clinical route is not oral, the oral route is usually selected as a secondary route for acute toxicity testing to provide information relevant to accidental oral ingestion. A rough estimate of oral bioavailability can be based on a comparison of the acute toxicity associated with various doses administered by the oral and parenteral routes. Acute toxicity testing conducted for other purposes is usually more limited in scope. Most regulatory agencies no longer require a full complement of species and routes of administration to render decisions on acute toxicity.

There are a few characteristics of acute toxicity testing that are not common in other toxicity protocols. In a typical repeated dose toxicity study, several groups of animals are treated concurrently with predetermined doses of test substance and a control substance. To reduce animal use in acute toxicity testing, studies that include more than one dose group are usually dosed sequentially, with an interval of at least 24 h between dosing of subsequent groups. This allows the effects of the previous dose to be fully manifested and allows selection of the subsequent dose to provide the highest probability of contributing more useful information. Another unusual aspect of acute toxicity studies is the nutritional status of the animals at dosing. Because some schools believe that the results of acute toxicity testing are more reliable if all animals are in a uniform nutritional state, mice to be dosed orally are often fasted overnight prior to dosing. Fasting allows dose volumes to be higher than in repeated dose studies, and because dosing only occurs on 1 day, dietary stress is considered tolerable. The scientific merits of this practice are debatable, but fasting is "traditional" in oral acute toxicity studies (and in initial human clinical studies). Although the practice of conducting gross necropsies at the end of acute toxicity studies is growing in popularity, this practice rarely yields useful information. The toxicity resulting from acute exposure is usually associated with a biochemical or functional imbalance rather than with a

change in the gross or microscopic architecture of an organ system. Changes observable at gross necropsy are more often associated with repeated dosing at sublethal levels. For similar reasons, microscopic examination of tissue is rarely conducted in acute toxicity studies unless there is some scientific reason to expect it would be useful.

The results of a well-designed acute toxicity study can help to predict likely target organ systems and possible outcome in the event of massive human overexposure, can help in establishing risk categories for EPA or Department of Transportation classification, and can help in dose selection for the initial repeated dose toxicity tests to be conducted. An example of an acute toxicity study design is in Table 2.22.

Short-Term Toxicity Studies

The objective of short-term or subchronic toxicity studies is to describe and define the toxicity associated with repeated administration of high, but generally survivable doses of a test substance. This may include identification of target organs and systems, definition of the maximum survivable repeated dose, and the highest "clean" or no effect dose. Short-term repeated dose

TABLE 2.22　Typical Acute Toxicity Study Design for Mice

studies also serve as dose range-finding studies for longer-term repeated dose studies.

Short-term toxicity studies range in duration of dosing from about 7 to 90 days. Mice typically receive a single, daily dose of the test substance, 7 days/week by the expected clinical route of administration. If the test substance is administered in the diet (or rarely, the drinking water), that admixture is available continuously. Short-term studies usually include three to four groups of mice exposed to different dose levels of the test substance, and an additional group exposed to the carrier to serve as a control for the effects of treatment. Group sizes for these studies are on the order of 5–10 mice/sex/dose. Ideally, dose levels should be selected for these studies such that a few animals die at the highest dose prior to the completion of dosing (to assure exposure to the maximum survivable dose), and all survive at the lowest dose with minimal evidence of toxic effects. The middle dose or doses should be set at approximately equal log increments between the high and low doses. It is important to begin to identify the highest dose level that is free of serious toxic effects to determine whether the test substance is likely to be toxic to humans at the expected therapeutic dose or exposure level.

Parameters monitored in a typical short-term repeated dose study may include daily observations for clinical signs of toxicity and mortality, weekly physical examinations, body weight and feed consumption, and terminal measurement of serum glucose and urea concentrations, serum aspartate aminotransferase, alanine aminotransferase (ALT), and alkaline phosphatase activity. Animals found dead or killed by design are typically submitted for gross necropsy, and selected tissues, such as adrenal gland, bone (sternum, including marrow), brain, heart, kidney, liver, lung, testis, and thymus are collected, weighed (except for bone and lung), and processed for routine microscopic examination by a qualified veterinary pathologist. An example of a short-term toxicity study design is in Table 2.23.

Chronic Toxicity Studies (26 weeks–2 years)

The objective of chronic, or long-term, toxicity studies is to refine the description of the toxicity associated with long-term administration of high, survivable doses of a test substance. Chronic toxicity studies are more commonly conducted in rats than in mice, but such studies can be conducted in mice, and this discussion describes objectives and practices for conducting such studies. Target organs and systems have usually been identified prior to the conduct of chronic studies, but it is the chronic study that provides the best opportunities to understand the subtle changes associated with

long-term administration of high doses and to focus more closely on the highest "clean" or no effect dose. Chronic toxicity studies also serve to refine the doses to be administered in the carcinogenicity studies that typically follow them.

Chronic, or long-term, toxicity studies range in duration of dosing from about 26 weeks to as long as 2 years, but now it is, most commonly, only 6-months in rodents. Single, daily doses of the test substance are administered by the expected clinical route of administration. If the substance is intended for oral administration, the convenience and economy of administration in the diet (or rarely the water) becomes important. Diet admixtures are made available ad libitum unless they must be removed for a specific procedure during the study. Chronic studies usually include three groups of mice exposed to different dose levels of the test substance and an additional group exposed to the carrier to serve as a control for the effects of treatment. Chronic toxicity studies often include "reversal groups," or subsets of each dose group that are not sacrificed immediately on the completion of treatment. The purpose of the reversal groups is to determine whether any toxic effects associated with treatment are permanent or subject to recovery or reversal. Mice in the reversal groups may be allowed from 2 to 4 weeks of recovery time from the end of treatment until necropsy. Group sizes for chronic studies are

on the order of 20–50 mice/sex/dose. Sizes of the reversal groups, if they are included, may be about 25%–35% of the original dose groups. Dose levels should be selected for these studies such that there is substantial toxicity at the highest dose, but few if any treatment-related deaths. The low dose in chronic studies should confirm, or if necessary, refine previous estimates of the highest dose level that is free of serious toxic effects, and thereby reinforce previous estimates of the relative safety of the test substance at the expected human dose or exposure level. The middle dose should be the approximate geometric mean of the high and low doses.

Parameters monitored in a typical chronic toxicity study may include daily observation for moribundity and mortality, weekly physical examinations, body weight and feed consumption, and terminal measurement of serum glucose and urea concentrations, serum aspartate aminotransferase, ALT, and alkaline phosphatase activity. Hematological parameters for mice are often limited to differential smear evaluations. Although red blood cell (RBC) counts, white blood cell counts, and hemoglobin concentrations can be determined, the values for mice are somewhat variable from many of the commonly used laboratory instruments, so these parameters are not always evaluated. Animals found dead or killed by design are typically submitted for gross necropsy, and a list of 30–50 selected tissues are collected, weighed (except for bone and lung), and processed for routine microscopic examination by a qualified veterinary pathologist. An example of a chronic toxicity study design is in Table 2.24.

Carcinogenicity Studies (18–24 months)

The objective of carcinogenicity studies is to determine whether the test substance is a carcinogen when administered at maximum tolerable doses for a period approaching the life expectancy of the mouse.

This objective is simpler in many respects than the objective of the longer toxicity studies. It is assumed that by the time carcinogenicity studies are undertaken, the chronic toxicity studies have been essentially completed, and the actual toxicity of the substance is about as well understood as it can be based on animal studies. Carcinogenicity studies are not usually encumbered by tests to further the understanding of toxicity, but rather are focused to maximize the ability to answer the single question of carcinogenicity.

Carcinogenicity studies in mice are generally designed to expose the animals for a period of 18 months to 2 years. Improvements in animal husbandry during the past decade have increased the life expectancy of most strains of mice, so there has been a

TABLE 2.24 Typical Chronic Toxicity Study Design for Mice

tendency to extend carcinogenicity studies in mice to 2 years. The study design normally contains provisions to allow for termination of the study prior to the intended end point if excessive mortality is encountered. This provision is intended to ensure that an adequate number of survivors are sacrificed with successful collection of all necessary tissues for a meaningful, statistical analysis of tumor incidence. Carcinogenicity studies usually include three groups of mice exposed to different dose levels of the test substance and an additional group exposed to the carrier to serve as a control for the effects of treatment. Group sizes for these studies are on the order of 50—70 mice/sex/dose.

The high dose in carcinogenicity studies should be the MTD. This dose should produce evident toxicity by the end of dosing. A commonly held minimum criterion for evident toxicity is a decrement in body weight or body weight gain of at least 10% from the control to the high-dose group. If the test substance is not very toxic, most regulatory agencies will accept a carcinogenicity study in which the high dose is the highest dose that can be practically administered, even though that dose does not produce evident toxicity. In this example, the animal has, in effect, "tolerated" the highest dose that could be administered.

The selection of lower doses is not as critical as in chronic studies because the concept of a "clean dose"

of a known carcinogen is not widely accepted, and it will be of little value in attempting to commercialize a product.

The middle dose may become important if the high dose has been inadvertently set too high, resulting in excessive toxicity and early mortality. In that case a middle dose that elicits evident toxicity without excessive mortality may become an acceptable MTD and may effectively "salvage" the study. As in chronic studies, the middle dose should be at the approximate geometric mean of the high and low doses.

The most important data generated in a carcinogenicity study are the histopathology data. Of particular importance are the data on the incidence of various types of malignancies in the different treatment groups. Control or even untreated mice normally will have some "background" incidence of various types of malignancies over the course of a carcinogenicity study. The key question then is whether the treated groups have a significantly higher incidence of "normally expected" tumor types than the control group, whether they have occurrences of "nonnormal" tumor types that are not seen (concurrently or historically) in control animals, and, most importantly, whether such incidence is attributable to the test substance.

Other parameters monitored in a typical carcinogenicity study may include daily observation for survival and moribundity, periodic physical examinations, periodic examinations for palpable masses, body weight, and feed consumption (especially important in dietary admix studies), and for some studies periodic peripheral blood smears and terminal red and white blood cell counts. Animals found dead or killed by design are submitted for gross necropsy, and a comprehensive list of 40—50 prescribed tissues plus any tissue masses, suspected tumors, and an identifiable regional lymph tissue are collected from each animal to be processed and examined histologically by a qualified veterinary pathologist for evidence of carcinogenicity. An example of a carcinogenicity study design is in Table 2.25.

Teratology Studies

Mice are occasionally used in teratology studies to assess the effects of test substances on congenital defects in the young when administered to pregnant females. Mice have a regular, short estrus cycle, a short gestation period, high fertility, and typically produce relatively large litters of young. Mice rank behind rats and rabbits as the species of choice for assessing teratology, but there may be good scientific reasons to use mice in some instances. The conduct of Segment II teratology studies in mice and rabbits with Segment I and III studies in rats provides an opportunity to evaluate teratogenicity

TABLE 2.25 Typical Carcinogenicity Study Design for Mice

in three species. Although there is an advantage in conducting teratology studies in at least two species, preferably one of which is a nonrodent, some substances (e.g., certain antibiotics) are especially toxic to rabbits, making teratology testing impractical in that species. In that case, mice become the second best species available (behind rats) for teratology testing and are usually the choice as the second species. A significant disadvantage in using mice for teratology studies is that they are much more cannibalistic than rats or rabbits. This characteristic renders the species unusable for Segment I and III studies, in which pregnant females are allowed to deliver their young, and limits them to use in Segment II studies, in which the young are delivered by cesarean section on gestation day 18, prior to delivery. Mating can be confirmed in mice by daily inspection of cohabitating females for the presence of a vaginal plug. The copulatory plug in mice is much more persistent than in rats, in which mating must be confirmed by vaginal lavage and microscopic examination.

Segment II Teratology Studies

A Segment II teratology (embryo-fetal development) study is conducted to assess the effects of a test substance on fetal survival and congenital malformations (teratology). Females are mated and monitored daily for the presence of copulatory plugs. The presence of a plug confirms that mating has occurred, and the day of discovery is defined as gestation day 1. Mated females are dosed with the test substance from gestation days 6

through 15, a period that begins soon after implantation (day 5), and continues through completion of organogenesis (day 13). This dose period exposes the young throughout the period of organogenesis, but it tends to minimize preimplantation embryotoxicity and postorganogenesis maternal and fetal toxicity. The young are delivered by cesarean section on gestation day 18, prior to normal parturition on day 19, to avoid cannibalism. The maternal reproductive organs are examined for numbers of corpora lutea, implantations, resorptions, and live and dead fetuses. The fetuses are weighed, sexed, and examined for gross, visceral, and skeletal abnormalities. An example of a Segment II teratology study design is in Table 2.26.

Genetic Toxicity Studies

The objective of genetic toxicity testing is to identify and describe the effects of agents that specifically produce genetic alterations at subtoxic doses. Mice are used in a variety of genetic toxicity study designs in an effort to achieve this objective. Neither a comprehensive listing of genetic toxicity procedures using mice nor a comprehensive description of any number of those procedures is within the scope of this chapter. Rather, a few of the most commonly employed procedures will be summarized. The reader is referred to other sources such as Brusick and Fields (2014), DeAngelis et al.

(2007), and Dean (1983, 1984) for more detailed discussions of genetic toxicity, and more comprehensive descriptions of some of the specific tests used in that field. Kaput (2005) reviews the interaction between nutrition and genomics.

Mouse Micronucleus Assay

The objective of the mouse micronucleus assay is to determine whether a test article causes disruption and separation or breakage of chromosomes. The mouse micronucleus assay is one of the most commonly conducted in vivo tests for genetic toxicity. Comparison of the incidence of micronuclei in proliferating cells from treated versus control mice provides an indirect measurement of chromosome damage in somatic cells. Micronuclei can only be formed as a result of disruption and separation or breakage of chromosomes, followed by cell division. The preferred cells for evaluation are newly formed erythrocytes in mouse bone marrow because the micronuclei formed in these cells are not expelled during the last division in which the nucleus is extruded from the normoblast.

One or more dose levels of test article and a control treatment are administered to separate groups of at least five mice per sex. The highest dose should be the MTD, or one that produces some evidence of cytotoxicity. It is important that high quality (e.g., specific pathogen-free) mice of known genetic stability and consistent species, strain, source, age, weight, and clinical condition be used to assure comparability with historical controls. Each animal typically receives a single dose of test or control article. Bone marrow samples are collected at a minimum of three different intervals after dosing, ranging from 12 to 72 h. At least 1000 polychromatic erythrocytes are evaluated for the presence of micronuclei for each test and control mouse. An example of a mouse micronucleus assay study design is in Table 2.27.

Heritable Translocation Assay

The objective of the heritable translocation assay (HTA) is to assess the potential of a test article to induce reciprocal translocations between chromosomes in germ cells of treated male mice. This assay has the advantage of detecting transmissible genetic alterations, which are potentially more damaging to the gene pool than non-transmissible or lethal changes. Induced translocations can be detected by mating the F1 progeny of treated males with untreated, unrelated females. Translocations will be evidenced by a reduction in the number of viable fetuses sired by affected males. The presence of translocation figures in meiotic metaphase serves as cytogenetic verification of the presence of reciprocal translocations.

The HTA typically consists of three groups of 30 male mice each, treated with different dose levels of the test

article, and a negative control group treated with the dosing vehicle. A positive control group is optional. As the period of spermatogenesis in the mouse is about 7 weeks, all treated and control animals are dosed on a daily basis for 7 weeks. The dosing route is usually oral gavage, and the dose levels are selected on the basis of the oral LD_{50}. The high dose is typically one-eighth of the LD_{50}, and the medium and low doses are about one-third and one-tenth of the high dose, respectively. On completion of dosing, each male is mated to two females. Two hundred healthy males are selected from the offspring of each of these groups of mating and allowed to reach sexual maturity, whereupon each male is mated to three virgin females. The females from this second mating are sacrificed about 3 weeks after cohabitation with the males was initiated, and the number of living fetuses and resorbing embryos present in the uteri are counted. Any male that produces 10 or more living fetuses in any one female is considered fertile, and no further mating is needed. Males falling below those criteria are mated to an additional set of three females, and the evaluation is repeated. Failing males may be remated up to three times. Males that never succeed in producing at least one litter of 10 or more living fetuses are considered sterile (or semisterile) and are sacrificed, and their gonadal cells are examined for cytogenetic evidence of translocations. An example of an HTA study design is in Table 2.28.

Microbial Host-Mediated Assay

The objective of the microbial host-mediated assay is to determine the ability of a mammalian system (e.g., the mouse) to metabolically activate or detoxify a test article with respect to its mutagenic potential. The mutagenic potential is measured by means of one of a variety of

microorganisms, depending on the specific types of mutations being investigated (e.g., base-pair substitution, frame shift). Some of the microorganisms used for this type of testing include various strains of *Salmonella typhimurium*, *Escherichia coli*, and *Neurospora crassa*. The results of the host-mediated assay can be compared with the direct effect of the test article on the same test strain of microorganisms to determine whether the host (e.g., mouse) is metabolically activating, detoxifying, or having no effect on the mutagenic potential of the test article. The microbial host-mediated assay, then, is an attempt to combine the convenience of microorganisms for detecting hereditary changes with the metabolism of the test article gained by administration to a whole animal.

The microbial host-mediated assay consists of three groups of about 10 mice each, treated with different dose levels of the test article, a negative control group treated with the dosing vehicle, and a positive control group. Doses are administered daily for up to about 5 days. The high dose is usually about one-half of the LD_{50}, with the medium and low doses about one-third and one-tenth of the high dose, respectively. The preferred route of administration is oral, but im or ip injection may be used if necessary. At the end of the period of test article administration, the test strain of microorganism is administered, usually intravenously. Following appropriate incubation periods (e.g., 1, 2, and 4 h), mice are sacrificed and the microorganisms are collected, frequently from liver tissue. The collected microorganisms are grown on minimal agar plates to assess mutation rate. An example of a microbial host-mediated assay study design is in Table 2.29.

Special Studies

The diversity of toxicity study designs using the mouse as a test system to examine a specific hypothesis defies description. Many of these designs do not strictly fit within the major section headings chosen for this chapter and might be referred to as "special studies." This chapter is intended to focus on the more commonly conducted types of toxicity studies in mice, but it might be useful to describe two special study designs here as examples of some of the interesting end points that can be evaluated in this species.

Mouse Ear Swelling Test

The concept of a mouse ear swelling test (MEST) is that sensitization can be detected by measuring edema in the ear of a mouse that results from topical application of a test article to an animal that has been previously sensitized by means of dermal application to the abdomen (Gad et al., 1986).

The objective of the MEST is to provide an alternative test for dermal sensitization potential that makes more efficient use of animals, labor, and other resources than traditional study designs conducted in guinea pigs. A MEST test is often preceded by a dose-finding activity to identify the highest concentration of test article that is no more than minimally irritating to the abdominal skin, and the highest concentration that is nonirritating to the ear. These concentrations are then employed in the sensitization assay.

The sensitization assay is carried out in three phases: an induction phase, a challenge phase, and if necessary, a rechallenge phase. The sensitization assay requires 15 mice treated with the test article and 10 treated with a control substance, typically the vehicle used for the test article. During the induction phase (study day 1), the abdomen is shaved using a small animal clipper, and 20 μL of 1:1 emulsion of Freund's complete adjuvant in distilled water is injected intradermally (id) at each of two abdominal sites on opposite sides of the ventral midline. Once daily on study days 1, 2, 3, and 4, the stratum corneum is stripped from the abdominal skin using adhesive tape, and the appropriate concentration of test article is applied to the abdomen at a volume of 100 μL.

On study day 11, the challenge phase is initiated. The appropriate concentration of test article is applied to the skin of the left ears of all treated and 5 of the 10 control mice at a volume of 10 μL, and an equal volume of the control (vehicle) is applied to the right ears of those same animals. Thicknesses of both ears of all treated and the five selected control mice are measured on days 12 and 13. Any mouse with a left ear thickness ~120% of its right ear thickness is considered to be a positive responder. If one or more mice are judged positive in the absence of primary irritation (any control

Number of male mice/dose group	15/treated group, 5/control group
Number of dose groups	1
Number of control groups	2
Dosing frequency	Once daily
Dosing days	Days 1, 2, 3, and 4 (induction)
	Day 11 (challenge)
	Day 18 (optional rechallenge)
Survival checks	Daily
Clinical observations	Not done
Body weights	Not done
Ear thickness measured	Day 10, 12, and 13 (challenge)
	Day 17, 19, and 20 (rechallenge)
Necropsy	Not done
Tissue collection	None

mice with left ear thickness >110% of right ear thickness) on study day 12 or 13, the test article is considered to be a sensitizer. Evidence of primary irritation requires that the test be repeated using a lower concentration for the challenge dose.

If results are negative (all mice with a left ear thickness increases of <10%) or equivocal (some mice with increases of 10%−19%, but none >20%), a rechallenge is conducted on study days 17 through 20. Baseline ear thicknesses are measured on study day 17. The test article is applied to the right ears of all test mice and the control mice that were not used during the initial challenge on study day 18. Ear thicknesses of the right ears of all test mice and the new control mice are measured on study days 19 and 20, and they are compared to the baseline thicknesses taken on day 32. The criteria for positive response are the same as for the initial challenge. An example of a MEST study design is in .

Dermal Carcinogenicity (Skin Painting) Study

The concept of the dermal carcinogenicity (or skin painting) study is that carcinogens, or of more recent interest, cocarcinogens and tumor promoters can be evaluated or their potencies compared in as little as a few months of testing.

The carcinogenicity of some chemicals (e.g., polycyclic aromatic hydrocarbons) can be detected easily by the production of papillomas or carcinomas. Mouse skin apparently functions in this system because it contains enzymes necessary to produce the active intermediates that lead to initiation. Tars from tobacco, coal, and various petroleum products show active carcinogenic potential in this system, although many of the same products are not carcinogenic when administered systemically. Hepatic detoxification of systemically administered doses may account for this difference.

This study design has been especially useful in recent years in the study of cocarcinogens and tumor promoters. In a typical study design, groups of 25−50 mice might receive from one to a few systemic doses of a known tumor initiator. Following receipt of the initiator, the fur over the anterior portion of the back is shaved, and the suspected tumor initiators are applied to the skin of the back at a frequency of 2−3 times per week. Shaving will need to be repeated approximately weekly. Development of papillomas or carcinomas of the skin is readily visible in the shaved area. Active chemicals are often detected within a few months' treatment. This study is generally intended to continue treatment for a period of about 30−40 weeks, but it may be continued for up to 2 years if necessary.

Obvious advantages of this study design include its relative efficiency in terms of animal numbers and labor and its relative brevity compared to a conventional 18- to 24-month carcinogenicity bioassay. It is reasonable to conclude that positive findings of carcinogenicity in this test would make a conventional carcinogenicity bioassay unnecessary. Negative findings in a dermal carcinogenicity test, however, would not assure the absence of carcinogenic potential, and a conventional bioassay would still be necessary.

Disadvantages of this procedure include difficulty in accurate quantification of dose, as the topically applied

dose can run off the animal, be scratched or licked off, or can accumulate as a crust, effectively reducing absorption. Another criticism centers around the fact that if treatment with a suspected promoter is interrupted after a period of 60 days or so, evident papillomas often regress, raising the question of whether they represented sites of true carcinogenicity.

ROUTES OF TEST SUBSTANCE ADMINISTRATION

Techniques are available to administer test substances to mice by most routes of potential human exposure. The choice of a route of administration for a toxicity study should consider the expected route of human exposure and any other scientific objectives that need to be achieved to facilitate safe use of the test substance. Of the various routes available, most test articles will have the most rapid onset of effects and the greatest potency when administered by the iv route, followed in approximately descending order by the inhalation, ip, sc, im, id, oral, and topical routes (Eaton and Gilbert, 2013). The expected route of human exposure is probably the most important single determinant of route for toxicity testing. In the discussion that follows, the most commonly employed routes for toxicity testing in mice, oral dosing, will be discussed first, followed by the less commonly employed routes.

Oral Administration

Oral administration is probably the most frequently used route of exposure for toxicity testing in mice. Many products are intended for oral administration to humans, and many others are subject to accidental ingestion. Oral administration subjects the test substance to limitations of absorption and metabolism that are similar but not necessarily identical to those in humans. Mice, like rats, differ from many other species in that they do not have an emetic response. For this reason, large doses of substances that would cause emesis in dogs or primates will be retained in the stomachs of mice. Although this characteristic facilitates testing at high doses and maximizes potential exposure to toxic effects, it may lead to an overestimate of potential human toxicity because the animal lacks the protective aspect of the emetic response. Another area in which mice differ from dogs and primates is that mice are nocturnal. This characteristic adds some pharmacokinetic variables to the equation for extrapolating toxicity findings from the mouse to the human. Doses that are administered during the day are administered to animals that are in the lower phase of their circadian

metabolic cycles. This may mean slower absorption, slower metabolism to either more or less toxic metabolites, and/or slower elimination of the test substance. Conversely, test substances administered in the diet or drinking water will be largely consumed at night, as that is when mice consume most of their daily intake of food and water. Although this regimen more closely approximates human consumption during the active part of the day, it makes observation of the animals during the period of peak exposure and metabolism difficult. The three means of oral administration are oral gavage, dietary admixtures, and mixture with the drinking water.

Gavage

Oral gavage offers the advantages of precisely measured doses that can be administered at precise times. Doses can be administered during the day so animals can be conveniently observed for toxic effects during the first few hours after dosing. Volatile substances and those that lack stability over longer periods in the presence of diet, air, or water can be effectively administered by this method. Gavage allows administration of unpalatable substances that might not be accepted in the diet or water. There are disadvantages associated with gavage administration. The test substance must either be a liquid or be soluble or suspendible in a liquid vehicle system. The method is relatively labor-intensive compared to diet admix. The processes of daily handling and intubation of all animals engenders the risk of injury during the intubation process, including esophageal puncture and aspiration of test article. In addition, the process of frequent handling causes stress to the animals. Although it is convenient to administer doses during the day, daytime is the period of lowest metabolic activity for nocturnal species such as mice. This circadian effect may not be most representative of diurnal species such as humans.

Description of Technique

Gavage administration entails intubation of the mouse with an intubation needle or soft plastic catheter attached to a graduated hypodermic syringe. The dose is administered into the esophagus. Intubation needles for mice are typically constructed of stainless steel tubing with a stainless steel ball tip to reduce the probability of esophageal perforation and reflux and aspiration of the dose. Acceptable tubing sizes range from 22- to 18-gauge, with the larger bore reserved for older mice (e.g., ≥25g). Tubing length is not critical but may range from 1 to 3 in. The ball tip is typically 1.25−2.25 mm in diameter. Intubation needles are available commercially (e.g., Popper & Sons, Inc., New Hyde Park, New York) in straight and curved configurations. The choice of shape is a question of personal preference on the part of the

dosing technician. Prior to dosing, the test substance must be prepared in a liquid form at an appropriate concentration. Liquid test substances may require dilution. Solid substances will require either dissolution or suspension in an innocuous vehicle. The preferred vehicle is water. If the substance is insoluble in water, various agents may be added to improve wetting (e.g., 0.1% v/v polysorbate 80) and to reduce settling (e.g., 0.5% w/v methylcellulose). Suspensions should be analyzed prior to administration to assure proper concentration, homogeneity, and stability of the substance in the suspending vehicle. Appropriate dose volumes for gavage administration are in the range of 5−10 mL/kg of body weight, but volumes as high as 20 mL/kg can be administered carefully, particularly in acute studies in which the mice have been fasted prior to dosing.

For the actual process of dose administration, the mouse should be weighed, and the individual dose calculated. The appropriate dose volume should be drawn into the dosing syringe and any air bubbles should be expelled. The mouse is then picked up by the skin of the back and neck, and the head is tipped back to form a straight line from the nose through the back of the throat and to the stomach.

The intubation needle is inserted to the back of the mouth, then gently tipped back, if necessary, to enter the esophagus. The mouse will usually facilitate entry into the esophagus by swallowing the ball of the needle. One successful approach is to envision the tip of the sternum as a "target" for the tip of the intubation needle. When properly positioned, the tube can easily be inserted to a reasonable depth, but it need not reach the stomach. When in position, the dose should be administered slowly to avoid reflux, but promptly enough to reduce the likelihood that the mouse will struggle and injure itself.

Dietary Admixtures

Oral administration by dietary admixtures offers several advantages, including ease of administration, minimal handling of animals for dosing, and elimination of the risk of injury associated with intubation. The method offers relatively precise dose administration for the group (better than water mix; not as good as gavage), as both mean food consumption and mean body weight for periods of a week or longer are easily measured. Dry, insoluble substances can be administered easily, and administration of test substances to mice during the "awake" phase of their circadian cycle is an advantage. There are disadvantages associated with dietary admix. Accuracy of individual doses is lower than with gavage, and there is not a single identifiable time of dosing. Volatile substances and those that lack stability over periods of at least 4−7 days in the presence of diet, air, or water are precluded from this method. Diet admixtures must be sampled and the samples be analyzed periodically to assure proper concentration and homogeneity of the mixture during the course of the study. Unpalatable test substances typically result in reduced dietary intake, which leads to an increase in the concentration of test substance in the diet during subsequent weeks in an attempt to reachieve the desired doses. The increased concentrations may be even less palatable, leading to further reduction in dietary intake, and in some cases, eventually to malnutrition. In any dietary study, results should be evaluated carefully to discriminate between changes associated with altered nutritional status and true test substance toxicity.

Description of Technique

Oral administration of dietary admix entails presentation of a mixture of the test substance in the diet in place of the normal diet received by the animals. The concentration of test article in the diet is adjusted, based on the most recently collected data on mean body weight and food consumption for each sex and dose group, to provide the desired doses of test article during the period in question. Early in a study, when body weight and food consumption are changing due to rapid growth of the animals, projections of the mean body weight and food consumption for the coming period should be based on both the most recent measurements and the rate of change (slope of the plot) of those parameters over several recent periods. If test article stability permits, a convenient period for measurement of body weight and food consumption is about 1 week.

Test substances are usually mixed with the meal form of rodent diet in one or more of a variety of mechanical blenders. Common types of blenders include the Turbula, paddle style, and twin shell, or "Y" blenders. When large quantities of diet admix are required, it may be advantageous to blend the test substance with the diet in two steps, preparing a premix of 1−2 kg in a blender such as a Turbula, and then adding the premix to a larger-scale blender, such as a paddle blender. This procedure often produces a more homogeneous mix in a shorter blending period.

Following mixing, the appropriate concentration of blend is dispensed into animal feeders for presentation to the mice. Feeders are weighed when they are placed in the cages and when they are removed to determine the average amount of feed consumed per day. Mice are weighed at the same time, both to determine body weight gain over the period and to calculate the food consumption in grams per kilogram of body weight per day. Based on this calculation, the concentration of test substance in the diet may be varied up or down to more closely approach the intended doses of test substance in milligrams per kilograms per day.

Among potential problems that may be encountered in conducting dietary admix studies, two may lead to inappropriate calculations of feed consumption, leading to incorrect calculation of concentrations for future periods. These problems are excessive feed spillage, which may result from mice digging or playing in their feeders, and contamination of the feeder with urine and feces, which may result from mice living in their feeders. Feeders should be checked daily for excessive spillage at the time survival checks and/or observations are conducted, and excessive spillage should be documented. Contamination with urine and feces will lead to an incorrectly high feeder weight at the end of the feed consumption period and an underestimate of true feed consumption.

Excessive contamination should be documented. Animals with excessive spillage and those with excessive contamination of feeders should be excluded from the calculation of mean body weight and food consumption used to prepare future concentrations of diet admix.

Drinking Water

Administration of a water-soluble test substance in the drinking water has many of the same advantages as administrations of a dietary admix. This method is rarely used for toxicity studies, however, because of the difficulty in accurately measuring the quantity of water actually consumed. Although graduated water bottles can be used, spillage due to mice rubbing against sipper tubes, inefficient drinking, evaporation, vibration, and leaking bottles makes these measurements imprecise. If that practical problem could be solved, administration in the drinking water would bear little conceptual difference from dietary admix. Stability of environmental temperature and humidity is essential to the conduct of a study in which the test article is mixed in the drinking water, as increased temperature and/or lowered humidity lead to increased water consumption. Water consumption must remain relatively stable to allow calculation of appropriate concentrations of test article in water to achieve study objectives.

Description of Technique

From a practical standpoint, administration of test article in the drinking water has many similarities to administration by dietary admix. It is essential that the test article be both soluble and chemically stable in water for the period of presentation. That period should be in the range of about 2 days to a maximum of about 1 week. Water remaining in a water bottle for periods in excess of a week may become heavily contaminated with bacteria. Analogous to the situation with diet admix, the precision of dose administration is directly related to the accuracy with which average daily water consumption and body weight can be measured.

Concentrations of test article in water should be adjusted, if necessary, after each measurement of average daily water consumption and body weight to assure precise dose administration.

As solubility in water is a prerequisite for this method, mixing procedures are usually simpler than for diet admixes. Homogeneity analysis should not be required for a true solution, but samples should be analyzed regularly to confirm that concentrations are what they were intended to be.

Water can be provided in graduated bottles. Contents of the bottles should be recorded at the beginning of the consumption period (but after the bottles are placed on the cages to accommodate spillage during that operation), and again at the end of the consumption period to determine average daily water consumption. Evidence should be documented. Difficulty in accurately measuring the amount of water actually consumed by the mice is the largest disadvantage to this method of administration.

Intravenous Injection

Intravenous injection offers the advantages of immediate, complete systemic availability of a precise dose at a known point in time. The process of absorption is eliminated, as it is the possibility that some or all of the test article may be metabolized by the liver prior to distribution to the systemic circulation and target organs. Most substances exhibit the biggest potency and rapidity of onset of activity of all routes of administration when administered intravenously. Intravenous administration provides a useful benchmark against which absorption and bioavailability from administration by other routes can be compared.

It is essential that test articles administered intravenously be in solution at the time of administration and remain in solution after injection. Solutions that are subject to precipitation by changes in pH, temperature, or osmolarity should be confirmed at physiological conditions to assure that they will not precipitate after injection. Introduction of insoluble particles, such as those in a suspension, introduces a high probability of embolism, particularly in the pulmonary capillary bed, which will produce severe moribundity or death. The toxicologist is left with the problem of differentiating such moribundity or mortality from the true toxicity of the test article.

Other characteristics of an iv solution that should be evaluated prior to undertaking an iv toxicity study involving repeated dosing include the potential for the solution to cause hemolysis or vascular or sc irritation. Hemolysis may be a result of the administration of solutions of inappropriate osmolarity (hypotonic solutions

are particularly damaging); in which case the problem can be resolved by adjusting the osmolarity of the solution.

Ideally, solutions for iv administration should be isotonic to blood and have a pH of about 7. Usually a pH in the range of about 5–9 will be acceptable. Solutions that cause appreciable vascular or sc irritation may result in sufficient injury to the veins and surrounding tissue to preclude repeated administration.

The rate of iv injection is an important variable that must be controlled fairly precisely to achieve reproducible results within a study. If the iv toxicity of two or more test articles is to be compared, it is essential that each be administered at the same rate. Intravenous injections can be administered as a bolus over a period as short as a few seconds, as a continuous, 24-h/day infusion, or over just about any interval in between.

There is nothing particularly magical about any specific dosing period, but it is critical that it remains constant. As a practical matter, an injection period of about 2 min is a reasonable upper limit for hand-held injections into caudal veins of reasonable numbers of mice. Longer periods lead to very slow injections and increase the risk of extravasation, are time-consuming, and are difficult and tiring for the toxicologist. Injection periods much shorter than 1 min increase the likelihood that an inordinately high peak plasma concentration may precede mixing with the total blood volume and may compromise the survival of the animal. A corollary to the artificially high peak plasma concentration associated with a short injection period can occur if the injection is administered at an uneven rate. It is particularly critical that the rate of injection not be increased during the last half of the injection period, as this is a time when the animal has already received an initial "loading," and the deleterious effect of increasing the rate of administration will be amplified. In our laboratory, we have found that administration of volumes of 5–10 mL/kg body weight (0.15–0.30 mL for a 30-g mouse) administered evenly over a period of 2 min represents a good compromise. One of the biggest disadvantages of iv administration is that it is a very labor-intensive procedure, requiring more time per animal than any other route. In addition, repeated, daily administration to caudal veins of mice for periods longer than 2–4 weeks becomes technically difficult owing to the accumulation of scar tissue and occasional trauma.

Long duration or continuous, 24-h/day infusions, though possible, are technically difficult and will not be discussed in detail here. As a practical matter, long-duration injections or continuous infusions are typically administered through a surgically implanted catheter using an infusion pump. The catheter is usually placed in a large, superficial vein such as the jugular or femoral vein, and then exteriorized at a site such as between the scapulae, which is difficult for the animal to chew or scratch. The surgical procedure is relatively simple. The difficulty lies in keeping the cannula patent and secure in the vein during recovery after surgery, then through the period of dosing. The maximum volume of infusion, even over a continuous 24-h period should not exceed about 20–30 mL/kg/day, which will typically be less than 1 mL administered over a 24-h period. This infusion rate is so slow as to be difficult to administer, even with a high-quality infusion pump. The catheter must be attached to the mouse in a way that prevents mutilation of the catheter by the animal without undue limitation of mobility.

Description of Technique

Intravenous administration entails injection of the desired dose into an appropriate vein. In a typical study, mice will receive a single injection daily over a period of about 2 min or less. Such injections are usually administered into a lateral IMM (tail) vein, using a hypodermic needle attached to a graduated syringe. Hypodermic needles used for caudal vein injections in mice are usually no more than 1" in length and in the range of about 23–25 gauge. The smallest hypodermic syringe that will contain full dose volume will provide the greatest precision in dose measurement, but 1-cc disposable syringes are often used.

The needle should be installed on the syringe such that the bevel of the needle faces the side of the syringe that will be used to measure the dose. This will allow the graduations to be read easily when the needle has been inserted into the vein in an up configuration. A stopwatch that is easy to read is useful for timing dose administration, and an electronic timer that is activated by a foot pedal is most convenient. A convenient restrainer should hold the mouse securely, but without undue risk of suffocation or injury, while allowing five accesses to the tail. A source of warm water and/or a tourniquet device are useful, as is a supply of small gauze sponges. A tourniquet can be constructed from a disposable plastic syringe and a piece of suture. The larger the syringe size, the more pressure it is able to exert on the suture loop. Relatively large (e.g., size 0) braided silk suture should be used for the loop to minimize the risk of cutting the skin of the tail. The suture loop is attached to the plunger inside the barrel of the syringe and then threaded out through the tip of the syringe.

Prior to dosing, the dosing solutions should be prepared. Solutions should be analyzed periodically to assure that proper concentrations are being attained. Each mouse should be weighed and its dose calculated. As previously noted, doses in the range of 5–10 mL/kg are acceptable for injection over periods of about 30 s to

2 min. The mouse is placed into the restrainer, and the appropriate dose is drawn into the syringe. Any air bubbles should be expelled from the syringe. This is most important for iv injections. A tourniquet device can be applied at this point but should not be applied too tightly. The objective is to block venous return, but not arterial supply, thus dilating the veins. As an alternative to a tourniquet, some toxicologists prefer to warm the tail with a gauze sponge wetted in warm (not hot) water to enhance vasodilation. The tail is now held in one hand while the needle is inserted with the other. The needle should be inserted with the bevel up to minimize the chance of puncturing through both sides of the vein. Successful venipuncture will result in the reflux of a small amount of blood into the hub of the needle. Owing to the small volume of blood that usually refluxes, this phenomenon will be most easily visualized if needles that have transparent "flashback" hubs are used. The initial attempt at venipuncture should be made toward the tip of the tail, such that if the vein is missed, a subsequent attempt can be made closer to the base of the tail without risk that the dose will leak out of the initial hole. When the needle is securely in the vein, it can be held with the "tail-holding hand" while the plunger of the tourniquet is depressed to open the vein with the "dosing hand."

Now that the needle is in the vein and the vein is open, the timer can be started, and the dose can be administered. One convenient method to assure even dose administration is to divide the dosing period and the dose volume into a convenient number of parts. A 2-min dosing period might be divided into eight 15-s intervals, and the dose volume divided by eight. The doser can then administer one-eighth of the total dose volume over each 15-s interval for 2 min to assure a relatively even rate of injection. When the full dose has been administered, a clean dry gauze sponge should be pinched over the injection site and the needle should be withdrawn. Maintaining pressure on the site of the injection for 10–30 s after withdrawal of the needle is usually adequate to prevent bleeding. The mouse can now be removed from the restrainer. As iv injections typically result in a rapid onset of activity, it is often appropriate to observe a mouse for the first few minutes after dosing for clinical signs of toxicity.

Intraperitoneal Injection

The ip (intraperitoneal) route of administration generally offers the second most rapid absorption of a test article among the parenteral routes, with systemic availability second only to iv injection. Rapid absorption is conferred by the large surface area of the lining of the peritoneal cavity, and by the rich blood supply to that area.

Intraperitoneal administration leads to absorption primarily through the portal circulation. As a result, test articles that are metabolized by the liver are subjected to extensive (or even complete) metabolism prior to reaching systemic circulation and target organs, unless, of course, the target organ is the liver, in which case toxicity may even be amplified. Test articles that are excreted in the bile are similarly subject to elimination prior to reaching the systemic circulation and target organs. Water-insoluble mixture aqueous suspensions, for example, can be administered by the ip route. This may provide the opportunity for rapid systemic absorption of lipid-soluble or certain other test articles. Solutions or suspensions for ip injection should be adjusted to a pH in the range of about 5–9 to reduce the potential for irritation. Osmolarity of the dosing formulation is not critical, as it is for iv injection. Dose volumes for ip administration are in the range of 5–10 mL/kg/day, but volumes as high as 20 mL/kg/day are acceptable, particularly if the study is of limited duration, or if it is known that the test article will be absorbed by the ip route.

One of the most significant disadvantages of ip administration is the risk of peritonitis. Peritonitis can result from any of three primary causes: physical irritation caused by accumulation of a truly insoluble or irritating test article in the peritoneal cavity, introduction of exogenous microbiological contamination, or microbiological contamination resulting from injury to the gastrointestinal tract or urinary bladder. The potential for a test article to produce physical irritation or chemical peritonitis can be assessed in studies of one to a few days in duration. Although physical or chemical peritonitis is the most frequently seen form of peritonitis in toxicity studies, it is still found with only a small percentage of test articles. Mice are relatively resistant to microbiological infection, so microbiological peritonitis is even less common than physical or chemical peritonitis. Peritonitis resulting from injury during the injection process is extremely rare when injections are administered by qualified toxicologists. There is a slight risk to the animals of physical injury to a major organ or vessel during the injection process, but again this is extremely rare in the hands of qualified dosers.

Description of Technique

Intraperitoneal injections are administered into the peritoneal cavity using a hypodermic needle attached to a graduated syringe. Each mouse receives a single daily dose, administered as a bolus, for the duration of the toxicity study. The injection should be administered into the animal's lower, right abdominal quadrant to minimize the risk of injury to the liver, spleen, and bladder. For initial training purposes in dosing by the ip route, it is useful to sacrifice a mouse, in which the

abdominal cavity is opened to expose the internal organs that may be susceptible to injury during the injection procedure. This will allow a novice to hold the animal in a dosing position and clearly visualize where the lobes of the liver, the spleen, and the urinary bladder will be, and the area of less vulnerability between these organs. Hypodermic needles used for ip injections to mice need be no longer than about 5/8 in and should be the smallest diameter that will allow easy injection of the dose volume to minimize the trauma to the abdominal wall with commensurate potential for leakage. Needles in the range of 23—25 gauge are appropriate for use with solutions and suspensions of low viscosity. Suspensions of high viscosity may require the use of needles with a larger bore. Needles as large as 19—20 gauge can be used, but they require great care to avoid injury and leakage of the test article from the injection site.

Prior to initiation of a toxicity study, dosing formulations should be prepared, and samples are analyzed for concentration and homogeneity of suspensions, if appropriate. Each mouse should be weighed and its dose calculated. The appropriate dose is then drawn into syringe, and air bubbles are expelled. The mouse is picked up with one hand, and held with the ventral surface toward the doser. Movement of the animals' right hind leg should be restricted to limit interference with the needle during dosing. The needle should be inserted at an angle of about 15—30 degrees into the abdominal cavity to facilitate penetration of the abdominal wall.

The location should be to the right of the midline (to avoid the spleen) at a position about midway between the lower edge of the liver and the urinary bladder to a depth of about 1 cm (3/8 in.). Following insertion, the needle is withdrawn slightly, moved about, and the angle of insertion is reduced to assure that the tip has not penetrated or snagged any internal organs. The dose is now administered as a bolus and the needle is withdrawn. If a large-bore needle has been used, it may be necessary to apply gentle finger pressure over the injection site for a few seconds to prevent leakage of the dose.

Intramuscular Injection

The im route of administration is less commonly used in toxicity testing, but it may be appropriate if the test article is intended for im administration to humans. The im route generally results in slower absorption of a test article, with lower peak plasma levels, but more sustained effects than iv or ip injection. The rate of absorption can be influenced by the amount of vascular perfusion of the tissue surrounding the injection, the

vehicle, and the injected volume, which indirectly may alter the surface area of tissue available for absorption. Coadministration of a vasodilator generally increases the rate of absorption, whereas coadministration of a vasoconstrictor generally decreases that rate. Administration of the test article as a solution or suspension in a viscous, poorly absorbed vehicle generally retards absorption. The ability to control the rate of absorption can be a significant advantage in some cases, as it allows the toxicologist to administer a dose of a test article that may be absorbed over a period of many hours or even days. This can be especially useful in the case of test articles that have short half-lives after absorption, as a result of rapid metabolism and/or elimination. Limitations to im dosing include the limited number of muscle groups in the mouse that are large enough to accept dosing, e.g., the muscles of the posterior aspect of the femoral region and the small dose volume that can be administered. If possible, the same injection sites should not be treated every day to allow time for absorption and recovery from the trauma of dosing. This means that while a single acute dose might be divided into the hind limbs, repeated daily doses should be administered into alternate limbs. The dose volume should not exceed 1.0 mL/kg per injection site, or about 0.03 mL for a 30-g mouse, and smaller volumes are preferable. An acute study in which each animal is dosed once would allow 1 mL/kg to be administered into each hind limb, for a total dose volume of 2 mL/kg. This dose volume coupled with the limit of solubility or suspendability of the test article in the vehicle selected may restrict the maximum dose of test article below toxic levels. A further limitation on toxicity testing by the im route is that the formulation to be injected must not cause significant local irritation, particularly if repeated doses will be administered. This limitation may require that a separate study be conducted to assess im irritation potential prior to initiation of a repeated dose study by this route. Intramuscular injection is more labor-intensive than most other routes with the exception of iv injection.

Description of Technique

Intramuscular injections are administered into the large muscle groups of the posterior aspect of the femoral region using a hypodermic needle attached to a graduated syringe. Each mouse receives a single daily dose, administered as a bolus into alternate hind limbs for the duration of the study. Hypodermic needles used for im injection should be the smallest diameter that will allow injection, but in the range of 27 gauge up to a maximum of about 23 gauge. Prior to dosing, the same procedures for formulation, analysis, weighing of mice, and calculation of doses should be followed as those recommended for ip dosing. The dose is drawn into a syringe, and air bubbles are expelled. The mouse

may be held by an assistant, and the needle inserted to the approximate center of the muscle mass. The dose is injected as a bolus, and the needle is withdrawn. The muscle may be massaged gently to distribute the dose prior to returning the mouse to its cage.

Subcutaneous Injection

The sc route of administration is not commonly used in toxicity testing, but may be appropriate if the test article is intended for sc administration to humans, or as a more practical substitute for im testing in mice. The sc route is similar in many characteristics of absorption to the im route, and generally results in slower absorption of a test article, with lower peak plasma levels, but more sustained effects than ip administration. The rate of sc absorption can also be influenced by the amount of vascular perfusion of the tissue surrounding the injection, the vehicle, and the injected volume, which indirectly may alter the surface area of tissue available for absorption. Coadministration of a vasodilator generally increases the rate of absorption, whereas coadministration of a vasoconstrictor generally decreases that rate. Administration of the test article as a solution or suspension in a viscous, poorly absorbed vehicle generally retards absorption. The ability to control the rate of absorption is similar to that seen with im injection and can offer the same advantages, as it may allow the toxicologist to administer a dose of a test article that may be absorbed over a period of many hours or even days. Some limitations to im dosing do not apply to sc dosing. Subcutaneous doses can be injected at a wide variety of sites, if necessary. In addition, dose volumes of up to 10−20 mL/kg/day may be administered repeatedly if they are well absorbed and do not cause excessive local irritation. These large dose volumes allow administration of much higher total doses than can be administered im. It may still be necessary to conduct a separate study to assess sc irritation potential prior to initiation of a repeated dose toxicity study. Subcutaneous injections can easily be administered to mice without assistance.

Description of Technique

Subcutaneous injections are administered into the region beneath the skin using a hypodermic needle attached to a graduated syringe. Each mouse receives a single daily dose, administered as a bolus. Daily doses may be administered at the same site if absorption is complete and irritation is minimal, but sc trauma may be reduced if the injection site can be changed from day-to-day. Hypodermic needles used for sc injection should have the smallest diameter that will allow injection, but in the range of about 26 gauge up to a maximum of about 20 gauge. Although larger volumes

can be administered, dose volumes of about 10 mL/ kg/day are preferable.

Prior to dosing, the same procedures for formulation, analysis, weighing of mice, and calculation of doses should be followed as those recommended for ip dosing. The dose is drawn into a syringe, and air bubbles are expelled. The mouse is grasped by a fold of skin. One of the most convenient injection sites is the skin in the midscapular region, which allows the restraint and dosing of the mouse with minimal risk of being bitten. The needle is inserted through the skin into the sc region. The dose is injected as a bolus, and the needle is withdrawn. The injection site may be pinched for a few seconds to prevent leakage, and the area around the injection site may be massaged gently to distribute the dose prior to returning the mouse to its cage.

Intradermal Injection

Intradermal injection is not a route that is commonly used for toxicity studies. It may be appropriate to test products intended for id administration to humans by that same route in mice, and studies of limited duration are technically feasible. The id route offers the advantage of slow absorption owing to the poor vascular perfusion of the skin relative to tissues in other areas of potential administration. This slow absorption is typically associated with longer time to onset of effects, lower peak plasma levels, but more sustained effects than routes that result in faster absorption. To the extent that the test article may be metabolized by the skin, the id route would be expected to offer greater opportunity for such metabolism than sc injection, but less than topical administration. Injected volume for id dosing should be limited to about 1 mL/kg per injection site or less, with smaller volumes preferred if repeated doses will be administered. It is acceptable to administer id doses at multiple sites simultaneously if higher total doses are required. Irritating formulations of the test article must be avoided, especially if multiple doses will be administered, as ulceration and necrosis of the skin can result.

Description of Technique

Intradermal injections can be administered at a variety of accessible sites, but the skin of the abdomen or back is often used. The area in which the injections will be administered should be shaved with a small animal clipper to allow good visualization during and after dosing. Doses can be administered using a small hypodermic needle attached to a graduated tuberculin syringe. Needle diameter should be limited to 27 gauge or smaller, and 30 gauge is preferable. The use of a needle with an id bevel is not necessary. Prior to dosing, the

same procedures for test article preparation and analysis of formulations, weighing of mice, and calculation of doses should be followed as recommended for ip dosing. The dose is drawn into the syringe and air bubbles are expelled. The mouse is held in one hand, and the needle is inserted into the skin at a shallow angle with the bevel of the needle up to avoid penetration into the sc space. With practice, the toxicologist can feel the needle penetrate into the sc space, if that happens by accident, and can relocate the needle prior to injection. A properly administered id dose will appear as a small bleb on the surface of the skin. A dose administered into the sc space will not appear as a bleb, as the dose will be distributed over a larger area.

Topical Administration

The topical route of administration is occasionally used for toxicity testing. This choice of route may be appropriate for testing the systemic and local toxic effects of substances intended for human topical administration or which are likely to come into accidental contact with human skin. Data suggest that the mouse is one of the less appropriate species for extrapolation of percutaneous toxicity to the human, as the permeability of mouse skin (as well as rat and rabbit skin) is substantially higher than the permeability of human skin (Maibach and Wester, 1989). Nevertheless, topical application to mice may be appropriate in special cases, such as the conduct of the MEST for dermal sensitization potential (Gad et al., 1986).

Historically, the skin was perceived as a barrier to absorption. It is now clear that lipophilic compounds are readily absorbed into and across the skin, and also that the skin may be a source of significant metabolism of some chemicals (Maibach and Wester, 1989). Variables, in addition to lipophilicity, that are likely to affect dermal absorption include the integrity of the skin at the treatment site, the vehicle employed for dosing, occlusion, and/or restraint of the mouse after treatment, and whether the test article is washed off after some prescribed period. Variations on the integrity of the skin include totally intact skin, skin from which the outer epidermal layers have been tape stripped using a surgical adhesive tape (e.g., Dermiclear), and skin that has been abraded. The presumption is that nonlipophilic test articles will penetrate stripped (thinned) or abraded (interrupted) skin more extensively than they would in intact skin. The proper choice of a vehicle may enhance the permeability of the skin to a nonlipophilic chemical. Occlusion of the treatment site and/or restraint of the mouse after application of a topical dose improve retention of the dose in contact with the skin and reduce the probability that the animal will orally ingest the topical dose. Washing excess test article from the treatment site after a prescribed time will limit the exposure period to a known interval. The appropriate choices for the above (and other variables) in topical toxicity study design are a function of the specific objectives of the study, and the physical and chemical characteristics of the test article.

Description of Technique

As the number of procedural variables for topical dosing is so great, the procedures described for topical dosing in the MEST (Gad et al., 1986) will be described as a representative technique. In that procedure, the hair is clipped from the treatment site (e.g., abdomen or back) on the first day of treatment and the epidermal layer is tape stripped until the site has a slightly shimmy appearance, typically 10—20 applications and removals of a surgical adhesive tape such as Dermiclear (Johnson & Johnson Co., New Brunswick, NJ). Next, a fixed volume, e.g., 100 μL, of the test article in a volatile solvent such as ethanol is applied to the treatment site. The solvent is allowed to dry using a warm air blower if necessary, and the animal is returned to its cage. On subsequent treatment days the tape-stripping operation can be reduced to about 5—10 applications of adhesive tape to achieve the shinny appearance.

Inhalation

The inhalation route of administration offers the most rapid absorption of most test articles, with systemic availability second only to iv injection. Efficiency of absorption by the inhalation route is conferred by the large surface area of the respiratory system, the close proximity of the inner alveolar surface to the blood circulating through the lungs, and the fact that the entire cardiac output passes through the lungs with each circuit of the blood through the body. Absorption of inhaled agents proceeds via one or more of the following mechanisms depending on specific characteristics of the agent: direct absorption into the blood stream, absorption from the gastrointestinal tract following deposit in the nasopharynx or transport by mucociliary escalation and swallowing, and/or lymphatic uptake following deposit in the alveoli.

Inhalation studies are particularly useful in estimating the risk of accidental or occupational exposure to a gas, vapor, dust, fume, or mist as well as in evaluating the toxicity of agents that are intended to be administered by inhalation. Administration by inhalation is the most technologically complex means of routine exposure, and a comprehensive description of the procedures is beyond the scope of this chapter. The reader is referred to other works (e.g., McClellan and

Henderson, 1989; Leikauf, 2013; Kennedy and Trochimowicz, 1982) for further description. Rather, this discussion will be limited to some of the advantages, disadvantages, and variables to be considered in inhalation testing. The primary advantage of inhalation is rapid, effective absorption. The primary disadvantage is the technological complexity of the method, with the associated risk of technical error and disregard of an important variable.

For a mouse to inhale a test article, the mouse must be placed in an environment that contains the test article in the form of a gas, vapor, dust, fume, or mist. The test article must exist in a particle size that is inspirable, generally having an aerodynamic diameter from 1 to about 10 A. Particle size dictates the location where the test article will be deposited and absorbed in the respiratory tract. Larger particles are deposited in the nasopharyngeal region, with successively smaller particles deposited in the trachea, bronchial, bronchiolar, and finally the alveolar region for particles of about $1\,\mu$ or less. The technology of particle generation and uniform distribution through the exposure apparatus is complex in itself. In addition to generating and uniformly distributing the test atmosphere, care must be exercised to capture the exhaust from the exposure apparatus, such that the test article can be contained without contamination of the laboratory or environment. Exposure periods can range from a few minutes, appropriate for test articles that may pose only an acute exposure risk to continuous exposure over a prolonged period, appropriate for test articles that may pose a risk of long-term environmental or occupational exposure. Exposure apparatus generally takes the form of a chamber that contains the whole animal or groups of animals, or a device that exposes only the head or nose of the animal(s) to the experimental atmosphere.

Chamber (Whole Body)

Inhalation chambers allow relatively large numbers of mice to be exposed simultaneously without restraint. The aerodynamic considerations are complex, but simpler than for a head-only or nose-only exposure system. The flow rate through a chamber must be adequate to provide temperature and humidity control. Disadvantages of whole body chambers include the tendency for test article to accumulate in the fur, from which it can be ingested; on the skin and eyes, which may interfere with the intended route of exposure and the difficulty in monitoring respiratory volume and rate of individual animals.

Head/Nose Exposure (Head Only/Nose Only)

Head- or nose-only exposure apparatus limits exposure of the mouse to the test article by routes, other than inhalation, as only a small amount of skin and fur are exposed to the test environment. In addition, it is possible to monitor respiratory volume and rate of individual animals with some of the head-or-nose-only equipment. Disadvantages to this equipment include the fact that only a relatively small number of animals can be simultaneously exposed, and those animals must be restrained in a position that keeps their heads or noses in close contact with the exposure apparatus. This restraint imposes stress on the animals and virtually precludes continuous exposure, as the processes of eating and drinking are not possible with most of this equipment. The restrainer may limit the animals' ability to dissipate excess body heat.

END POINT DATA COLLECTION

Types of data that are routinely collected during the conduct of toxicity studies in mice fall into three broad categories: clinical observations and physical examinations, clinical laboratory evaluations, and postmortem procedures. Cardiovascular parameters are not measured in routine toxicology studies. Heart rates in awake mice have been measured in the range of 300 to more than 800 beats/min (Hoyt et al., 2007). Reliable blood pressure measurements are best made by cannulation of a major artery, such as the carotid. Such procedures require anesthesia and surgery, neither of which is especially desirable during the course of a study that may be of long duration and involve many animals.

Clinical Observations and Physical Examinations

Clinical observations entail the recording of effects that can be detected by direct observation, such as abnormal gait and body weight. For the sake of this discussion, a variety of parameters that can be observed or measured directly will be discussed in this section. Clinical observations often provide the first indication of which physiological systems are being affected by the test article.

Mice should be observed regularly throughout the in-life portion of a toxicity study. The type and frequency of these observations should be tailored to meet the scientific objectives of the specific study. Most effects observed following administration of acute (single) doses occur within a relatively short time after dosing. As acute iv doses are often associated with almost immediate effects, it might be appropriate to observe treated mice within 5 min, at about 15, 30, and 60 min, and again at 2 and 4 h after dosing. Observations should be repeated at least once daily on all subsequent study days throughout the postdosing

observation period. This schedule should provide information on the times of onset, peak activity, and remission from toxic effects as well as information on the sequence and severity of effects observed. The high intensity of data collection on the day of dosing in acute studies requires that the system for conducting and recording observations be simple and time efficient. Typically, a system of "exception reporting" is used, in which observations of exceptions from the norm are recorded, and the absence of comment on a system (e.g., respiration) implies that parameter is normal. Clinical observations in repeated dose studies should be conducted at approximately the same time each day to assure that changes in findings over the course of the study can be attributed to the accumulation of or adaptation to toxic effects rather than incidental changes attributable to circadian rhythm or time after dosing. Minimally, all animals should be observed early in the day, prior to daily dosing, and it is highly desirable to conduct at least one additional daily observation at 2–4 h after dosing (or late in the day) to be aware of effects that may be associated with higher blood levels of test article usually found from a few minutes to a few hours after dosing.

The simplest form of clinical observation is an observation for survival and moribundity. This or a higher level of observation must be conducted at least once daily in all toxicity studies. The next level of observation is an observation for clinical signs of toxicity, such as abnormal level of spontaneous motor activity, abnormal gait, abnormal respiration, and abnormal quantity or quality of fecal output.

The next level of observation is more structured, and is typically conducted about once in a week during studies of a few weeks' duration to as infrequently as about once in a month during the later phases of 26-week to 2-year studies. During the conduct of a physical examination, specific parameters are evaluated, such as quality of coat, body orifices (for excessive or unusual discharges), eyes, respiratory sounds, and in studies longer than about 26 weeks, animals are examined carefully for evidence of visible or palpable masses. Body weight and feed consumption are typically monitored in studies longer than a few days. An appropriate interval for measuring body weight and feed consumption is about a week. These two parameters should be measured concurrently, such that changes in one can be compared directly to changes in the other. In longer studies, in which the mice have reached maturity and body weight gain has approached zero, the frequency at which body weight and feed consumption are measured can be reduced to as infrequently as once per month. The interval over which they are measured would remain at about a week, however.

Clinical Laboratory Evaluations

Clinical laboratory evaluations of mice refer to evaluations of blood and urine. Blood is routinely collected at sacrifice in repeated dose studies, and small quantities (e.g., about 0.10 mL) of blood can be collected at interim periods during the course of the study for the purpose of evaluating differential smears or other limited objectives. Interim (nonterminal) blood samples can be collected by retro-orbital venous plexus puncture, cardiac puncture, and tail snip, among other techniques. Each of these techniques has certain disadvantages. Retro-orbital puncture is technically difficult and may require anesthesia or immobilization of the animal. Cardiac puncture typically requires anesthesia, and cardiac injury may compromise the histological evaluation of cardiac tissue. Tail snip often yields samples that are contaminated with extravascular, extracellular fluids. Any administration of anesthetic agents during the study of a test article that is not thoroughly understood engenders some risk to the interpretation of the study, as potential interactions of the anesthetic with the metabolism or direct effect of the test article are nearly impossible to predict. Blood collected at the time of sacrifice is typically drawn from the inferior vena cava or the abdominal aorta while the mouse is under anesthesia. In the case of terminal blood collection, potential interaction of the anesthetic agent with the test article, induction of liver enzymes, etc., is not an issue.

Parameters evaluated in blood samples drawn from mice include evaluation of differential smears for morphological abnormalities and differential white counts, measurement of serum glucose and urea concentrations, serum aspartate aminotransferase, ALT, and alkaline phosphatase activity. RBC counts, white blood cell counts, and hemoglobin concentrations can be measured, but these parameters are quite variable for mice on many of the commonly used laboratory instruments, so they are often omitted. In addition, bone marrow smears may be prepared but are usually only prepared at sacrifice in mice. Bone marrow smears may help in understanding hematological changes. Caution should be exercised in comparing experimental data with results obtained from the literature or with results obtained on different instrumentation or by different procedures. For greatest utility, a set of normal values should be compiled for the laboratory procedures and equipment used to produce the data in the toxicity study.

As a practical matter, urine is not usually collected in routine toxicity studies. The primary difficulty in conducting urinalysis is that the mouse produces a very small volume of urine during a reasonable collection period (e.g., 16–24 h), and of that volume, considerable and variable quantities are lost to evaporation and on

the surfaces of the collection apparatus. As a result, attempts to evaluate urinary concentrations of practically anything can be very misleading.

Postmortem Procedures

Postmortem procedures, literally those procedures performed after the death of the animal, include confirmation of the identification number and sex of the animal, an external examination, examination of the significant internal organs in place prior to removal, and then removal, weighing of appropriate organs, and collection of tissue specimens for histological processing and microscopic examination. The microscopic examination of tissue specimens by a qualified veterinary pathologist may be the single most important source of information in understanding the toxicity of a test article. The pathologist's findings should be carefully integrated with the other study data (e.g., clinical observations, body weights, feed consumption, and clinical laboratory findings) to fully comprehend the effects of the test article on the mouse under the conditions of study.

Ordinarily, the list of tissues to be routinely weighed, collected, and processed for histological examination will be specified in the study protocol. In addition to the tissues specified in the protocol, specimens are usually collected of all lesions or target organs that have been identified during the course of the study or at gross necropsy. It is important to provide the necropsy staff with a current list of abnormal clinical observations, especially any evidence of visible or palpable masses, as this is the time when the visible and palpable lesions can be linked to the histopathological evaluation of those lesions. Every effort should be made to locate all lesions described and collect representative tissue from those sites.

A detailed description of necropsy procedures is beyond the scope of this discussion. It should be emphasized that the necropsy process, particularly when conducted on a large number of animals at the scheduled termination of a study, is a process in which a large number of tissue samples may be collected and a similarly large quantity of data may be gathered during a short period of time. As such, this process presents many opportunities for loss or misidentification of samples and data. A rigorous system of accounting for which tissues have been collected from each animal, and for tracking the samples and data collected is critical to the accurate interpretation of the toxicity study.

SUMMARY

In summary, the mouse is one of the most useful species for toxicity testing. Mice have been used in biomedical research for hundreds of years. As a result of long usage, many techniques have been developed to dose and evaluate mice, and a wealth of historical data has been accumulated in the literature. A wide variety of genetic strains have been developed for specific purposes. It is often possible to select a strain for testing that is particularly vulnerable or resistant to either the test article or a particular type of lesion that might be expected to be associated with that test article. The small size of the mouse confers economy in acquisition, husbandry, handling, and test article consumption. The relatively short gestation period and life span of the mouse are useful in conducting reproductive studies, or studies in which the test article will be administered for a high percentage of the lifetime of the animal.

The small size of the mouse is responsible for most of the disadvantages of the species as well. The species is relatively susceptible to environmental stress. Small size and blood volume makes it difficult or impossible to collect multiple samples of blood and urine over short periods of time. Assays that might require large volumes of blood or urine are precluded. Certain physiological evaluations, such as electrocardiograms, are difficult owing to the small size and high activity level of the species.

The Hamster

The hamster is the third most frequently used laboratory animal following the rat and mouse at a level of ∼146,000/year (Renshaw et al., 1975; Silverman, 2012), although its use in toxicology is somewhat limited. Although historically the hamster saw extensive use in carcinogenesis testing, as will be overviewed, this has changed. It has many attractive features as a laboratory animal because of its reproduction ease, unique anatomical and physical features, rapid physiological development, short life span, low incidence of spontaneous diseases, and a high susceptibility to induced pathological agents. Hamsters historically have been used in several fields, especially in carcinogenesis because of its low incidence of spontaneous tumors, but currently most of their use is seen in testing associated with buccal delivery of drugs (Gad, 2016). Hamsters have also played an important role in blood vessel physiology because their cheek pouches with thin vascularized walls are very accessible. The hamster is also a major model in diabetes research.

SPECIES

The following is a discussion of the eight hamster species maintained in the laboratory. Table 2.31 lists these hamsters' common and scientific names and their chromosome numbers.

Syrian Hamster

The Syrian hamster is the most common laboratory hamster. Eighty percent of all hamsters used in research are Syrian. The remaining 20% are primarily Chinese, followed distantly by European, Armenian, Rumanian, Turkish, South African, and Dzungarian hamsters. The Syrian was originally native to the arid, temperate regions of Southeast Europe and Asia Minor. It was first described as a new species (*Cricetus auratus*) in 1839. For almost 100 years, no hamsters were caught in the wild. The only proof that the species existed was the preservation in alcohol of two hamsters, one in London and the other in Beirut. Specimens of the species were finally obtained from the wild starting in the 1900s and have since been bred in multitudes in captivity. It lives in deep tunnels that ensure cool temperatures and increased humidity. It is a nocturnal animal. The Syrian is virtually tailless and has smooth short hair. Normal coloration is reddish gold with a grayish white ventral portion. The dorsal side may have a black stripe. The ears are pointed with dark coloration; and the eyes are small, dark, and bright. The average life span is 2 years, but these animals can live up to 3 years. The animal is 14–19 cm in length and weighs 114–140 g at adulthood. The female is usually heavier and longer than the male.

The Syrian hamster was introduced into the laboratory in 1930 to study the Mediterranean disease kala-azar. Israel Aharoni (Hebrew University, Jerusalem, Israel) collected 11 young golden hamsters from Syria in 1930 while on a zoological expedition. The litter with their mother had been found in their burrow 2.5 m under a wheat field. Aharoni and his wife kept the hamsters in their house until one night when they all escaped. Nine hamsters were recovered and given to the animal facilities supervisor of the Weizmann & Seiff Institute, Jerusalem, Israel. Of the nine, five escaped the first night in the new facility, leaving only one female. The female was mated and gave birth to a litter of healthy pups. In a year's time, these hamsters produced more than 300 offspring and were the forbearers of today's laboratory-bred Syrian hamster. There is no record of any further captures of Syrian hamsters from the wild.

The Syrian has been involved in oncology, virology, endocrinology, physiology, parasitology, genetics, and pharmacology research. The cheek pouch of the Syrian hamster has provided the technology for studying microcirculation and the growth of human tumors.

Chinese Hamster

The Chinese hamster is native to China. It is 39–46 g in weight and 9 cm long at adulthood. Its life span is 2.5–3.0 years under laboratory conditions. Though the Chinese hamster is smaller than the Syrian, its testicles, spleen, and brain are larger.

The Chinese hamster was originally used for the first time in 1919. Mice were extremely scarce at the time so hamsters were used to determine the best therapy for the patients with pneumonia. The Chinese hamster was also used to study TB, influenza, diphtheria, and rabies. Robert B. Watson, in December 1948 (right before the Communist takeover of China), was given 10 female and 10 male hamsters from C. H. Hu of the Peking Union Medical College. Watson placed the hamsters on what he believes was one of the last Pan Am flights out of China to San Francisco. From San Francisco, the hamsters were sent to New York. V. Schwenter of the Harvard Medical School obtained the hamsters and eventually successfully bred them in the laboratory. Of the original 20 hamsters, 4 of the females and 3 of the males produced offspring that gave rise to the present Chinese hamster population. The Harvard colony has since become extinct; however, colonies were established at the Upjohn Company (which became Pharmacia and most recently was acquired by Pfizer), Kalamazoo, Michigan, and the C. H. Best Institute in Toronto, Ontario, in the 1960s.

TABLE 2.31　Common and Species Names and Chromosome Number

Common Name	Species Name	Chromosome Number
Syrian (Golden)	*Mesocricetus auratus*	44
Chinese (Striped, Black)	*Cricetus griseus* or *barabensis*	22
European (Common, Black, Field)	*Cricetus cricetus*	22
South African	*Mystromys albicaudatus*	32
Rumanian (Newtoni's)	*Mesocritceus newtoni*	38
Turkish (Kurdanti)	*Mesocricetus auratus*	42/44
Armenian (Gray, Migratory)	*Cricetulus migratorius*	22
Dzungarian (Hairy-footed)	*Phodopus sungorus*	28

The Chinese hamster has been used primarily in research for cytogenetics because of its low chromosome number (Fenner, 1986), and in diabetes mellitus because (1) some strains have very high incidences of the disease and (2) the course of the disease in this species is similar to that seen in humans.

European Hamster

The European hamster was first found in a West Germany industrial area. Its natural habitat is the lowlands of Central and Eastern Europe. The European hamster is a very aggressive animal, and in the wild each adult lives in its own burrow. It has a white face and feet, bodies are dorsally reddish brown and ventrally black with white patches laterally. They are about the size of a guinea pig, averaging 27−32 and 22−25 cm in length and weighing 450 and 350 g for males and females, respectively. Males reach sexual maturity at 60 days of age, whereas females at 80−90 days of age, and they are mainly seedeaters. In the wild, they hibernate in the winter months. In their natural habitat, European hamsters can live up to 8 years, whereas under laboratory conditions, the average life span is 5 years. This reduction is believed to be due to the lack of hibernation afforded to a laboratory-raised European hamster (Mohr and Ernst, 1987).

The European hamster has been used only in hibernation studies and in inhalation studies because its tidal volumes are the largest of any laboratory rodent species.

Armenian Hamster

The Armenian hamster is native to the Union of the Soviet Socialist Republic (USSR). Its body size, weight, care, and maintenance are similar to that of the Chinese hamster.

The Armenian hamster was first introduced as a laboratory animal in 1963. It was brought to the United States as a part of the US−USSR. Cultural Exchange Program. Scientists in the United States wanted to find more species of the dwarf hamster (like the Chinese), and the Armenian species has been the only species found. Although the Armenian hamster has been used on a limited basis, its research use has been in cytogenetics and oncology.

Turkish Hamster

The Turkish hamster is native to Iran and Turkey. It was originally trapped in 1962. As an adult, its average body weight is 150 g and its average life span is a little less than 2 years, although they have lived as long as 4 years. Some populations of the Turkish hamster have

a diploid number of 42 and others a number of 44. These hamsters interbreed readily and produce offspring with a diploid number of 44. Hamsters with diploid number of 42 hibernate less than those with 44. Besides hibernation research, Turkish hamsters have been used in immunology, genetics, and reproductive behavior research (Yerganian, 1972; Cantrell and Padovan, 1987).

Rumanian Hamster

The Rumanian hamster was initially trapped and described in 1965. It is native to the Bucharest area and is used in the laboratories surrounding that area. Its care, size, and management are similar to that of the Syrian hamster, although it does not reproduce as well as the Syrian. The Rumanian hamster adult averages 100 g weight. Its face is more pointed and ratlike than the Syrian hamster, but it is similar in appearance to the Turkish hamster.

Dzungarian Hamster

The Dzungarian hamster is very timid. The males are 11 cm long and 40−50 g in weight; the females are 9 cm long and weigh 30 g at maturity. The Dzungarian hamster has a short tail about 1 cm in length, which is usually hidden by the body fur. The fur on the dorsal side is gray with a dark-brown or black stripe from the nape of the neck to the base of the tail. The ventral fur is white. The average life span has been reported to 1 year by Herberg et al. (1980) and 2 years by Heldmaier and Steleinlechner (1981).

The Dzungarian hamster, native to the USSR, was originally trapped in Siberia and provided to the United States by the USSR. The present Dzungarian hamster population is the result of the mating of one female to two males who were domesticated in 1965. The Dzungarian has been used in research involving photoperiodism, the pineal gland, and thermoregulation.

South African Hamster

The South African is the only member of its genus and the only hamster native to Africa. The first colony was established in South Africa in 1941. In its natural habitat, South African hamster is a nocturnal, solitary burrowing rodent. Unlike other hamsters, it does not have cheek pouches. The hamster has gray to brown fur on its dorsal aspect with white on the ventral surface, feet, and tail. The tail is 5−8 cm long. Its ears are erect and the eyes are dark and bright. Adult males and females weigh 145 and 95 g, respectively (Hall et al., 1967). The average life span is 2.4 years, with a maximum life span of 6.2 years (Davis, 1963). The

United States received its first South African hamster in 1962. These hamsters have not had much of an impact in biomedical research except in diabetes mellitus and infectious disease research.

SPONTANEOUS TUMORS

Table 2.32 lists the most common spontaneous tumors in hamsters by incidence and their total incidence. The most frequent tumors are seen in the adrenal cortex and intestinal tract, followed by the lymphoreticular system, the endometrium, endocrine system, and ovaries of aging females (Sher, 1982). The benign tumors found are usually adenomas of the adrenal cortex and polyps of the intestinal tract. In a study by Dontenwill et al. (1973), adenocarcinomas were age related with a rate of greater than 50% in hamsters over 100 weeks of age. The rate of small intestinal adenocarcinomas (0.8%) seen by Fabry (1985) was higher in hamsters than in rats or mice. Lymphosacromas are the most common malignant tumors of the Syrian hamster. Tumors of the liver, pituitary, lung, urinary bladder, and mammary gland are practically unknown in the hamster, but these do occur spontaneously in older rats and mice (Homburger et al., 1979a,b). Genetic drifts seen in many colonies of hamsters may influence the rate of spontaneous tumors as in the rat and mouse.

TABLE 2.32   Incidence of Spontaneous Tumors in Syrian Hamsters

Neoplasm	Males	Females	Total
Adrenal adenoma	12.7	9.4	11.0
Lymphoreticular neoplasm	3.7	2.3	3.0
Uterus endometrial polyp		3.0	
Uterus endometrial carcinoma		3.0	
Adrenal carcinoma	3.0	2.0	2.5
Pancreas islet cell adenoma	3.7	1.3	2.5
Vagina papilloma		2.0	
Stomach papilloma	1.7	1.7	1.7
Thyroid carcinoma	1.0	2.0	1.5
Uterus leiomyoma		1.0	
Small intestine adenocarcinoma	0.3	1.3	0.8
Pituitary adenoma	0.0	1.3	0.7
Pancreas islet cell carcinoma	0.7	0.7	0.7
Ovary fibroma		0.7	
Ovary theca cell tumor		0.7	

ANIMAL IDENTIFICATION

Hamsters are usually identified by tagging, punching, or coding of the ear or ear tattooing, which is done aseptically.

DOSING PROCEDURES

Oral Administration

To dose a hamster orally (p.o.), the animal is grasped by the skin of the neck and back. The gavage tube (metal 18- or 20-gauge) or a polyethylene catheter (2—3 cm in length) is passed into the mouth via the interdental space. The tube is passed gently into the esophagus and the fluid administered. The method is similar to the procedure done in the mouse and rat.

Subcutaneous Administration

The hamster is restrained for sc dosing as described for oral dosing. The needle is placed into the skin that is tented by pulling up a fold of skin on the back firmly between the thumb and index finger immediately behind the head. The injection is made into the skin parallel to the back. The hamster's loose skin enables large volumes to be injected sc in comparison to other rodent species of the same size (Collins, 1979).

Intradermal Administration

To administer an agent id, the skin over the desired injection site is shaved. Holding the animal as described above, the needle (30-gauge) is advanced just a few millimeters into the skin. If there is suddenly no resistance, then the needle can been pushed through the skin. Withdraw and advance the needle again. Following administration of the material, a small welt will be visible.

Intramuscular Administration

To administer an im dose, the muscles of the posterior and anterior thighs of the hamster are the most frequently used sites. The animal is restrained as described for oral dosing by an assistant and one leg is held by the doser. The quadriceps are held between the forefinger and the thumb of the doser. The material is injected into the muscle mass.

Intraperitoneal Administration

To dose a hamster ip, the animal is grasped as described previously. The needle is pushed parallel to the line of the leg through the abdominal wall into the

peritoneal cavity. Following the leg line avoids administration into the urinary bladder or the liver. Administration may occur when there is no resistance to the needle passage.

Intravenous Administration

It is best that the hamster is anesthetized to administer materials iv. The veins that can be used are the femoral, jugular, and cephalic. The areas must be shaved, a skin incision made to expose the vein, and then a needle may be placed into the vein and the material administered.

BLOOD COLLECTION TECHNIQUES

Retro-orbital Method

The retro-orbital is the method of choice for collecting blood from the hamster. The method used is that as described for the rat. A 23-gauge needle or a microhematocrit tube may be used to obtain the blood. Three milliliters of blood may be collected retro-orbitally; however, for repeated sampling a volume of 0.5 mL is best for the animal. The use of anesthesia is preferable in the hamster.

Cardiac Puncture

Cardiac puncture in hamsters requires practice because the heart can be difficult to locate or can rotate away from the needle. A 25-gauge 3/8-in needle is the suggested equipment. A safe volume to draw from the heart with minimal damage is 1−2 mL. Repeated sampling from the heart is not advised because the mortality rate due to the blood withdrawn can be high (Wechsler, 1983). The use of anesthesia is suggested in the hamster. On exsanguination, 5 mL can be withdrawn from a 95-g hamster (Schermer, 1967).

Tail Clipping Method

Tail clipping is a method suitable only for a maximum of six samples because the tail is so short. To facilitate blood flow, place a suction bell (which is connected to a water pump) on the base of the tail. Anesthesia is not necessary if the hamster is placed in a narrow tube with the hind legs protruding so they can be held.

Femoral Vein Method

To collect blood from the femoral vein, a tourniquet is placed above the stifle and the fur over the area clipped. A skin incision is made to expose the vein and a 25-gauge 5/8-in needle is placed into the vein. The blood is collected from the needle hub with a capillary microcontainer or a microhematocrit tube.

Jugular Vein Method

To collect blood from the jugular vein, the hamster should be anesthetized, the area shaved over the jugular, a skin incision made, and a 25-gauge 5/8-in needle placed into the vein and the blood withdrawn.

Saphenous Vein

First a body tube is used to immobilize the animal. The skin over the ankle is stretched, allowing for ease in shaving the area above or around the vein. A 25-gauge, 5/8-in needle is slid into the vein and blood is withdrawn. This method is as of 2005 the recommended approach to nonterminal blood collection (Hem et al., 1998).

URINE COLLECTION

The best method is to collect the urine over 17−24 h as the animal voids. A preservative such as thymol can be added to the collection vessel before starting. Catheterization of the ureter can be done; however, there is always the chance of blood or tissue contamination. A hamster's urine is normally a thick, milky fluid.

PHYSICAL PARAMETERS

Neonatal Body Weights

At birth, Syrian hamsters weigh 2−3 g and Chinese hamsters weigh 1.5−2.5 g. Neonate hamsters are hairless with the ears and eyes closed. Table 2.33 lists information about the early development of the eight laboratory hamsters.

Body Weights and Weight Gains

The average adult body weight for each of the species is discussed in the Species section of this chapter.

In a study by Borer et al. (1977), Syrian hamsters gained 2 g/day from birth to 5 weeks of age. From days 30 (weight = 65 g) to 70 the hamsters gained 1 g/day. From day 70−88 the hamsters gained 0.3 g/day. Syrian hamsters at maturity weighed from 100 to 135 g. Normal fetal and maternal weight gain is well documented in Davis (1989).

TABLE 2.33   Neonatal Data for Hamsters

Species	Birth Weight (gm)	Day Eyes Open	Day Ears Open	Day Pups Solid Food	Day Weaned	Teeth at Birth
Syrian	2—3	15	5	7—10	21	Yes
Chinese	1.5—2.5	10—14	10—14		21—25

South African	6.5	16—25	3—5	21—25		No[a]

[a]Incisors erupt at 3—5 days.

Dentition

The dentition of a Syrian hamster is monophyodont, bunodont, and brachyodont. The incisors of the Syrian species grow irregularly depending on age and sex of the hamster. The adult European hamster has one set of permanent teeth that consists of four continuously growing incisors and 12 molars.

Life Spans

The average life spans for each of the laboratory species are discussed in the Species section of this chapter.

Sexual Maturity

Sexual maturity for female hamsters begins at 4—6 weeks of age. At this time, there are 10 mature and 25 reserve follicles in each ovary. A female's first spontaneous estrus and ovulation are at 4—5 weeks and 30 days, respectively. In young immature females (4 weeks of age), ovulation may be artificially induced with 30 IU pregnant horse serum (Magalhaes, 1970). The estrus cycle is 94 h or >4 days in length with four distinct stages: proestrus, estrus, metestrus, and diestrus. Identification of the stage can be determined from differentiation of a vaginal smear through examination of cell types. During estrus (which occurs before and after ovulation) the female will show lordosis and will mate. The end of estrus is the appearance of a copious postovulatory discharge. The discharge is creamy, white, opaque, and very viscous with a pungent cheesy odor. Ovulation occurs regularly every 4 days, 9—10 h after the peak concentrations of luteinizing hormone (LH). The breeding life of a hamster is usually about 10—12 months, or after the production of six litters.

Syrian hamster males reach sexual maturity at 6—7 weeks of age and have a breeding life of about 1 year. The testicles of male Syrian and Chinese hamsters descend at day 26 and 30, respectively.

The secondary sex characteristic of the Syrian hamster is a scent organ (flank organ), which is located on the flank. The male touches the female's organ with his paws during copulation. The intensity of the pigmentation is an indication of androgen activity. The males have a darker pigmentation than females. The pigmentation is first seen at 25 days of age and is more marked at 35 days of age.

Respiratory Rate and Oxygen Consumption

The minimum respiratory rate (breaths/min) is 33, and the maximum is 127. The average respiratory rate is 74 and the mean resting respiratory rate is 30—33 breaths/min (Robinson, 1968). Hamsters are nose breathers and have a resting oxygen consumption of 2.3 mL/g/h. It is possible to implant sensors to measure these, but such is uncommon in hamsters.

BLOOD PRESSURE

The blood pressure measured by cannulation of the carotid artery of the hamster is 111 mmHg (Storia et al., 1954). The blood pressure measured on the cheek pouch by Berman et al. (1955) was 90 ± 11.3 mmHg. Another measurement of blood pressure by photoelectric tensiometry was 108 mmHg. Although there is no direct comparison of these measurements because of the techniques used, the values obtained are similar and can be used as reference values for each method described.

HEART RATE

The mean heart rate (beats/min) of the Syrian hamster is 450 with a range of 300—600.

ECG PATTERNS

The rate of contraction in the Syrian hamster is 350–500 beats/min. The PQ interval is 48 ms with a range of 40–60, the QRS interval is 15 ms with a range of 13–20, and the T- and P-wave amplitudes are 0.33 t 0.07 mV and 0.19 t 0.03 mV, respectively. For measurement of ECGs, the hamster needs to be anesthetized because of its aggressive behavior. The ECG tracings of hamsters resemble human ECG tracings (Lossnitzer et al., 1977).

CLINICAL LABORATORY

Clinical chemistry values for Syrian hamsters are listed in Table 2.34. The following will be a discussion of several interesting aspects of the hamster and its

TABLE 2.34 Clinical Chemistry Values for Syrian Hamsters

Test	Units	Male Mean Values	Female Mean Values	Range Both Sexes
Bilirubin	(mg/dL)	0.42	0.36	0.20–0.74
Cholesterol	(mg/dL)	54.8	51.5	10.0–80.0
Creatinine	(mg/dL)	1.05	0.98	0.35–1.65
Glucose	(mg/dL)	73.4	65.0	32.6–118.0
Urea nitrogen	(mg/dL)	23.4	20.8	12.5–26.0
Uric acid	(mg/dL)	4.58	4.36	1.80–5.30
Sodium	(mEq/L)	128	134	106–146
Potassium	(mEq/L)	4.66	5.30	4.0–5.9
Chloride	(mEq/L)	96.7	93.8	85.7–112.0
Bicarbonate	(mEq/L)	37.3	39.1	32.7–44.1
Phosphorus	(mg/dL)	5.29	6.04	3.4–8.24
Calcium	(mg/dL)	9.52	10.4	7.4–12.0
Magnesium	(mg/dL)	2.54	2.20	1.9–3.5
Amylase	(Somogyi units/dL)	175	196	120–250
ENZYMES				
Alkaline phosphatase	(IU/L)	17.5	15.4	3.2–30.5
Acid phosphatase	(IU/L)	7.45	6.90	3.9–10.4
Alanine transaminase	(IU/L)	26.9	20.6	11.6–35.9
Aspartate transaminase	(IU/L)	124	77.6	37.6–168
Creatinine phosphokinase	(IU/L)	101	85.0	50–190
Creatinine kinase	(IU/L)	23.1		
Lactic dehydorgenase	(IU/L)	115	110	56.0–170.0
SERUM PROTEINS				
Total protein	(g/dL)	6.94	7.25	4.3–7.7
Albumin	(g/dL)	3.23	3.50	2.63–4.10
α_1-globulin	(g/dL)	0.64	0.55	0.30–0.95
α_2-globulin	(g/dL)	1.85	1.70	0.9–2.70
β-globulin	(g/dL)	0.56	0.83	0.1–1.35
γ-globulin	(g/dL)	0.71	0.67	0.15–1.28
A/G ration		0.87	0.93	0.58–1.24

Mitruka, B.M., Rawnsley, H.M., 1981. Clinical Biochemical and Hematological Reference Values in Normal Experimental Animals and Humans, second ed. Masson, New York.

clinical chemistry values. In comparison to humans, the hamster has lower bilirubin, cholesterol, alkaline phosphatase, creatine phosphokinase, lactic dehydrogenase (LDH), and A/G ratio values and higher blood urea nitrogen, bicarbonate, phosphorus, amylase, acid phosphatase, AST, and α2-globulin values. Because hamsters are such deep day sleepers, blood collection times should be noted because during light photoperiods clinical chemistry values can be variable. The anesthesia used may also affect clinical chemistry values. These must be taken into account when analyzing clinical chemistry data.

Glucose

Thiobarbiturate anesthesia may produce glucose levels as high as 300 mg/dL in adult male Syrian hamsters. The hyperglycemia can exist for up to 5 h after anesthesia exposure, and there is no relationship to the length of hyperglycemia compared to the duration of the anesthesia. Hyperglycemia has also been reported in hibernating hamsters (Newcomer et al., 1987).

Lipids

The lipids found in the hamster are cholesterol, phospholipids, triglycerides, and fatty acids. Cholesterol concentrations in hamsters are the highest when compared to other laboratory animals, but lower than human levels. Short photoperiods (10 h or less) can cause a decrease in cholesterol, but other lipids such as plasma triglycerides are not affected. Serum lipids do increase in the hamster during hibernation. A strain of spontaneous hypercholesterolemic Syrian hamsters show increases in cholesterol when exposed to low temperatures.

Urea Nitrogen

Hamsters who develop kidney disease during the aging process have increased urea nitrogen levels as seen in other laboratory animals.

ENZYMES

Serum obtained by cardiac puncture may be contaminated by AST, LDH, ALT, and creatine phosphokinase owing to the high concentrations of these enzymes already present in the heart.

Alkaline Phosphatase

The alkaline phosphatase in the hamster is composed of isoenzymes from bone, liver, and intestine. Alkaline phosphatase is a more sensitive indicator of liver damage than bilirubin or ALT. Dramatic increases are usually indicative of bile duct obstruction. Immature hamsters have elevation of values two- to threefold compared to adults.

Alanine Aminotransferase

ALT is specific for liver damage in dogs, cats and rats. In the hamster, ALT levels are increased in both acetaminophen-induced and viral-induced hepatic necrosis.

Aspartate Aminotransferase

The activity of AST is low but increases following muscle injury. Increased AST levels have been seen in hamsters with liver neoplasms.

Creatine Kinase and Lactic Dehydrogenase

Cardiomyopathic Syrian hamsters show elevated creatine kinase and LDH activities. Normal creatine kinase levels are 23.1 IU/L, whereas in cardiomyopathic hamsters the levels are 730 IU/L.

Thyroid Hormones

Thyroid hormones are of interest because of the hamster's hibernation. Basal T_3 and T_4 decrease with age. T_4 levels in 3-month-old hamsters are 6.75 ± 0.75 μg/dL and 3.59 t 0.16 μg/dL in 20-month-old hamsters. T_3 levels in 3-month-old hamsters are 62 ± 2 ng/dL and 42 ± 3 ng/dL in 20-month-old hamsters. These changes are also seen in humans and in other rodent species. Older hamsters show less of an increase in T_3 and T_4 levels after thyroid-stimulating hormone (TSH) administration. During short photoperiods there is a decrease in TSH, T_3, and T_4. Lower temperatures also cause decreases in T_3 and T_4 levels, whereas in cold conditions there is an increase T_3 and a decrease in T_4. Pregnant hamsters may metabolize thyroid hormones differently because there is a decrease in protein-bound iodine during pregnancy.

Reproductive Hormones

During estrus there is one LH surge and the follicle-stimulating hormone (FSH) is biphasic. The first burst of FSH occurs concurrently with LH. The second burst is thought to be responsible for the initiation and/or maintenance of follicular growth for the next estrus cycle. Maintenance of functional corpora lutea is believed

to be performed by a combination of prolactin, FSH, and a small amount of LH.

Progesterone is the dominant hormone during the first 2 days of estrus, decreasing on day 3 but rising again on day 4. The levels of progesterone on days 1–2 are dependent on LH. Estradiol levels are low for the first 2 days and increase and decrease on day 4.

Adrenal Hormones

In the hamster, corticosterone and cortisol are secreted by the adrenal cortex. Corticosterone levels are 3–4 times higher than cortisol during the day. Adrenocorticotropic hormone stimulation increases both hormones; however, cortisol levels are stimulated at a higher rate. Basal cortisol levels are 0.45 ± 0.04 μg/dL and 0.38 ± 0.09 μg/dL in males and females, respectively, and corticosteroid levels are 7.4 ± 1.9 mg/dL (Tomson and Wardop, 1987). Pregnant hamsters can produce large quantities of cortisol (30 μg/dL), whereas nonpregnant females have relatively low levels (0.3 μg/dL) in comparison to other species. Increased plasma cortisol levels are seen after exposure to chronic stress.

Glucocorticoid levels follow the circadian pattern seen in other rodents.

PROTEINS

Chinese hamsters with spontaneous diabetes have 10%–30% of their total proteins being α_2, whereas control hamsters have only 3%–8%. Asymptomatic hamsters with significantly elevated α_2 proteins do develop chemical or clinical diabetes later on.

HEMATOLOGY VALUES

Hematological values for Syrian hamsters are listed in Table 2.35. Hematological values for European and Chinese hamsters are listed in Table 2.36. The blood volume of a hamster is 6%–9% of its body weight. The maximum safe volume for one bleeding is 5.5 mL/kg. The practical volume from adult hamsters for diagnostic use is 1 mL. Hematological values for a hamster vary considerably because they are deep day sleepers, although values between males and females are similar. The variations seen are changes in blood volume and quantity of blood components.

Erythrocytes

Erythrocytes in the hamster have a diameter of 5–7 μm. South African hamsters have larger erythrocytes than other hamsters and laboratory rodents. A small portion of erythrocytes show polychromasia (Schermer, 1967). Erythrocytes have a life span of 50–78 days. Desai (1968) saw an increase in erythrocyte longevity during hibernation. Nucleated or basophilic cells are rare, but reticulocytes are found from 3% to 4.9%.

Leukocytes

Hamster leukograms are similar to those of other laboratory rodents. During photoperiods the total leukocyte counts range from 5000 to 10,000/μL, whereas during hibernation counts drop to 2500/μL. During sleep, the lymphocyte:neutrophil ratio is 45%:45%, whereas in awake animals the neutrophil percentage varies between 17% and 35%.

Coagulation

Hamster blood starts to coagulate at 15–20 s (Schermer, 1967) with a mean coagulation time of 142 s (Desai, 1968).

Trypanosomes

Hamsters frequently have trypanosomes in the blood. These microorganisms are parasitic but not pathogenic. They have been observed in other laboratory animals, including sheep and monkeys, but not in the large numbers as seen in the hamster. The counts of trypanosomes can be very large, sometimes equaling the leukocyte counts. Professor Enigk of the Bernhardt-Nocht Institute, Germany (personal communication) found that 50% of his hamster colony had trypanosomes. Transmission is not known; however, trypanosomes are not considered harmful and will not interfere with the outcome of a hamster study (Schermer, 1967).

BLOOD GASES AND pH

The values for blood gases are Pa_{O_2} 71.8 ± 4.9 mmHg, Pa_{CO_2} 41.1 ± 2.4 mmHg, HCO_3 29.9 ± 2.9 mEq/L, and the blood pH is 7.48 ± 0.03. Measurements of exercising hamsters show an increase of 12.9 ± 7.9 in Pa_{O_2}, a decrease of 6.6 ± 2.6 Pa_{CO_2}, and a decrease of 3.5 ± 2.3 in HCO_3 concentrations.

URINE VALUES

The range of urine volume is 5.1–8.5 mL/24 h in normal hamsters. In diabetic Chinese hamsters, the urine volume can be as high as 25 mL/day. Sodium

TABLE 2.35 Hematological Values for Syrian Hamsters

Test	Units	Male		Female	
		Mean	Range	Mean	Range

and potassium concentrations are 70 and 120 mmol/L, respectively. The pH is basic, proteins are excreted about 10 times the rate of humans, and cholesterol is the main lipid excreted.

SPECIES PECULIARITIES

The hamster cheek pouch is unique because it accepts heterologously neoplastic tissue but rejects normal human tissue. This led to the discovery that a biological difference existed between malignant and nonmalignant tissues. The cheek pouch has been used for the transplanting of neoplastic tissue for evaluation of growth. When this method was standardized, it became a screening tool for chemotherapeutic agents (Newcomer et al., 1987).

The cheek pouch is transparent and very accessible. It is ideally suited for in vivo studies of microcirculation and the behavior of formed blood elements. These features have also made the hamster the model of choice for buccal administration and evaluation of oral and mucosal irritation. The hamster cheek pouch is, indeed, the standard model for evaluating acute or cumulative

(28 day) irritation/tissue tolerance, as well as providing a popular model for the induction and study of squamous cell neoplasia (Heller et al., 1996).

STRAIN-RELATED CONSIDERATIONS

In a study by Althoff and Mohr (1973) comparing the chronic respiratory response of the Chinese, Syrian, and European hamsters to diethylnitrosamine (DEN) and dibutylnitrosamine (DBN), strain-related differences were found. In the Chinese hamster, DEN did not produce neoplasms in the respiratory tract. In the Syrian species, DEN caused tumors in the trachea and lungs followed by the nasal cavity. In European hamsters, DEN produced benign and malignant tumors in the respiratory tract and caused death after 15 weeks of daily treatment.

In the Chinese hamster, DBN caused papillary tumors and malignant neoplasms in the nasal and paranasal cavities. In the Syrian species, DBN caused tumors, primarily in the trachea, and then the nasal cavities and lungs. At the high dosages in European hamsters, DBN caused carcinogenic effects in the trachea, lungs,

TABLE 2.36 Hematological Values for European and Chinese Hamsters

Parameter	Units	European Range	Chinese Range

and nasal cavities, whereas low dosage groups had lung carcinomas.

As indicated by this study, hamsters are good models to study respiratory carcinogenesis; however, different species can have different responses to a chemical. The spontaneous rate of respiratory tumors, metabolism, and the nature of chemical need to be known before cross-species extrapolation can be done.

TYPICAL STUDY PROTOCOLS

Carcinogenicity Toxicity Testing

Hamsters are highly suitable animals for carcinogenicity testing because of a low incidence of spontaneous tumor development, but they are highly susceptible to experimentally induced carcinogenesis. The incidence of spontaneous tumors in Syrian hamsters is reported to be lower than the incidence seen in mice or rats (Homburger et al., 1979a; Althoff and Mohr, 1973). Although the hamster does have a short life span, substance-related effects and neoplasms develop rapidly, during which spontaneous diseases and tumors may not occur. However, hamsters are infrequently used in testing, and a 2004 inquiry of (the more than 90) known contract laboratories succeeded in only

identifying one with current experience in performing such studies.

The carcinogenicity protocols used for rats are satisfactory for hamster studies. Changes that need to be incorporated are that blood collections should be kept to a minimum and the length of the study usually is shortened (to 96 weeks) owing to the hamster's shorter life span.

Hamsters are specifically recommended for long-term testing with aromatic amines, polycyclic hydrocarbons, and other agents suspected of being pulmonary carcinogens (Aufderheide et al., 1989). Urinary bladder carcinomas induced by aromatic amines can take up to 7 years to induce in dogs, but they can cause neoplasms in less than 1 year in hamsters (Witschi et al., 1993).

Nitrosamines caused tumors in the hamster fore stomach, liver, pancreas, nasal cavity, lung, trachea, and occasionally the esophagus. The common site for nitrosamine tumor induction in the rat is the esophagus, demonstrating species specificity for a target organ site. Hamsters are not more susceptible to nitrosamines because some nitrosamines are more toxic in the rat than the hamster and vice versa (Newcomer et al., 1987). The hamster does show a nitrosamine-induced pancreatic tumor similar to pancreatic tumors in humans.

Inhalation and Intratracheal Studies

Inhalation studies constitute a significant portion of the toxicological research using the hamster as the test species. The hamster is deemed useful because it has a lower incidence of spontaneous respiratory tumors and of respiratory diseases (Werner et al., 1979), and its respiratory epithelium is more similar to that of humans than other laboratory rodents. The hamster has similar lung absorption characteristics to those of the rat and mouse for aldehydes, ozones, and other irritant gases (Morris, 1997; Steinberg and Gleeson, 1990). Because of its more mixed breathing pattern, it compares favorably to the rat (an obligatory nose-breather) for studying fiber and particulate inhalation (King-Herbert et al., 1997; Geiser et al., 1990; Gelzleichter et al., 1999; Warheit and Harsky, 1993; Warheit et al., 1997). In studies with cigarette smoke, certain in-bred species of the hamster are the only laboratory rodents where carcinogenesis can be induced by inhalation. A laryngeal cancer in the hamster is caused by tar fractions or cigarette smoke. This cancer has been found to be histologically identical to the cancer seen in humans (Homburger et al., 1979a). The species thus continues to be popular in studying the toxicity of cigarette smoke and its

mechanisms (Tafassian et al., 1993; DiCarlantonio and Talbot, 1999).

Acute and subacute inhalation toxicity studies using the hamster have studied nickel monoxide (NiO), cobaltous oxide (CoO), and chrysotile asbestos. Hamsters exposed to asbestos for 11 months developed asbestoses and those exposed to NiO developed pneumoconiosis, occupational disease states seen in humans.

In whole body exposure, inhalation study designs, the exposure chamber has to be large enough to allow an adequate number of animals to be exposed simultaneously. It should be equipped with the means to regulate temperature and humidity and have identical chambers for all treatment groups. The hamsters should be housed separately; however, if there are space limitations, animals may be housed in groups. The position of the cages should be rotated from exposure-to-exposure. The animals should be housed in an area other than the inhalation chamber when not being treated. This will reduce the contamination of the exposure chamber by bodily fluids.

Current practice makes nose only exposure with animals restrained in tables more popular, but hamsters do show extensive stress-related physiology responses to such restraint, including marked body weight loss (King-Herbert et al., 1997).

Animals are randomly distributed to test groups based on body weights as performed in other types of animal studies. The animals should have free access to water at all times. Feed should be available when animals are not being exposed unless exposure times are very lengthy. If feed is provided during exposure, then the feed is also being exposed to the test materials and may be an important aspect of the study. The number of exposures whether once or several times a day and the length of exposure time can be decided by the investigator; however, once decided, exposure time should remain consistent throughout the study. The concentration and particle size of the aerosol should be determined periodically and the aerosols should be evenly distributed in the chamber (Raabe et al., 1973). Data may be collected concerning clinical signs, body weights, pharmacokinetics, mortality, hematological and clinical chemistry functions, organ weights, and gross and microscopic observations.

For intratracheal instillation studies, the same procedures as described for inhalation studies are used except animals are exposed to the control and test articles via intratracheal administration. The common dose volume is 0.2 mL per animal, and the animal is usually anesthetized during dose administration. The number of treatments per day and the length of the study may be decided by the principal investigator.

Teratology Studies

The hamster has been a popular alternative species for teratology and reproductive toxicity studies because of its predictable estrus, short pregnancy period, rapid embryonic development, and a low incidence of spontaneous malformations (Wlodorezyk et al., 1995; Williams et al., 1991; Wolf et al., 1999; Gomez et al., 1999; DeSesso et al., 1998).

Retinoic acid (vitamin A) has been shown to be a teratogen in hamsters (Frierson et al., 1990; Willhite et al., 1996, 2000). Thalidomide was found to be a teratogen in certain in-bred strains of the Syrian hamster making it a viable alternative to rabbits. Other hamster teratogens are dinocap (Rogers et al., 1989), cyclophosphamide (Shah et al., 1996), hydrocortisone, colchicine, vincristine, vinblastine, heavy metals such as cadmium compounds, organic and inorganic mercury, 2,4,5-T (2,4,5-trichlorophenoxyacetic acid), and 2,4-D (2,4-dichlorophenoxyacetic acid) alone or contaminated with dioxin (Newcomer et al., 1987). The study design for teratology studies should take into account the embryonic development of the hamster, the strain-specific fertility seen in hamsters, and the age of the mother.

Toxicology Studies

The protocols used for rats in acute and long-term toxicity studies are satisfactory for the hamster; however, blood collection should be kept to a minimum and the length of the test may need to be adjusted (shortened) because of the shorter life span of the hamster.

The majority of toxicology work involving hamsters has been buccal inhalation and respiratory studies, although intratracheal has also been a popular route because of the possibility of precise control of doses (Biswas et al., 1993). The hamster has been found to be a useful model in the study of toxicity; however, it has some biochemical and physiological characteristics not seen in other rodent species. The hamster has a strong resistance to certain pharmacological agents such as barbiturates, morphine, and colchicine, but it is very sensitive to halothane and sevoflurane-induced changes in diaphragmatic contractility (Kagawa et al., 1998). The hamster oral LD_{50} of colchicine is 600 times the lethal dose known to humans, whereas morphine when given to hamsters at the LD_{50} does not produce a narcotic reaction. These characteristics should not be considered a barrier to the use of hamsters in toxicology studies.

Of 304 compounds evaluated by the IARC, 130 were carcinogenic in at least one rodent species. Of the 130,

only 38 compounds were tested in both hamsters and rats, 35 were tested in hamsters and mice, and 78 tested in both rats and mice. Of those tested in hamsters and rats, 84% of the compounds had similar results in both species, 86% in both mice and hamsters, and in mice and rats 90% had similar results. Based on this information, hamsters are not more or less sensitive to toxicity than other rodent species used in long-term testing (Arnold and Grice, 1979).

CHINESE HAMSTER OVARY CELL CHROMOSOME ABERRATIONS

The purpose of this assay is to evaluate the ability of a compound to induce chromosomal aberrations (clastogenic responses) in the Chinese hamster ovary (CHO) cells. The realization that fully 60% of drugs listed in the *Physicians' Desk Reference* have positive CHC chromosome aberration findings associated with them have raised concerns about this assay.

The CHO cells used in this assay may be obtained from the American Tissue Culture Collection, Rockville, Maryland (Brusick and Fields, 2014). The original cells were obtained from a Chinese hamster.

The assay is divided into two parts, nonactivation and activation, with S9 rat liver as the activating agent. EMS (0.5 μL/mL) is the positive agent for the nonactivation, whereas for the activating studies it is dimethylnitrosamine at 0.5 μL/mL. The solvent used to dissolve the test article is used as the solvent vehicle for the control and positive control articles. The dosages selected for the test article are one toxic (loss of growth potential) and four lower (usually in a half-log series) concentrations. These dosages are determined in a range-finder with the cells exposed to the test article for 4 h and incubated for 24 h.

The CHO cells are grown in 10% fetal calf serum/ Ham's F12 media. The cell density should be kept at $1.5 \times 10^6/75$ cm^2 plastic flask. For the assay, approximately 0.25×106 cells per well per test article concentration are tested. The cells are exposed to the test article for 2 h at 37°C. Cells used in the activation section receive the S9 rat liver along with the test article before the 2-h activation. The cells are then washed with sterile saline and given fresh media. For each of the test article dosages, half of the plates per treatment group will receive 5-bromo-2'-deoxyuridine at a concentration of 10 μM. The cells are then incubated for 24 h with colcemid (2×10^{-7} M) added at hour 17. After incubation, the metaphase cells are collected by mitotic shake-off. These cells are swollen with 0.0075 M KCl solution, washed with a methanol: acetic acid (3:1) fixative,

dropped onto glass slides, and air dried. The slides are stained with 10% Giemsa (pH 6.8) and scored for chromosomal aberrations such as chromatid and chromosome gaps, breaks, and chromatid deletions.

SYRIAN HAMSTER EMBRYO CELL TRANSFORMATION ASSAY

Another genotoxicity assay currently being promoted for use as an alternative for the CHO and a screening assay for clastogens is the Syrian hamster embryo (SHE) (LeBoeuf et al., 1996). The SHE cell transformation assay evaluates the potential of chemicals to induce morphological transformation in karyotypically normal primary cells. Induction of transformation has been shown to correlate well with the carcinogenicity of many compounds in the rodent bioassay. Historically the assay has not received widespread use because of technical difficulty (Leonard and Lauwarys, 1990). This was the subject of an entire issue of *Mutation Research* (1996) and is currently being further evaluated by regulatory agencies, using a low pH technique that is technically easier to use and reproduce (LeBoeuf et al., 1996; Kerckaert et al., 1996; Aadema et al., 1996; Isfort et al., 1996; Custer et al., 2000; Isfort et al., 1996).

MODELS OF DISEASES

Cardiomyopathy

Cardiomyopathy in hamsters originates from a genetically (recessive autosomal gene) determined metabolic defect that induces degenerative lesions in all striated muscles with particular intensity and consistency in the heart (Bajusz, 1969; Gertz, 1973). The clinical and pathological aspects of the disease resemble nonvascular myocardial disease in man. Animals appear normal, although there is cardiac muscle degeneration. The lesions appear histologically in both sexes at 350 days of age for males and 25−30 days of age for females. The first lesion is an acute myolysis with primary dissolution of the myofilaments. This lesion is healed and replaced by connective tissue by day 100 (Gertz, 1973). The disease becomes clinically apparent with a whole body sc edema; however, there are no ECG changes to foretell edema formation or to tell degree of lesion formation. The ECG changes are observed after lesion formation and consist of alterations in pathways of cardiac excitation and high-frequency alterations in the QRS interval. In the late stages of the disease, ascites, hydrothorax, and hydropericardium appear. In the

terminal stage, animals are hyperpneic and cyanotic. At necropsy, the liver, spleen, kidney, heart, and other visceral organs show congestive changes such as enlargement and increases in volumes. Cardiomyopathic hamsters show an edema response to therapy with digitalis, diuretics, and salt restrictions. The average life span of hamsters with this disease is 146 days. Because this model responds to therapy in a manner similar to humans and the disease state has similar manifestations, it is considered well suited to study heart failure in humans due to cardiac muscle impairment.

Dental Caries

Caries is a disease of poorly developed and poorly calcified teeth in the hamster. It is considered transmissible and infectious. It can be induced in normal hamsters by inoculation with cariogenic microflora. Animals are infected by adding microflora to drinking water or exposing the animals to infected feces. The carious lesions are in the molars. The lesions start with changes in enamel translucency, surface depressions, and fissures. The disintegration goes into the dentine with eventual exposure of the pulp. Bacterial (putrefactive) infections, inflammation, and complete necrosis of the molar occurs. With the testing of this model, fluoride was found to be beneficial to hamsters and this prompted clinical trials in humans (Keyes, 1960).

Diabetes Mellitus

Diabetes mellitus was first described in 1959 and 1969 in the Chinese hamster and South African hamsters, respectively (Stuhlman, 1979). Only certain strains of the Chinese species are affected, and the disease is probably transmitted by a recessive gene. The disease in the Chinese hamster has a rapid onset between 1 and 3 months of age. The indications of the disease are polyuria, polydipsia, glycosuria, and ketonuria. A normal Chinese hamster has glucose levels of 110 ± 6 mg/100 mL, whereas a diabetic hamster has levels of $200-800$ mg/mL. The diabetes mellitus seen in the Chinese hamster is very similar to the disease state in humans. There is a variation in the syndromes (chronic, insulin dependent), the occurrence of secondary manifestations (cataracts), discrepancies in established parameters of native insulin values, and what role heredity plays in the disease.

In the South African hamster, which has a 22% incidence of diabetes mellitus, the disease is inherited as a nonsex linked polygenic trait. With the South African hamster, the hyperglycemia varies in incidence, age of onset, degree of severity, and rate of progression, as in humans, but it is not influenced by age, sex, or state of obesity. Obesity is not a feature seen in the diabetic South African hamster, though it is seen in the Chinese hamster.

Either of these models will provide insight into diabetes mellitus. These models can be used to study the disease pathogenesis, development of secondary complications, exact genetic mechanisms, and possible therapeutic regimens.

Leprosy

The hamster was first injected with leprosy bacilli in 1937. It was the first time a laboratory animal was found to be susceptible to the agent. In recent years, leprosy bacilli has been grown in cell culture systems and in the tail and foot pads of the mouse, so the role of the hamster in leprosy research has declined (Frenkel, 1987).

Muscular Dystrophy

The muscular dystrophy (MD) syndrome can be induced in hamsters by feeding them a diet deficient in vitamin E from weaning until death. The gross appearance of the disease state does not occur before the 11th or 12th month. Strains of cardiomyopathic Syrian hamsters (BIO 14.6 and BIO 53.38) do have genetic dispositions for this disease. The clinical signs appear $60-200$ days after birth, and all skeletal muscles, including the heart, are affected. The lesions are pleomorphic, characterized by focal degeneration of myofibrils, coagulation necrosis, the formation of contraction clots, and alignment of muscle nuclei in chainlike rows within the fiber (Homburger and Bajusz, 1970). In the final stage of the syndrome, the myofibrils convert to granular mass in which the nuclei have disintegrated. Earliest changes occur at 33 days of age with death usually by 220 days due to cardiac failure. These hamsters have morphological manifestations of MD.

This model is excellent to study the mechanism of MD from an in vivo system to intact animals.

Osteoarthritis and Degenerative Joint Disease

Osteoarthritis and degenerative joint disease are diseases that a hamster may develop in old age. These diseases are rare in hamsters under 2 years of age. The diseases are characterized by separation of the zone of calcification of the cartilage with sclerosis and dislocation of the bone, fibrillation of ligaments, and fibrosis of the synovial membrane. Organisms such as *Mycoplasma*, *Streptobacillus moniliformis*, *Corynebacterium kutscheri*, hormonal imbalances, and chemical and physical agents are associated with the disease. The

disease in hamsters is similar to that seen in humans (Handler, 1965), which makes this an excellent model to study.

Pancreatic Cancer

Pancreatic cancer is a very difficult neoplasm to induce in laboratory animals. It can be induced in Syrian hamsters with nitrosamines. The neoplasms, histogenesis, and enzymatic patterns seen in human pathogenesis are similar to those in the hamster. Occasionally, hamsters develop diabetes during the pancreatic carcinogenesis, as is also seen in the pathogenesis in humans.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Toxicology is a continuously evolving field, borrowing its every expanding set of technologies primarily from other fields of biomedical and biological research. Although the actual integration of new technologies at the laboratory level into the field is fairly prompt, it is generally not accompanied by any of the already employed technologies (for our purpose, end points or biomarkers measured in standard studies) being deleted. Also not prompt is the inclusion of new technologies or biomarkers being reflected in changes in regulatory guidelines.

So while the last 5 years have seen proteomic more relevant clinical chemistry end points, species-specific immune functions measures, and measurement of in vivo changes of physiologic function (heart rate, blood pressure, EKG parameters, respiratory rate) and internal chemical end points (blood gases, glucose and glucagon) by implanted telemetry sensors (Gad, 2013), these have not been significantly utilized (or offered by) CRO's or integrated into guidelines, regulations, or integrated safety assessments.

Progress will entail the available new technologies being incorporated into our standard approaches to safety assessment, and hopefully a thoughtful consideration of which of the large set of measurements now taken have relevance and should be carried forward into a new synthesis of study designs.

Göttingen Minipigs as Large Animal Model in Toxicology

Henrik Duelund Pedersen, Lars Friis Mikkelsen

Ellegaard Göttingen Minipigs A/S, Dalmose, Denmark

PIGS AND MINIPIGS IN TRANSLATIONAL RESEARCH

Over the last 2 decades, a significant increase in the use of pigs and especially minipigs in translational research, including nonclinical toxicology and safety assessment, has led to an enhanced understanding of human diseases and improvement in human health. The advantages of using the pig (*Sus scrofa*) for translational research include a defined genome sequence and similarities to humans in terms of anatomy, physiology and biochemistry. The minipig also offers the additional advantages of reduced size and decreased time to sexual maturity (Monticello and Haschek, 2016).

The RETHINK project (Forster et al., 2010) highlighted the use of the minipig as an alternative to the traditionally used nonrodent species, that is, the dog and the nonhuman primate. This conclusion was later confirmed by the Preclinical Safety Leadership Group (DruSafe) of the International Consortium for Innovation and Quality in Pharmaceutical Development, and the group concluded that the minipig is a viable nonrodent model for the development of small molecules and dermal products (Colleton et al., 2016). The latest developments in the use of pigs and especially minipigs in translational research, with an emphasis on toxicological pathology and nonclinical safety assessment, were addressed in a recent special issue of *Toxicologic Pathology* (Monticello and Haschek, 2016). Considering the comparative biology and practical features of toxicology testing in minipigs, it has been stated that the minipig represents a favorable profile as a nonrodent toxicology model in terms of similarity to man and applicability to different study types (Bode et al., 2010).

From information in the public domain and especially from within the European Medicines Agency and the US Food and Drug Administration, minipigs have already been fully accepted for use as a nonrodent species in toxicology testing of pharmaceutical products (Van der Laan et al., 2010). They are also recognized by the International Conference on Harmonization and the International Organization for Standardization Guidelines as a suitable animal model due to their similarities to man. Thus minipigs may be considered an acceptable choice as a nonrodent species, provided adequate scientific justification for this choice is made.

From an economic perspective, the costs of testing in minipigs are not significantly greater than the costs for a study in dogs (Van der Laan et al., 2010). The cost of testing in nonhuman primates is greater than the cost in minipigs. Furthermore, there is political and societal pressure on decreasing the use of nonhuman primates, which also is reflected in the European legislation (EU Directive 2010/63/EU).

LEGISLATION AND SPECIES SELECTION

Ensuring human safety in clinical trials and when medicines are on the market requires toxicology testing in a rodent and a nonrodent mammal. Selecting the correct nonrodent or large animal species is very important to maximize human safety, clinical benefit, and animal welfare (Smith and Hubrecht, 2001). Several factors should be considered in the large animal species selection process, including available scientific information, experience with and availability of a full range of species, and the need to balance scientific, ethical, and legal constraints. In terms of the latter, the European legislation (Directive 2010/63/EU) only allows the use of nonhuman primates if it is undertaken with a view to the avoidance, prevention, diagnosis, or treatment

of debilitating or potentially life-threatening clinical conditions in human beings and if—for scientific reasons—a species other than nonhuman primates cannot be used. Furthermore, Directive 2010/63/EU clearly states that the species to be used should be that with the lowest capacity to experience pain, suffering, distress, or lasting harm. The use of nonhuman primates in scientific procedures is still necessary in biomedical research, but due to their genetic proximity to human beings and their highly developed social skills, their use raises specific ethical and practical problems in terms of meeting their behavioral, environmental, and social needs in a laboratory environment. In contrast, the housing of Göttingen Minipigs is simple, and it is much easier to keep minipigs to a good standard of welfare under laboratory conditions (Ellegaard et al., 2010). Ethical arguments also need to be considered where the use of nonhuman primates is of the greatest concern to the public. In addition, funding bodies recognize concerns about the use of nonhuman primates in research and the difficulties associated with meeting the environmental, behavioral, and social needs of these highly intelligent animals in a laboratory (National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs), London, UK).

The toxicology testing of pharmaceuticals in animals is subject to regulation by national and international bodies. Many published guidelines make recommendations regarding the scope of testing and methods to be used for each specific type of product. Some of these guidelines also recommend which animal species should be used. Overall, a variety of experimental approaches and technologies are available to assist in the selection of the relevant species for the conduct of toxicological studies. These methods for analysis, however, should be selected prudently based on the test article and its pharmacology to facilitate the minimization of risks and create better awareness of risks during clinical development of the drug candidate (Subramanyam et al., 2008). Species selection must always be made on a case-by-case basis by balancing the benefits and scientific evidence relating to the predictivity of the animal model against the harm that may accrue to the animals both from the test procedures and their lifetime experience within the laboratory environment (Webster et al., 2010). Therefore minipigs should be considered up-front as nonrodent species for legislative, scientific, economic, and ethical reasons.

GÖTTINGEN MINIPIGS AS AN ANIMAL MODEL

The most commonly used minipig species for translational research is the Göttingen Minipig (Fig. 3.1).

FIGURE 3.1　Göttingen minipig is the most commonly used minipig species for translational research.

Göttingen Minipigs have been available in the major R&D regions for more than 3 decades, and huge amounts of data and many publications are available with relevant and important background data. For example, data comparing minipig, dog, monkey, and human drug metabolism and disposition (Dalgaard, 2015), data on spontaneous background pathology (Jeppesen and Skydsgaard, 2015; Helke et al., 2016), and data on vehicle systems and excipients used in Göttingen Minipigs (Weaver et al., 2016), all highlighting and validating the use of Göttingen Minipigs in toxicological research. Furthermore, when using Göttingen Minipigs, the genetic management and standardization (Simianer and Köhn, 2010) plus the high health status (www.minipigs.dk) are advantages compared with other minipig strains along with the low body weight (Fig. 3.2).

Apart from the scientific justification, it is very easy to fulfill the natural behavioral needs of the minipig, which include social housing in harmonious groups in a challenging and spacious environment, giving them the opportunity to choose specific sites for defecation and urination while keeping their sleeping areas dry. Straw should be provided as comfortable bedding and to keep the animals occupied with rooting and chewing activities (Bollen et al., 2010). In some experimental settings, the provision of straw or hay can be a challenge and could be replaced by other types and combinations of environmental enrichment, such as balls or chains hung from the ceiling or roof of the cage (Swindle, 2007) to still fulfill their strong instinct for rooting, chewing, and exploring. It is important to provide an environment with sufficient complexity allowing expression of these key behaviors—to avoid boredom, frustration, and stereotypies (Ball, 2012). In order to facilitate stress-free handling, dosing, and sampling, the focus on acclimatizing and training minipigs should be highlighted. In order to minimize the stress related to
FIGURE 3.2 Growth curve illustrating how male Göttingen Minipigs increase linearly in body weight with approximately 2 kg/month for the first year, and 1 kg/month for the following year to reach their full size at approximately 2 years of age. Also, notice the early age at which Göttingen Minipigs become sexually mature.

handling and consequent impact on experimental variability, positive-reinforced socialization to human contact and training of the minipigs for procedures that they will experience are essential (Ellegaard et al., 2010), which easily can be applied through relevant training of staff in species-specific handling, dosing, and sampling (www.minipigs.dk).

DOSING ROUTES AND FORMULATIONS

All dosing routes commonly used in the development of new drugs are regularly used in Göttingen Minipigs. Guidelines have been published describing dosing routes in general and the administration volumes considered good practice in commonly used species (Diehl et al., 2001). The tolerability of the minipig to the many different excipients used in drug development studies has been reviewed, and a substantive conclusion was that minipigs tolerate several of these, such as cremophor and polysorbate 80, much better than the dog (Weaver et al., 2016). Also, the tolerability to many compounds is higher and more human-like in the minipig than in the dog. For instance, dogs show excessive vomiting in response to many compounds, including anticancer compounds (Mahl et al., 2016), and have a low tolerance to nonsteroidal anti-inflammatory drugs (NSAIDs), expressed as gastrointestinal lesions (Swindle et al., 2012).

Dermal and subcutaneous dosing is especially attractive in the Göttingen Minipig because of the similarities of the skin and subcutaneous tissue with the corresponding tissues in humans. The Göttingen Minipig has been shown to be a good model for in vitro permeation through human skin, considering that the age of the Minipig can influence the flux of certain compounds (Qvist et al., 2000; Yamamoto et al., 2017). The pale skin and the sparse and nonpigmented body hair make dermal effects easy to evaluate, and the Göttingen Minipig is, therefore, the species of choice for dermatotoxicology studies in most laboratories, and in the article by Willard-Mack et al. (2016), study designs and practical considerations of such studies are discussed.

Subcutaneous dosing is commonly used, and the minipig offers major advantages regarding this route due to similarities with human subcutaneous tissue. In humans, a subcutaneous injection is often made by injecting into a skinfold, leading to injection into subcutaneous fat. In minipigs, it is also possible to inject into subcutaneous fat by injecting behind the base of the ears. To be certain that the correct type of tissue is present at the expected depth, the injection site can be examined by ultrasound prior to injection and a suitable site marked by pen or tattoo. In other (furry) experimental animal species, a subcutaneous injection is made by lifting the skin and injecting into the loose connective tissue under the skin. Should it be desired, it is also possible in minipigs to inject into such loose connective tissue, for instance in the medial thigh region. The difference in subcutaneous tissue type can be important when assessing local toxicity, as such differences can lead to differences in compound distribution and tissue reaction toward the formulation. Also, regarding the pharmacokinetics, such tissue differences can play a key role, as suggested by findings using compounds as different as fast-acting insulins and monoclonal antibodies (Plum et al., 2000; Zheng et al., 2012).

The oral route is the most commonly used, and there are several ways of dosing orally in Göttingen Minipigs.

To ensure proper dosing and assist when dosing by gavage, a dosing chair, such as the one described in Ellegaard Göttingen Minipigs Newsletter Number 47 (www.minipigs.dk), can be very helpful. The advantages of using the minipig for oral dosing studies are the fact that the gastric pH in the fasted minipig is much less variable and more comparable to that in humans than it is in the dog (Preuße and Skaanild, 2012). Minipigs are also much less inclined to vomit as a response to various compounds and formulations than the dog. The gastric emptying of the minipig, on the other hand, is longer than that observed in humans (Suenderhauf et al., 2014; Christiansen et al., 2015). By removing the straw bedding and potentially replacing it with another enrichment type, such as cotton towels, the stomach content remaining after an overnight fast can be markedly reduced (Suenderhauf et al., 2014).

Several types of catheters can be used for intravenous access in Göttingen Minipigs; depending on the specific study needs. An educational package describing some of the many options is available on the Ellegaard Göttingen Minipig homepage (www.minipigs.dk). Recommended maximum blood sample volumes have been published (Diehl et al., 2001), and the same publication also describes different sampling sites that can be used if a catheter is not in place.

Other routes of administration might be used in more rare cases, including inhalation (Koch et al., 2001; Windt et al., 2010), intraperitoneal (Overgaard et al., 2017), and intraocular (Proksch et al., 2008).

AGE AND SEX

Göttingen Minipigs become sexually mature at an early age. Based on testicular and epididymal histology, puberty in male animals was recently found to occur at 8 weeks of age (Taberner et al., 2016). In female Göttingen Minipigs, hormonal analyses showed that puberty occurs at approximately 4–6 months (Peter et al., 2016). Based on this, it is common for pharmaceutical companies to use minipigs for toxicological studies at an age of approximately 4 months, when the animals weigh approximately 8–11 kg. As can be seen on the growth curve in Fig. 3.2, Göttingen Minipigs continue to grow until they reach a body weight of 30–40 kg at 2 years of age, if they are fed restrictively according to the recommendations provided by the breeder (www.minipigs.dk).

As a reflection of the growth curve, the levels of various bone biomarkers decrease markedly during the first 12 months of age, moderately during the next 12 months, and very little after 24 months of age (Tsutsumi, 2012).

If allowed to eat ad libitum, even feeding a regular pig diet leads to severe obesity after approximately 1–1½ years, with female minipigs weighing approximately 90 kg and having 45% body fat (Raun et al., 2007). Intact males are protected, to some degree, from diet-induced obesity and perturbed glucose metabolism and have very high circulating levels of testosterone and estradiol (Christoffersen et al., 2010, 2013).

HEMATOLOGY

Table 3.1 shows hematology reference values for Göttingen Minipigs. Reference data are also available for piglets and animals that are 3 and 6 months of age at www.minipigs.dk. It is important to acknowledge that age has a significant effect on many of the values. For instance, juvenile Göttingen Minipigs have been found to have markedly higher white blood cell counts than adult animals (Jorgensen et al., 1998). Regarding the platelet count, several studies have found that blood stabilized with standard concentrations of ethylenediamine tetraacetic acid (EDTA) can spontaneously aggregate over time, resulting in falsely low platelet counts (Olsen et al., 2001; Erkens et al., 2017). The life-span of minipig platelets (8–10 days) and red blood cells (80–100 days), as well as neutrophils, is similar to that found in humans (Moroni et al., 2011).

It has been shown that Göttingen Minipigs are a useful species for use in coagulation analyses (Petroianu et al., 1998). Again, there are important age differences. Fetal minipigs, for instance, have a lower activity of most coagulation factors (Petroianu et al., 1998). Most markedly, fetal minipigs have 10-fold lower fibrinogen concentrations compared with adult minipigs—a finding that is in accordance with findings in premature human infants (Petroianu et al., 1998). It should also be noted that not all immunoassays usually used in humans will work in pigs (Münster et al., 2002). Finally, it is important to consider that dyslipidemic animals are in a procoagulant state, likely caused in part by increased platelet activity (Kreutz et al., 2011).

BLOOD BIOCHEMISTRY

A blood panel is included in most studies, and reference values of commonly used biochemistry parameters for Göttingen Minipigs are shown in Table 3.2. Values for piglets and older animals 3–6 months of age may be found at www.minipigs.dk. Age and sex have an influence on many serum chemistry parameters (Jorgensen et al., 1998), and there can be minor differences in values from laboratory to laboratory. However, these issues rarely pose a problem because a control group is

most often included in the study design. In young Göttingen Minipigs, values of several parameters (urea, bilirubin, globulin, alkaline phosphatase, and triglycerides) have been shown to decrease from 2 to 9 weeks of age, and albumin was found to increase over the same age range (Feyen et al., 2016).

A wide range of less common blood biochemistry markers has been used with success, and a literature

search will usually help to show the types that can be used in each setting, as well as a reference to specific methods. A few guiding comments might, however, be useful for some of the parameters. For example, one should be aware that glycosylated hemoglobin (HbA1c) cannot be used in any pigs as measure of long-term plasma glucose levels because porcine erythrocytes are practically impermeable to glucose (Higgins et al., 1982). The plasma levels of fructosamine can be used instead (Christoffersen et al., 2007). Insulin is often measured in studies focused on diabetes, and C-peptide is often used as an indicator of insulin secretion due to its longer plasma half-life in humans. In pigs, however, C-peptide has practically the same half-life as insulin (Oyama et al., 1975), and therefore this parameter offers little advantage, as the curves for insulin and C-peptide will be almost identical (Christoffersen et al., 2013). Also, it should be noted that the plasma level of lactate is higher in Göttingen Minipigs than in domestic pigs, so it is, therefore, important that reference values for blood lactate concentrations in pigs reflect the breed of interest (Alstrup, 2016).

The concentrations of plasma lipids will vary according to the diet fed to the minipigs. With an atherogenic diet, a marked dyslipidemia can be obtained, leading to severe human-like atherosclerotic changes within 5–10 months (Ludvigsen et al., 2015).

ORGAN WEIGHT, BACKGROUND FINDINGS, AND COMPARATIVE ASPECTS

The pig is a monogastric omnivore, and many organs show great resemblance in anatomy and physiology to the corresponding organs in humans. For instance, the heart has a similar coronary artery distribution with negligible coronary collateral circulation, which is in contrast to the dog. The kidneys are very similar to human kidneys in function and ability to concentrate the urine (Schmidt-Nielsen and O'Dell, 1961). The skin and subcutaneous tissues are very similar to the corresponding tissues in humans, and the liver shows great resemblance to the human liver in terms of metabolism, especially regarding the cytochrome P450 enzymes (Dalgaard, 2015). Many more examples could be mentioned, and the comparative biology of the minipig and usage in regulatory toxicology studies has been reviewed in detail elsewhere (Bode et al., 2010; Swindle et al., 2012; Schomberg et al., 2016).

Reference values for organ weights for Göttingen Minipigs aged 8 weeks and 6 months are shown in Table 3.3. In the table, the organ weights are given both as absolute

The 23 8-week-old male minipigs were 61 ± 4 days of age (range 55–65 days), while the 20 female minipigs were 57 ± 3 days of age (range 52–61 days). The 20 6-month-old male minipigs were 198 ± 11 days old (range 183–235 days), while the 20 females were 191 ± 10 days old (range 170–209 days).

weights and as a percentage of the body weight, as often done in toxicology studies. A normalization to body surface area (BSA) would, however, in most cases be more correct biologically. For example, using the formula $BSA(m^2) = 0.121BW(kg)^{0.575}$ (Swindle et al., 2012). The background pathological findings in minipigs have been published and excellent references are available describing both common and infrequent findings (Jeppesen and Skydsgaard, 2015; Helke et al., 2016; McInnes and McKeag, 2016).

SAFETY PHARMACOLOGY

The marked similarity between Göttingen Minipigs and humans regarding the cardiovascular system extends into aspects important for safety pharmacology

TABLE 3.4   Electrocardiographic data in Göttingen Minipigs

studies. Thus detailed studies of the ion channels in the heart and the repolarization process support the use of the Göttingen Minipig as nonrodent species in cardiovascular safety pharmacology studies (Bode et al., 2010; Laursen et al., 2011; Arlock et al., 2017). The background prevalence of arrhythmias and other ECG abnormalities is low, as can be seen from Table 3.4. As stated in the table, the most common arrhythmia is premature atrial contractions, but these arrhythmias often disappear in unstressed animals. To obtain reliable data, safety pharmacology studies should be performed using telemetry. It is possible to measure cardiovascular parameters without the use of telemetry in seemingly relaxed animals restrained in a sling and, in this way, obtain values that might be used for some research purposes (Cimini and Zambraski, 1985). However, the blood pressure and heart rate obtained in such a setting will usually be higher than for truly relaxed and unrestrained animals, and the variation in the data will also often be larger. Examples of telemetry implant

placement and typical data obtained can be found in Ellegaard Göttingen Minipigs Newsletter Number 50 (www.minipigs.dk). It is also possible to simultaneously measure left ventricular pressure (Markert et al., 2009) or to use very small implants and amplify the signal by means of a jacketed system.

There are a few important considerations when designing safety pharmacology studies in minipigs. First, Göttingen Minipigs are often active for a few hours after feeding (depending on the manner in which they are fed), a fact that is reflected in the heart rate and blood pressure (Stubhan et al., 2008). This should be taken into consideration when planning the time of dosing and feeding. Second, body temperature has been found to have a marked influence on the QT interval in Göttingen Minipigs (Laursen et al., 2011), a fact that is especially important to consider in explorative studies in anesthetized animals and in studies of compounds which have an influence on body temperature. Finally, it is recommended that the heart rate dependency of the QT interval should be corrected individually (Stubhan et al., 2008).

IMMUNE SYSTEM

The importance of the pig as a livestock species, together with its long-standing role as a model for human infectious diseases and vaccine development (Meurens et al., 2012; Murtaugh, 2014), explains that the immune system in the pig is extremely well characterized and that there is a large toolbox available to study it. In the last decade, knowledge of the porcine immune system and the tools to study it have increased tremendously. Much is known about the porcine immune system, which in many aspects is quite like that in humans (Bode et al., 2010; Dawson et al., 2013, 2017a; Rubic-Schneider et al., 2016; Saalmüller and Gerner, 2016). Since no major differences between the immune system in pigs and minipigs have been reported so far, minipigs are thus well-suited for studies involving the immune system.

Structurally, a few aspects should be acknowledged. For example, pig lymph nodes have a unique "inverted" structure, with reversed cortical and medullary areas and lymph flow, resulting in lymphocytes leaving the lymph nodes via the high-endothelial venules rather than the medulla. The porcine mucosa-associated lymphoid tissue shows a high degree of similarity with other mammalian species including man. However, in pigs, Peyer patches can be seen in the jejunum with 1 long Peyer patch in the terminal ileum. The structure of the porcine thymus and the composition of T-cell progenitors are very similar to that of other mammalian species, albeit much of the thymus is located in the neck (Kuper et al., 2016). The thymus increases in size after birth, reaching the largest relative weight within the first

month postnatally and the largest absolute weight 3–6 months postnatally (Kuper et al., 2016).

Regarding the innate immune system, detailed gene family analyses have revealed a large overall pig–human homology of pattern recognition receptors, and transcriptome analyses using next-generation sequencing revealed human-like responses to interferon (IFN)-γ and lipopolysaccharide (LPS) (Dawson et al., 2017a). In this context, it should be mentioned that LPS has surprisingly low potency in cynomolgus macaques (Picha et al., 2004). The major acute phase proteins in pigs and minipigs include C-reactive protein (CRP), major acute-phase protein, and haptoglobin (Heegaard et al., 2011; Christoffersen et al., 2015). Regarding the complement system, an aspect of significant importance regarding immunological safety is complement activation-related pseudoallergy caused by formulations containing Cremophor EL or liposomes. The Göttingen Minipig was recently shown to be a sensitive and reproducible animal model for regulatory testing for this (Jackman et al., 2016). It should also be mentioned that pigs differ from humans in the presence of a larger number of pulmonary intravascular macrophages in addition to the alveolar and interstitial macrophages (Bode et al., 2010). The body temperature in the Göttingen Minipig is usually in the range of 37.5–39.5°C but occasionally slightly higher or lower. However, above 40°C in an unstressed animal is usually a sign of disease (Moroni et al., 2014).

The adaptive immune responses in pigs and minipigs are also human-like, and in line with that pigs have been used in studies aimed at improving human vaccines against, for instance, tuberculosis and cancer (Bruffaerts et al., 2015; Overgaard et al., 2015). A major difference from humans includes that there are no maternally derived antibodies in newborn piglets; until they acquire them via the colostrum (Bode et al., 2010). It is also characteristic of pigs that they have high proportions of $\gamma\delta$ T-cells and CD4$^+$CD8$^+$ T cells (Rubic-Schneider et al., 2016).

There is a large immunology toolbox available for studies of the porcine immune system. Tools are available for studying the humoral and the cellular immune response, allowing the identification of different porcine B- and T-cell subsets and their production of relevant cytokines, such as INF-γ, tumor necrosis factor α, and interleukin 17 (Talker et al., 2013; Summerfield et al., 2015; Bøje et al., 2016; Braun et al., 2017; Käser et al., 2017). In fact, flow cytometry tools have improved immensely in recent years, resulting in an increased understanding of porcine immune cells and their function. Furthermore, the genome is known in the Göttingen Minipig (Vamathevan et al., 2013), and a very large manually curated gene database is available for a vast number of porcine immune targets (Dawson

et al., 2017b), allowing for instance multiplex qPCR. Also, recent developments have been made within next-generation swine leukocyte antigen (SLA) typing (Sørensen et al., 2017), and methods for recombinant antibody expression and tetramers for antigen-specific T-cell responses in swine have been developed (Baratelli et al., 2017). Thus it is now possible to determine which immune cells are involved in response to a specific pathogen, which immune modulators these cells produce, and into which memory cells they develop.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Göttingen Minipigs are well-defined genetically and microbiologically, available worldwide, and are very similar to humans in their anatomy and physiology. For these reasons, they are widely used as nonrodent species in many types of pharmacological and toxicological studies. Significant improvements in areas such as gene-editing techniques, clinical diagnostic modalities, and analytical methods will likely render Göttingen Minipigs even more useful for such studies in the future.

Gene-editing techniques have improved significantly in recent years with vast perspectives in terms of generating novel genetically engineered porcine models (Klymiuk et al., 2016; Redel and Prather, 2016). These improvements imply that new genetically altered models can be produced much easier and faster and with less off-target effects. One area of interest is the generation of platform models, as exemplified by the generation of minipigs with severe combined immunodeficiency and minipigs that spontaneously develop cancer (Schook et al., 2015; Redel and Prather, 2016). Another area could be generation of models tailored for the development of specific novel new medicines, such as by humanization regarding a specific target. A third area is the generation of improved disease models with translation potential to humans, allowing research into the disease mechanisms and the best treatment. Finally, the area of transplantation is evolving rapidly, with improvements in both humanization, treatments to prevent rejection, and methods (using the CRISPR-Cas9 gene-editing technique) that can reduce the risk of transmission of porcine endogenous retroviruses (Niu et al., 2017).

Improvements are continuously being made in clinical diagnostic modalities, and as minipigs have a suitable size, these techniques can often be used with no or minor modifications. For instance, an optimized technique for optical coherence tomography scanning of ocular segments was recently described in Göttingen Minipigs, and in the same article, a panel of tissue-based biomarkers of the eye were established (Atzpodien et al., 2016). Another example involving imaging is the use of

echocardiography, which is easy to perform in minipigs, to monitor cardiac dimensions and function (van den Dorpel et al., 2017). More advanced imaging of atherosclerosis using intravascular ultrasound and positron emission tomography can also be performed, as described in Ellegaard Göttingen Minipigs Newsletter Number 46 (www.minipigs.dk). Another example involves the use of laser Doppler flowmetry to measure local blood flow (Poort et al., 2015). Finally, telemetry techniques are continuously improving and are now being used in many more areas than cardiovascular safety pharmacology studies. Such a technique was recently used to monitor the bladder function in female Göttingen Minipigs (Huppertz et al., 2015).

Analytical methods are also continuously improving. As mentioned in the section on the immune system, the genome is known in the Göttingen Minipig (Vamathevan et al., 2013), and a very large manually curated gene database is available for a vast number of porcine immune targets (Dawson et al., 2017b), allowing multiplex qPCR and expression analyses. The number of antibodies with documented good binding in the pig is also rapidly increasing, enabling advances in methods such as immune histochemistry, flow cytometry, and enzyme-linked immunosorbent assay (ELISA). Finally, in vitro and in silico methods are improving that will aid the selection of the most optimal nonrodent species for regulatory nonclinical toxicology studies. An example of this is the project aiming at establishing a panel of recombinant cytochrome P450 enzymes from Göttingen Minipigs, as described in Ellegaard Göttingen Minipigs Newsletter Numbers 47 and 50 (www.minipig.dk).

In summary, high-quality in vivo pharmacology and toxicology studies yielding reliable results can be performed in Göttingen Minipigs, and as discussed previously, the areas and issues that might be addressed using this species are expanding. A simple PubMed search for articles using the search term "Göttingen Minipigs" or synonyms thereof suggests that this occurs at an exponential rate.

Nonhuman Primates in Preclinical Research

Adam D. Aulbach, Daniel J. Patrick

Charles River Laboratories, Mattawan, MI, United States

INTRODUCTION

Nonhuman primates (NHPs) continue to be instrumental tools in biomedical research because of their anatomic, physiologic, and immunologic similarities to humans. In recent years, there has been an increased emphasis on translational discoveries enabling researchers to provide insights directly relevant to human patient populations. It is through translational discoveries such as next-generation renal biomarkers and advanced immunology assessments that NHP animal models provide their greatest contributions. The 2 most common NHPs used in biomedical research studies are the cynomolgus (*Macaca fascicularis*) and rhesus macaques (*Macaca mulatta*). Both species play a vital role in a wide range of studies ranging from preclinical pharmaceutical development to animal model research on metabolism, obesity, behavior, and aging. More recently the squirrel monkey (*Saimiri* spp.) and the African green monkey (*Cercopithecus aethiops*) have gained popularity in research because of their low cost and accessibility (Ward et al., 2008). Because cynomolgus macaques are by far the most common NHP used in preclinical safety assessment, the remainder of this chapter will primarily focus on this species unless otherwise specified.

The preclinical safety testing of biotherapeutics poses a particular challenge in selecting a relevant animal species for use in toxicology studies. Accurate prediction of the target effects of antibody-based therapeutics requires testing in a species which shows cross-reactivity, as these compounds are highly specific to their targets. Because of the restricted reactivity of many human-specific antibody compounds, NHPs are often the only available species for efficacy and safety studies (Jonker, 1990; Chapman et al., 2007). Furthermore, there is an increasing demand for the characterization of the immunotoxicologic effects of these compounds. Routine assessment of the immune system often includes the T-cell–dependent antibody response (TDAR) in which antibody responses to standardized antigens such as keyhole limpet hemocyanin and tetanus toxoid, are measured in NHPs treated with a new drug candidate. TDAR testing is commonly performed in NHPs and required by both the Food and Drug Administration and the Committee for Medicinal Products for Human Use for new drugs (Piccotti et al., 2005; Caldwell et al., 2007; Lebrec et al., 2011). Although similar assays are also commonly performed in rodents, the lack of cross-reactivity in rodent species and dissimilarity of the rodent immune system with that of humans often dictate the need for more applicable models such as NHPs (ICH S6 addendum, 2011).

CLINICAL PATHOLOGY IN NHPS

Recommendations of standard core testing for hematology, coagulation, clinical chemistry, and urinalysis in NHPs used in biomedical research studies have been published (Weingand et al., 1996; Tomlinson et al., 2013) and generally represent the consensus opinions of the major regulatory bodies and the international scientific community. Core testing panels are listed in Table 4.1 and do not generally differ from those required in other laboratory species. Several key guidance documents (FDA, 2003; OCED, 2009) have aided in harmonization of these practices which are aimed at providing key information on organ function/injury, pathophysiologic mechanisms, and overall health of the animals. Additional parameters or adjustments to the core panels may be necessary based on the type and duration of the study (e.g., acute, subacute, and chronic), type of compound being tested, and/or anticipated pathologic effects.

Depending on the volume desired, restraint method, and size of the animal, blood can be obtained from several venipuncture sites in NHPs. For large volume

TABLE 4.1   Standard Clinical Pathology Parameters in Nonhuman Primate Toxicology Studies

Hematology	Coagulation	Clinical Chemistry	Urinalysis
Erythrocytes (RBC)	aPTT	Sodium	Volume
Hemoglobin (Hgb)	Prothrombin time	Potassium	Specific gravity
Hematocrit (Hct)	Fibrinogen	Chloride	pH
MCV		Inorganic phosphorus	
MCHC		Calcium	
MCH		Alkaline phosphatase (ALP)	
Reticulocytes		Alanine aminotransferase (ALT)	
Platelets		Aspartate aminotransferase (AST)	
Leukocytes		Total bilirubin	
Neutrophils		Gamma-glutamyl transferase (GGT)	
Lymphocytes		Urea nitrogen	
Monocytes		Creatinine	
Eosinophils		Glucose	
Basophils		Total protein	
		Albumin	
		Globulin	
		Total cholesterol	
		Triglyceride	

aPTT, activated partial thromboplastin time; MCHC, mean cell hemoglobin concentration; MCV, mean cell volume.

collections, the femoral vein is most commonly used. For small samples, a sterile lancet may be used to puncture the marginal ear vein, a finger, or a heel. Although some animals may be trained to allow blood collections without the use of restraint, pharmacologic and manual restraint methods (e.g., squeeze cage and restraining chair) are commonly used for this purpose. Guidelines for maximum blood collection volumes vary somewhat by institution but are commonly in the range of 10 mL/kg in a 14-day period or up to 15% of the animal's total blood volume in a single collection. In addition, volumes of up to 20% may be collected over a 24-h period for the purposes of toxicokinetic evaluations (Diehl et al., 2001). Average total circulating blood volumes in NHPS range from approximately 60 to 70 mL/kg with minor species differences (Bernacky et al., 2002).

Primates are prone to eliciting a significant excitement/stress response during the handling and restraint associated with blood collection. Common stress effects on white blood cells include increases in total leukocyte, neutrophil, and/or lymphocyte counts although stress-induced decreases in lymphocyte and eosinophil counts are also common. Effects of stress on serum biochemical parameters may include increases in glucose and/or cortisol concentrations. Anesthetic agents are sometimes used for chemical restraint during prestudy or on-study examinations to minimize stress and facilitate handling; however, administration of anesthetics can have direct effects on clinical pathology values which must be considered (Kim et al., 2005).

Increases in muscle injury enzyme activities (e.g., aspartate aminotransaminase [AST], creatine kinase [CK], lactate dehydrogenase [LDH], and/or alanine aminotransaminase [ALT]) can be seen as a result of intramuscular dosing of anesthetic agents not only because of minor muscle trauma but also directly from certain anesthetics agents, including ketamine (Aulbach et al., 2017). The effects of stress are often greatest during initial handling and restraint in newly acquired animals but tend to diminish as animals become conditioned to the processes. These features emphasize the importance of prestudy acclimatization and performing sham blood draws before study initiation to reduce the impact of these variables.

Preanalytical Variation

Because of their longevity and varied origins, NHPs used in biomedical research often have complex histories leading to the potential for substantial preanalytical variations among a host of clinical pathology endpoints. Variations because of age, gender, species, geographic origin, duration in captivity, and estrus status have all been identified. In particular, substantial variations in lymphocyte counts, total protein, globulin, and C-reactive protein (CRP) levels are often encountered among wild-caught NHPs because of their varied background and environmental exposure to antigens and naturally occurring disease conditions (Hall and Everds, 2003). Consideration should be given to the

potential effects of these variables when interpreting clinical pathology data from NHPs.

Relative to other laboratory animal species, NHPs are often older and, as a result, have had exposure to differing husbandry, nutritional, and/or environmental practices. Examples of age-related effects on biochemical endpoints reported in NHPs include increases in urea nitrogen/creatinine in aged macaques (Kapeghian et al., 1984), reduced CRP levels in younger animals (Lamperez and Thomas, 2005), and progressive decreases in bone growth markers (e.g., bone-specific alkaline phosphatase [ALP]) with stabilization of elevated calcium concentrations, as younger animals reach skeletal maturity (Perretta et al., 1991). Variations among clinical pathology endpoints generally necessitate the establishment of both gender- and species-specific reference intervals although age stratification of historical data is usually unnecessary.

Subclinical infections with *Plasmodium* spp., unicellular parasites that cause malaria in their hosts, are an additional source of preanalytical variation that is not uncommonly encountered among wild-caught NHPs used in research studies. Malaria in NHPs imported from endemic areas has been reported to be as high as 43% in some regions (Ameri, 2010). Clinical or subclinical infections may confound data interpretation, especially in cases involving immunosuppression or immunotoxicity testing. Possible sequela of subclinical infections in NHPs includes periodic reductions in red cell mass associated with hemolysis, chronically elevated lymphocyte counts, and increases in serum globulins and/or total protein. Clinical disease can result in significant morbidity and/or mortality, especially in cases where the animals are immunosuppressed, stressed, or have had experimental surgical manipulation, including splenectomy (Sasseville and Mansfield, 2009). It is becoming increasingly more common to conduct polymerase chain reaction (PCR) testing for *Plasmodium* spp. prior importing NHP into the stock colony or testing facility.

Hematology

The importance of evaluating hematology in animal toxicology studies is emphasized by the often sensitive nature of the hematologic system to a wide range of pharmacologic compounds. Factors contributing to this sensitivity include the high mitotic rate of rapidly dividing hematopoietic cells, the short half-life of most blood cell types, and the systemic exposure of many test compounds. In addition to being a requirement among most of the major global regulatory agencies for preclinical work, effects on the hematologic system observed in preclinical safety studies have a high concordance rate (91%) with those observed in human clinical trials (Olson et al., 2000).

Guidelines for core hematology parameters have remained largely unchanged over recent years and are listed in Table 4.1 (Weingand et al., 1996; Tomlinson et al., 2013). Additional parameters obtained from modern hematology instruments such as the Advia 120/2120 (e.g., red cell distribution width (RDW), platelet distribution width (PDW), mean platelet volume (MPV), etc.) have recently gained favor and may be evaluated in conjunction with traditional endpoints to add supportive or mechanistic information to studies, which have identified the hematologic system as a target organ.

Red cell mass, if used to represent the overall circulating and functional red blood cell (RBC) volume, includes erythrocyte count (RBCs), hemoglobin concentration (HgB), and the calculated hematocrit value. All 3 of these individual analytes generally behave in parallel; however, HgB alone is often preferred as a stand-alone representative for red cell mass, as it is less likely to be artifactually influenced by analytical variables and its common use in human medicine. Mean cell volume (MCV) represents the average size of erythrocytes, whereas mean cell hemoglobin concentration (MCHC) represents the average hemoglobin concentration within circulating erythrocytes. Erythropoietin is the principal growth factor governing erythropoiesis and is produced by the peritubular interstitial fibroblasts of the kidney in response to low tissue oxygen tension (i.e., hypoxia). As tissue oxygenation decreases, erythropoietin will be released stimulating the bone marrow to produce more erythrocytes. Reticulocytes are young erythrocytes that are released in increased numbers from the bone marrow in response to increased demand. In such cases, an increased MCV with concurrent decrease in MCHC will usually correlate to the increase in reticulocyte release, which represents the increased cell size and relative decreased hemoglobin concentration seen in reticulocytes.

The most common cause of increased red cell mass in NHPs in preclinical safety studies is dehydration/hemoconcentration, which is a common sequela among animals that are anorexic, have gastrointestinal illness (e.g., diarrhea and vomiting), or otherwise having toxic effects that result in poor health (Hall and Everds, 2008). Increased red cell mass in these cases will usually be accompanied by supporting clinical evidence (e.g., increased skin tenting and sunken eyes), increases in total protein, electrolytes, and/or urea nitrogen and/or creatinine.

Direct toxic effects on the hematologic system more commonly result in reductions in red cell mass (anemia). These effects usually fall into 1 of 3 general categories, which include (1) blood loss, (2) increased erythrocyte destruction, or (3) decreased erythrocyte production. Evaluation of reticulocyte counts, erythrocyte morphologic abnormalities on blood smears, histopathologic data, and clinical observations, with consideration for

the study design and changes in concurrent controls, will help determine the underlying cause of red cell mass changes. When evaluating conditions involving reductions in red cell mass, it is critical to determine to what extent the bone marrow is involved. This is accomplished by evaluating reticulocyte concentration to conclude whether there is an appropriate regenerative response (increases in reticulocytes). Cynomolgus monkeys typically have resting reticulocyte percentages of <2.5%, which generally correspond to absolute concentrations of 20,000–60,000 cells/μL (Drevon-Gaillot et al., 2006). In cases where there is an increased demand for erythrocytes, as in anemia, reticulocyte concentrations will rise within 2–3 days postinsult and can reach magnitudes of 100,000–300,000 cells/μL depending on the severity, timing, and cause of the toxic insult.

Blood loss anemia occurs as a result of internal (e.g., body cavity or gastrointestinal tract) or external (may include intestinal tract) hemorrhage as related to trauma, surgery, platelet/coagulation disorders, gastrointestinal toxicity, or cardiac and vascular insults. The key feature that supports the conclusion of a blood loss anemia is a moderate to strong regenerative response (increase in reticulocyte count). Platelets are also often reflexively increased in blood loss via either splenic contraction and/or because of the cross-reactivity between erythropoietin and thrombopoietin receptors (Stockham and Scott, 2008). Concurrent decreases of serum protein (e.g., total protein and albumin) are often seen in cases of overt blood loss. Iatrogenic blood loss is a common cause of decreased red cell mass in NHP studies, and is typically the result of repeated blood collections for toxicokinetic, pharmacodynamic, and/or biomarker analyses. Concurrent controls can serve as a comparator for the expected magnitude of red cell mass decreases and reticulocyte

responses to help exclude a concurrent test article–related effect. Blood loss related to menses is also commonly seen in many female primate species on toxicity studies and can result in minimally to mildly lower red cell mass and increased reticulocyte counts. The magnitude of these effects is dependent on the duration of the menstrual phase, with the most pronounced changes seen in animals with menstrual phases lasting 7 days or more (Ochi et al., 2016).

Hemolysis is the early destruction of RBCs and may occur by direct lysis within the blood vessels or heart (intravascular) or by phagocytosis by cells of the mononuclear phagocyte system (extravascular; see Table 4.2). *Intravascular hemolysis* is relatively uncommon in toxicity studies but typically occurs secondary to red cell swelling or direct damage to the red cell membrane following intravenous administration of the test article. In vitro hemolysis testing can help identify test articles that are incompatible with blood and prevent the occurrence of intravascular hemolysis on toxicity studies. Intravascular hemolysis may also occur secondary to mechanical fragmentation of erythrocytes but is relatively uncommon in toxicology studies. Fragmented erythrocytes, including schistocytes, acanthocytes, and keratocytes, may be seen on blood smears. Lesions of the cardiovascular system, including vasculitis and endothelial damage, may accompany these findings. Alterations in erythrocyte membrane lipids may increase erythrocyte fragility and result in fragmentation of erythrocytes as well (Stockham and Scott, 2008).

Hemolysis on toxicity studies more commonly results from *extravascular hemolysis*, which occurs secondary to altered erythrocyte structure or membrane alterations. Abnormal erythrocytes are phagocytized by cells of the mononuclear phagocyte system as they pass through sinuses of the spleen, liver, or bone marrow.

TABLE 4.2   Characteristics of Intravascular Versus Extravascular Hemolysis

Characteristic	Intravascular Hemolysis	Extravascular Hemolysis
Site	Vasculature or the heart	Macrophages in the spleen, liver, and bone marrow
Timing	May be immediate	Typically following ≥2 doses
Clinical pathology findings	↓ RBC, ↑ reticulocytes ± Hemoglobinemia/uria ±↑ TBIL	Decreased red cell mass Increased reticulocyte counts Increased serum bilirubin (with increased urine bilirubin)
RBC morphology findings	*Mechanical fragmentation*: Acanthocytes, schistocytes, keratocytes	*Immune-mediated*: Spherocytes or agglutination *Oxidative injury*: Heinz bodies, eccentrocytes, and/or methemoglobinemia
Other findings	Hemoglobin in the renal tubule epithelial cells Local injection site irritation	Splenomegaly Erythrophagocytosis or iron pigment in the spleen, liver, or bone marrow

RBC, red blood cells; *TBIL*, total bilirubin.

TABLE 4.3 Classic Leukocyte Patterns

Physiologic Influence	WBC	Neutrophils	Lymphocytes	Monocytes	Eosinophils
Inflammation	↑↑	↑↑	±↑	±↑	−
Epinephrine	↑↑	↑↑	↑	−	−
Cortisol	↑	↑	↓	↑	↓
Marrow suppression	↓	↓	±↓	↓	↓
Lymphoid organ depletion	↓	−	↓↓	−	−

WBC, white blood cell.

Immune-mediated injury and oxidative injury are the 2 most common causes of extravascular hemolysis in toxicology studies. Immune-mediated hemolysis typically occurs as an idiosyncratic reaction after several doses of test article. These reactions may be unpredictable, lack a dose response, and occur in only a few animals on study. Large molecule drugs, those that undergo haptenization, and those that are administered via intravenous or intramuscular routes are more likely to be immunogenic (Renard and Rosselet, 2017).

Decreased erythrocyte production, or erythroid suppression, is the most common form of hematotoxicity observed in NHPs on preclinical studies. Direct bone marrow toxicity, which can be a common toxicity with high doses of many chemotherapeutic compounds, results in injury to the erythroid precursors in the bone marrow resulting in reduced reticulocyte production and eventual decrease in mature red cell mass. In short-duration (e.g., 7 days) studies, even complete destruction of erythroid precursors in the bone marrow may not result in meaningful effects on circulating red cell mass because of the substantial half-life of mature erythrocytes in NHPs (average 85−100 days; Moore, 2000). The key features in identification of erythroid suppression are reductions in reticulocytes and MCV in the face of reduced red cell mass. Correlative histologic findings in the bone marrow (e.g., decreased hematopoietic cellularity) are common in these cases.

Leukocyte or myeloid responses observed in NHPs in toxicology studies usually fall into one of several common categories, which include stress-induced (increased leukocytes), inflammation (increased leukocytes), myeloid suppression (decreased leukocytes), and lymphoid organ toxicity (decreased lymphocytes). Stress-induced changes on myeloid parameters occur as a result of concurrent effects of catecholamine (epinephrine/norepinephrine) and glucocorticoid release on circulating blood cells. These responses can be incited by such factors as blood collection, restraint, handling, solitary housing, fasting, and blood volume depletion among others. The classic "stress response" observed in most animal species is typically characterized by increases in neutrophil concentration and concurrent decreases in the concentrations of lymphocytes and eosinophils that result in an overall increase in total leukocytes (see Table 4.3). In NHPs, this response is more varied and usually results in increased neutrophils with increased or decreased lymphocyte concentrations (Bennett et al., 1992). As stated previously, stress leukograms in NHPs are commonly observed at the first and/or second hematology collections before dosing (i.e., pretest/baseline). These effects become diminished over time as animals become more habituated to blood collections and handling procedures (Aulbach et al., 2017).

Classic inflammatory changes in NHPs are characterized by increases in neutrophil counts, with or without increases in monocytes and lymphocytes, and/or a shift toward release of immature neutrophils (band cells) into circulation. Careful consideration must be given, as these findings often overlap or occur concurrently with stress-induced effects; hence, it is important to correlate these changes to clinical observations (lethargy, fever, lesions, etc.), microscopic findings of inflammation, and/or other signals of inflammation, including changes in acute phase proteins (e.g., fibrinogen, CRP, albumin). It should be noted that primary inflammatory effects of test compounds are not uncommon and will sometimes lack direct microscopic tissue correlates.

Decreased myeloid production, or myeloid suppression, is a common form of bone marrow toxicity observed in preclinical studies in NHPs. Similar to effects on erythroid precursors as described previously, direct bone marrow injury targeting the myeloid cell line results in reduced granulocyte (mostly neutrophils) production and eventual decrease in mature circulating neutrophils. If severe reductions in neutrophil counts occur (<1000 cells/μL) in NHPs, clinical immunosuppression and secondary bacterial infection and sepsis are likely to ensue.

Lymphoid organ effects are common in toxicity studies and are generally considered independent of bone marrow toxicity in NHPs. Although NHPs harbor substantial numbers of lymphocytes within the bone

marrow, circulating and functional lymphocyte counts are not typically impacted by direct insults to the bone marrow alone (Reagan et al., 2011). Circulating lymphocyte counts often correlate with lymphoid organ effects, particularly those observed in the thymus, spleen, and lymph nodes (decreased organ weights and/or decreased cellularity). Direct lymphoid organ toxicity usually results in dose-responsive decreases in circulating lymphocyte concentrations without impacting neutrophil or other granulocyte counts (see Table 4.3).

Coagulation and Hemostasis

Platelets are produced by megakaryocytes in the bone marrow and constitute the third major cell line within the hematopoietic system. They are discussed in this section as they are centrally involved in the process of hemostasis, which also involves a series of complex interactions with coagulation, fibrinolytic factors, and blood vessels. Bone marrow toxicity affecting the megakaryocytic cell line typically results in reductions in circulating platelet concentrations. Clinical observations and biologically relevant effects are generally not observed until severe reductions are reached (e.g., <15,000 platelets/μL) and include skin and mucosal petechiae and ecchymoses, mucosal bleeding, hematuria, and hyphema (bleeding into the eye), which can be life-threatening (Stockham and Scott, 2008). Thrombopoietin is the primary cytokine regulating the proliferation and differentiation of megakaryocyte progenitor cells and will increase secondary to decreased platelet mass. Platelet numbers in circulation vary considerably by species and reflect a balance of production, destruction, consumption, and redistribution to tissues like the spleen. Overall, platelets circulate for approximately 5–9 days in most species (Russell, 2010). Decreased platelet counts may occur from decreased or defective production by megakaryocytes or myelosuppression. Because of the circulating lifespan of platelets, low platelet counts resulting from decreased production will not be immediately apparent and are typically noted 1–2 weeks following induction of myelosuppression.

Activated partial thromboplastin time (aPTT) and prothrombin time (PT) are the standard assays used in the NHP to evaluate functional coagulation ability in preclinical safety studies (FDA, 2003; OCED, 2009). For evaluation of PT and aPTT, whole blood should be collected in trisodium citrate anticoagulant (3.2% or 3.8%) at a 9:1 blood to anticoagulant ratio. Prolongations in aPTT and PT on toxicology studies may reflect decreased production of coagulation factors by the liver (hepatic disease), increased coagulation factor inactivation or consumption (secondary to localized or disseminated coagulation), dilution of coagulation factors with excessive administration of plasma-poor fluids, or inhibition of coagulation factors by drugs, antibodies, or fibrin-degradation products. Spurious prolongations in aPTT and/or PT may occur with difficult sample collection, poor clinical condition of the animal, or with an inappropriate citrate ratio. Alterations in coagulation times should be interpreted with knowledge of the assay system and reagent set. Assay-to-assay variation can be quite substantial requiring background knowledge of historical data from the particular laboratory being used and/or the use of concurrent control animals. Even a minimally prolonged coagulation time usually represents an approximately >70% reduction in the factors involved in the assay; hence substantial effects on the biological system occurred before any effect on assay results are seen. This phenomenon is confounded by the fact that in many cases, these findings will occur in the absence of clinical observations or microscopic lesions, a reflection of the coagulation system's redundant functional capacity. Interfering substances causing false artifactual effects on coagulation tests have been documented and should be considered when effects occur in the absence of other correlative findings. Pegylated protein compounds have been shown to artifactually prolong certain aPTT reagent sets (Aulbach et al., 2012).

Fibrinogen is a positive acute-phase protein synthesized by the liver and is found in the plasma and platelet granules. Fibrinogen plays a critical role in hemostasis and is consumed during coagulation when fibrinogen is converted fibrin. Fibrinogen is also an acute phase protein, meaning its levels will increase under inflammatory conditions. For this reason, fibrinogen is a useful marker of inflammation in NHPs, and is an important link between inflammation and hemostasis. Increased fibrinogen concentration can result in shortening of PT and aPTT; however, because inflammation and coagulation occur over a continual spectrum of severity, and inflammation-induced activation of coagulation may eventually advance to hypocoagulation (Kurata et al., 2003), prolongations or shortening of coagulation times may be observed in conjunction with clinical and microscopic evidence of inflammation on toxicology studies.

Clinical Biochemistry

Key clinical chemistry analytes evaluated in NHPs are listed in Table 4.4 (Weingand et al., 1996; Tomlinson et al., 2013). This collection of assays is aimed at identifying major effects on the renal, hepatobiliary, metabolic, and fluid/electrolyte regulating systems. Additional markers of cardiac injury (e.g., cardiac troponin I [cTnI]), muscle injury, inflammation (e.g., acute phase

TABLE 4.4 Summary of Hepatocellular and Hepatobiliary Biomarkers

Hepatocellular Injury Markers	Hepatobiliary Injury Markers
Alanine aminotransferase (ALT)	Total bilirubin (TBIL)
Aspartate aminotransferase (AST)	Alkaline phosphatase (ALP)
Sorbitol dehydrogenase (SDH)	Gamma-glutamyltransferase (GGT)
Glutamate dehydrogenase (GLDH)	Total bile acids (TBA)
	5′ nucleotidase (5NT)

INDICATORS OF ALTERED HEPATIC FUNCTION

↑ Total bilirubin (TBIL)	↓ Glucose (GLU)
↑ Total bile acids (TBA)	↑ Coagulation times (aPTT and PT)
↓ Albumin (ALB)	↓ Fibrinogen
↓ Urea nitrogen	↓ Cholesterol

proteins), hormone characterization, and immunotoxicity (e.g., immunoglobulins and cytokines) may be added to this panel as the weight-of-evidence dictates.

Electrolyte evaluations typically measure concentrations of sodium, chloride, potassium, and phosphorus and are used as indicators of fluid and electrolyte balance, hydration status, acid/base status, renal function, gastrointestinal health, and even endocrine function. It is imperative to integrate electrolyte information with other clinical pathology endpoints and clinical observations before making final conclusions, as many cases involving electrolyte alterations involve multiple inter-related processes. Increases in sodium and chloride are consistent with dehydration; however, this should be substantiated by identifying concurrent increases in protein values, red cell mass, and/or markers of reduced glomerular filtration rate such as increased urea nitrogen, creatinine, and phosphorus. Reductions in sodium and chloride are common in cases of severe gastrointestinal fluid losses (i.e., vomiting and watery feces), diuresis, and/or prolonged polyuria (Stockham and Scott, 2008). The most common cause of electrolyte losses in NHPs is generally secondary to gastrointestinal distress/toxicity.

Urea nitrogen and creatinine are widely used in NHPs to assess renal function and represent the traditional method for detecting renal injury in toxicology studies. As in humans, extensive renal injury can occur before meaningful elevations in urea nitrogen and creatinine are observed, which makes them less sensitive than some of the newer biomarkers of renal injury discussed in greater detail elsewhere in this text (e.g., kidney injury marker 1 (KIM-1), neutrophil gelatinase-associated lipocalin (NGAL), cystatin C, microglobulins). Renal biomarkers generally have been classified into several groups indicating their association with injury to a specific part of the nephron (e.g., proximal tubule, glomerulus, and collecting duct). Recent work

suggests that there is a fair amount of overlap and redundancy among individual biomarkers in regards to their specific nephron segment; hence classifying biomarker effects to either the glomerulus or the tubules appears to be the most appropriate approach in most cases (Ennulat and Adler, 2015). The magnitude, timing, and sensitivity of positive signals among specific biomarkers will differ between test compounds and between assay methodologies and laboratories; hence the selection of specific biomarkers should be made with consideration of assay availability, species, anticipated pathophysiology, and analyte stability (Vlasakova et al., 2014). Any effects observed on renal injury markers should be correlated to microscopic findings in the kidneys to make definitive conclusions as effects on clinical pathology endpoints without histologic evidence of injury may indicate submicroscopic or even nonrenal causes (e.g., dehydration). Given the high sensitivity of many of the newer renal injury biomarkers, it is not uncommon to see signals among biomarker data in the absence of histologic effects. Under these circumstances, effects are generally considered submicroscopic or molecular in nature without meaningful biologic or toxicologic relevance.

Global regulatory guidelines dictate that for the detection of hepatocellular injury in nonclinical animal studies, a minimum of 2 or 3 of the following tests be included in clinical chemistry panel: ALT, AST, sorbitol dehydrogenase (SDH), glutamate dehydrogenase (alternatively known as GDH), and total bile acids (FDA, 2003; OCED, 2009). For the detection of hepatobiliary injury, at least 2 or 3 of the following should be included: ALP, total bilirubin (TBIL), gamma-glutamyltransferase (GGT), 5′ nucleotidase, and total bile acids. Many of the clinical pathology endpoints used in nonclinical toxicology studies to characterize effects on the liver are cell leakage markers that are indicators of liver tissue injury (e.g., ALT and SDH), whereas others are inducible markers of biliary stasis/injury (e.g., ALP, bilirubin, and GGT). The sensitivity of ALP as an indicator of cholestasis and biliary injury in NHPs is much poorer than in many other laboratory species (e.g., dog); hence it is important to corroborate with histologic findings and avoid being too dogmatic about ALP signals in NHPs. In macaques, GGT has been described as a more sensitive and specific marker for biliary disease than ALP (Hall and Everds, 2003). Bilirubin metabolism in NHPs, measured as TBIL, closely resembles that of humans and is an additional marker for hepatobiliary injury and function. Insults to the hepatobiliary system will often result in signals in multiple hepatobiliary markers (e.g., GGT, ALP, ALT, and TBIL). Both hepatic injury and muscle injury can cause elevations in ALT and AST because of their tissue distribution in the liver, both skeletal and heart muscle, and the kidney (Mohr et al., 1971). Mild to moderate elevations in ALT and

AST of skeletal muscle origin are commonly seen in NHP species following normal chemical restraint (Kim et al., 2005). Consequently, caution must be taken in attributing elevations of ALT and AST to hepatic injury when concurrent elevations in CK and/or LDH are present. It is important to correlate microscopic alterations in the liver or muscle to elevations in these injury markers before making final conclusions about the significance of such findings, as elevations in ALT and AST in the absence of microscopic tissue alterations are not uncommon (Boone et al., 2005).

Urinalysis

Urinalysis is typically included as part of the minimum required database for nonclinical toxicology studies in most species. Recommended core tests include determination of urine physical characteristics (color, clarity, and volume) and determination of specific gravity or osmolality, pH, total protein, glucose, blood, ketones, and bilirubin (FDA, 2003; OCED, 2009). Additional testing, including creatine clearance, protein-to-creatinine ratio, fractional excretion, or renal injury biomarkers, may be necessary if the compound is a known renal toxicant or a more thorough characterization of renal effects is desired.

Urinalysis data are heavily influenced by collection technique. The challenges associated with collecting appropriate urine samples from large numbers of animals on toxicology studies are not trivial. Most commonly, voided urine is collected into a pan system over a defined period of time (typically 16 h) because of cost and labor-intensive nature of other collection techniques. This method, however, is prone to inaccurate results because of contamination by other material collected in the pan, including food, water, feces, vomitus, hair, and residual cleaning solution. Various methods (collection on ice, fasting, gauze/mesh filters, etc.) can be used in nonclinical toxicology studies to minimize urine contaminants as much as possible. Contaminates may lead to a variety of false-positive results, including effects on urine volumes, glucose, protein, occult blood, and microscopic artifacts (Aulbach et al., 2015; Siska et al., 2017). Institutions should make operational efforts to minimize the frequency of these collection variables.

BACKGROUND MICROSCOPIC LESIONS IN NHPS

In preclinical research drug safety evaluation, one of the most important factors in the accurate determination of test article—related effects is an awareness and solid understanding of all potential spontaneous microscopic changes (changes that are not induced by the test article) in the particular animal model. These spontaneous changes are also referred to as "incidental" or "background" changes. It is important to note that these background changes may arise during the study or they can be preexisting, and they can also be exacerbated (or even sometimes diminished) by a procedure or test article. Determining the relationship of the test article to these changes often relies on the experience of the pathologist, the features and biology of the effect, how the severity and incidence of the change vary across groups, other study data, and historical control data. The importance of historical control data in NHP studies cannot be underestimated, especially because these studies typically have small numbers of animals (usually 3—4) in each group, which increases the possibility that a background change will only be present in the treated animals and absent in controls. Possibly representing one of the unwritten Murphy's-related toxicology laws, a background change will often only be present in the high-dose group, which can greatly confound the interpretation of the study and the accurate determination of spontaneous versus drug-induced findings. The following sections will provide a short description of some of the more notable background lesions in cynomolgus macaques, both from a preclinical research perspective and those involving "biomarker friendly" tissues such as the heart, liver, kidneys, and skeletal muscle. It is important to note that there is no generic NHP, and the background lesions can vary greatly between species, strain, and geographic origin.

Mononuclear Cell Infiltrates

Mononuclear cell infiltrates, also sometimes referred to as lymphocytic or lymphoplasmacytic infiltrates, are by far the most common background lesion in cynomolgus macaques. These infiltrates are typically comprised of focal aggregates of lymphocytes, plasma cells, and macrophages within a tissue, with little or no evidence of damage to the surrounding parenchyma (such as renal tubules, gastric glands, cardiac myocytes, or hepatocytes in the kidney, stomach, heart, and liver, respectively). Because of the typical lack of associated parenchymal damage, it is highly unlikely that these infiltrates would be detectable with current commonly available biomarkers. It has been demonstrated that serum cTnI concentrations are not increased in cynomolgus monkeys with myocardial mononuclear cell infiltrates, and thus serum cTnI does not appear to be a biomarker that can be used to screen cynomolgus macaques for this spontaneous cardiac finding (Dunn et al., 2012). Mononuclear cell infiltrates are of unknown cause and typically observed in many cynomolgus macaque tissues, with the most commonly affected sites being the liver (61%),

kidneys (29%), heart (26%), salivary glands (21%), and stomach (12%) (Chamanza et al., 2010). There are variations in the degree of mononuclear cell infiltrates between cynomolgus monkeys from different sources. When compared with Mauritian monkeys, cynomolgus monkeys from Southeast Asia (The Philippines and Vietnam) have been reported to have increased mononuclear cell infiltrates, which correlated with an increased white blood cell count (Drevon-Gaillot et al., 2006). Mononuclear cell infiltrates are also present in the uvea of the eyes of cynomolgus macaques in approximately 25% of drug safety evaluation studies and are not associated with other ocular histopathologic or ophthalmoscopic findings (Chamanza et al., 2010; Sinha et al., 2006). The most common site of mononuclear cell infiltrates is the liver, and these infiltrates can be present diffusely throughout the parenchyma or within periportal regions. The liver infiltrates are usually minimal in magnitude and can occasionally be associated with minimal focal hepatocellular necrosis. Typically, clinical chemistry changes (e.g., increased ALT or AST) are not associated with hepatic mononuclear cell infiltrates (Chamanza et al., 2010; Sato et al., 2012).

Mononuclear cell infiltrates in the heart can be of particular concern because they can be more difficult to distinguish from inflammation, can be associated with myocyte injury, and are also one of the primary histopathologic lesions associated with *Trypanosoma cruzi* infection (Chagas disease). *T. cruzi* protozoal amastigotes are often difficult to detect histologically, precluding a definitive microscopic diagnosis. Mononuclear cell infiltrates within the stomach (sometimes referred to as chronic gastritis) are one of the most common background findings in cynomolgus macaques, with recorded incidences of 100% affected animals reported in nearly half of the studies. These lesions are not usually associated with clinical signs, and *Helicobacter pylori* and *Helicobacter heilmannii*—like organisms are frequently observed in both sections with mononuclear cell infiltrates and in normal-appearing sections (Brady and Carville, 2012; Drevon-Gaillot et al., 2006; Sato et al., 2012).

Cardiovascular

Various heart muscle (myocardial) background lesions in cynomolgus macaques, such as degeneration/necrosis, hemorrhage, and fibrosis, can mimic test-article-related cardiac toxicity. Cardiomyopathy is characterized by cardiomyocyte disarray with cytoplasmic pallor to stippling and increased nuclear size (karyomegaly), fibrosis, and mononuclear cell infiltration. The disrupted cardiomyocytes are immunoreactive to desmin and cTnI antibodies and have a normal cross-striation pattern by phosphotungstic acid-hematoxylin (PTAH), indicating the chronic cardiomyopathy is not associated with active

cardiomyocyte damage (Zabka et al., 2009). Myocardial degeneration and necrosis, which in advanced cases is also associated with inflammation (myocarditis) and fibrosis or mineralization, has also been reported as an idiopathic heart background lesion in cynomolgus macaques (Chamanza et al., 2006, 2010; Drevon-Gaillot et al., 2006; Keenan and Vidal, 2006). Minimal to mild transient increases in cTnI can be detected in monkeys after oral, subcutaneous, or intravenous dosing of common vehicles, as well as serial chair restraint for venipuncture blood collection assays (Reagan et al., 2017). A higher incidence and severity of myocardial degeneration/necrosis, subendocardial hemorrhage with hemosiderin, myocardial fibrosis, and arterial medial degeneration/hemorrhage have been reported in Mauritian-source cynomolgus macaques (Vidal et al., 2010). Background vascular lesions include accumulation of mucopolysaccharides in the intima of the aorta, subendocardial areas of the base of the heart, and coronary arteries (most commonly without lipid accumulation, although occasionally atherosclerotic lesions have also been observed). Vasculocentric inflammation, which either involves the wall of vessels (vasculitis, arteritis) or tissues surrounding vessels (perivascular inflammation, perivasculitis, periarteritis), can be observed spontaneously in cynomolgus macaques and is usually only observed in one or a few tissues, with the most common sites being the heart, intestines, and epididymis (Chamanza et al., 2006, 2010; Sato et al., 2012). A spontaneous vasculitis that involves more tissues and includes vascular necrosis, resembling polyarteritis nodosa in humans, has been observed in cynomolgus macaques (Albassam et al., 1993; Porter et al., 2003). Background vasculocentric lesions can be extremely problematic in toxicology because similar-appearing drug-induced vascular lesions can be an incredibly serious toxicity and can pose a significant challenge to the advancement of the compound into humans. Periarteritis in the lungs, usually with edema, can be associated with continuous intravenous infusions.

Gastrointestinal and Hepatic

Acute inflammation of the stomach (acute gastritis) occurs at a much lower incidence than chronic mononuclear cell inflammatory infiltrates and is often associated with hemorrhage, erosions, ulceration, and/or glandular microabscesses (Chamanza et al., 2010). Serum pepsinogen I has been reported as a possible noninvasive biomarker for detection of gastric mucosal injury in monkeys (Ennulat et al., 2017). Gastric ulceration is uncommon, usually subclinical, and can be associated with *Helicobacter* infection; however, when the ulceration is severe, the animals may present with anorexia, weight loss, lethargy, and vomiting of blood. Upper gastrointestinal tract hemorrhage can be associated with vomiting,

regenerative anemia, and an elevated urea nitrogen. Background lesions in the intestine are uncommon but can occasionally be associated with diarrhea and diarrhea-related clinical pathologies such as dehydration, electrolyte disturbances, hemoconcentration, and, if associated with hemorrhage, hypoproteinemia, and anemia. It is important to note that diarrhea in cynomolgus macaques is usually of unknown cause (Chamanza et al., 2010). Amyloid can be deposited within the intestines (amyloid enteropathy) or systemically throughout numerous tissues, most commonly the liver and spleen. Intestinal amyloidosis can cause protein loss into the intestinal lumen (protein losing enteropathy) and can be associated with hypoalbuminemia.

Renal

Interstitial inflammation of the kidneys (interstitial nephritis or tubulointerstitial nephritis) consists primarily of infiltrates of lymphocytes, plasma cells, and small numbers of neutrophils and can be associated with tubular regeneration, interstitial fibrosis, intraepithelial pigment, and mineralization (Chamanza et al., 2010; Sato et al., 2012). Kidney glomerular lesions can include focal membranous and proliferative glomerulonephritis and glomerulosclerosis (Drevon-Gaillot et al., 2006; Sato et al., 2012). There are usually no gross pathologic findings or systemic disease associated with these glomerular or interstitial changes (Chamanza et al., 2010).

Skeletal Muscle

Background lesions in skeletal muscle are rare but important to recognize, as they need to be separated from drug-induced skeletal muscle injury. Biomarkers of muscle injury include alanine aminotransferase (ALT), aspartate aminotransferase (AST), CK, and/or LDH. Some of the more common non−drug-related background lesions in cynomolgus macaques include focal accidental trauma, vaccination-related inflammation, and infection with Sarcocystis spp. coccidian parasites (Chamanza et al., 2010). Sarcocystosis is usually not associated with other lesions; however, occasionally, cases exhibit inflammation characterized by infiltrates of lymphocytes, plasma cells, and eosinophils, as well as myofiber degeneration and fibrosis.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The science of toxicology will undoubtedly continue to evolve as scientists look to improve on the current approach of assessing the potential risk to human health. There is substantial social, economic, and scientific pressure to find ways to minimize the use of animals in preclinical research, particularly the use of NHPs. Toxicogenomics, proteomics, and metabolomics are just a few of the many exciting technologies with potential to revolutionize current approaches to preclinical toxicity testing. The success of these efforts will likely drive the next generation of toxicologists away from such heavy reliance on animal test systems.

In this chapter, we largely focused our discussion on traditional markers of toxicity and pathology. Although many of the new testing modalities are promising, it is important to remember that novel biomarkers and new testing methodologies must be benchmarked over time against well-characterized gold standards before they can be relied on for routine use. What good is a new renal injury biomarker if its relation to microscopic pathology or clinical pathology assessments are not known? Moving forward, we need to pursue new technologies without losing sight of traditional toxicology principles, which will continue to play a central role in toxicology assessments for the foreseeable future.

Biomarkers of Toxicity in Zebrafish

Stephanie Padilla

Integrated Systems Toxicology Division, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC, United States

INTRODUCTION

Given that zebrafish have now become an accepted model for toxicological studies in both the human health and ecological communities, this chapter takes stock of the status of biomarkers of toxicity that have been proposed for the zebrafish model. Most of what are discussed herein are biomarkers of effect, but the line between biomarkers of effect and exposure is often not well defined. Generally the chapter strives to present examples of many different types of biomarkers for many classes of toxicological "icities," but it should not be considered a comprehensive survey of all the zebrafish biomarker literature. Rather, the chapter gives a critical appraisal of the state of the effort to develop and identify biomarkers of toxicity in zebrafish.

ZEBRAFISH BACKGROUND

The zebrafish, a small (3−5 cm), freshwater teleost fish, not native to the Western Hemisphere (Spence et al., 2008), is a vertebrate species that is easy and inexpensive to rear and maintain in the laboratory. It is a model that is especially convenient for developmental studies because the offspring mature rapidly, with organogenesis completed by 3 days, and by 6 days the larvae are free swimming and feeding. The overall body plan is much like other vertebrates' and includes toxicologically relevant organ systems such as a liver with a large complement of cytochrome P450s (Tao and Peng, 2009; Goldstone et al., 2010; Otte et al., 2010; Stegeman et al., 2010; Weigt et al., 2011), a thyroid gland (Blanton and Specker, 2007; Porazzi et al., 2009; Walpita et al., 2009), and a blood−brain barrier (Jeong et al., 2008; Eliceiri et al., 2011). The model does, however, lack some other toxicologically relevant organs such as the mammary glands, lungs, and a prostate gland. Nevertheless,

there are many examples where key developmental signaling pathways and their regulation are conserved between fish and mammals. A comparison of the mammalian and zebrafish genomes revealed long-range conserved synteny (i.e., "the maintenance of gene linkage on chromosomes of different species"; Kikuta et al., 2007), attesting to the similarity in important regulatory sequences and overall similarity in the genomes (Kikuta et al., 2007; Howe et al., 2013). Additionally, zebrafish have been reported to possess orthologs for 86% of the 1318 human drug targets tested (Gunnarsson et al., 2008).

Because of the concordance between zebrafish and mammalian developmental pathways, the zebrafish model is often promoted for studying mammalian disease (reviewed in Penberthy et al., 2002; Shin and Fishman, 2002). For example, it has been suggested that zebrafish would be an excellent model for ocular disease (Gestri et al., 2012), ocular motor disorders (Maurer et al., 2011), autism (Tropepe and Sive, 2003), and, in general, for the molecular dissection of developmental pathways (Dodd et al., 2000; Fetcho, 2007; Duggan et al., 2008; Gunnarsson et al., 2008; Ito et al., 2010; Spitsbergen and Kent, 2003; Xi et al., 2010; Xu and Zon, 2010).

ECOTOXICOLOGICAL BIOMARKERS OF TOXICITY

Even though the zebrafish is not a species indigenous to either the United States or Europe, it is also often used in ecotoxicological research as a surrogate for indigenous species. This is partly because of the large literature base for zebrafish and the good correlation between zebrafish toxicity and toxicity tests in other fish species (Braunbeck et al., 2005; Lammer et al., 2009; Vaughan and van Egmond, 2010).

Zebrafish biomarkers are used in ecotoxicological studies to determine if environmental samples elicit

toxic responses in zebrafish and, in some cases, to identify the type of stressor, i.e., zebrafish toxicity profiles are used as biomarkers of aquatic pollution. In these cases, zebrafish are being employed as a sentinel species, and the information gathered is more concerned with the toxicity spectrum of environmental sample(s) rather than fish toxicity per se. One of the earliest and most commonly used ecotoxicological biomarkers is the P450 enzyme CYP1A for pollution monitoring (reviewed in Goksøyr, 1995), and it is still in use; for example, in ecosystem surveys assessing petroleum contamination (dos Anjos et al., 2011) or for monitoring PCB contamination (Hung et al., 2012). The CYP1A P450 subfamily, regulated by the aryl hydrocarbon receptor, is used as a biomarker because it is often integral to the detoxification of many exogenous chemicals (both xenobiotics and drugs) and is induced by polyaromatic hydrocarbons. There are also examples where zebrafish are used in situ to assess the toxic potential of bodies of water. Using caged zebrafish (Strömqvist et al., 2010), different bodies of water were assessed for the induction of CYP1A (biomarker of xenobiotic exposure) and vitellogenin (biomarker of endocrine disruption). In some cases, the biomarker is less diagnostic for the type of pollutant and is instead used to determine if the body of water is adverse to fish development. An example of this is a recent study (Fuentealba González et al., 2011) where the biomarker, arginase activity, was established as an indicator of growth in young zebrafish. Arginase is involved in the urea cycle catalyzing the conversion of L-arginine into L-ornithine and urea and is important in the regulation of the arginine/ornithine levels within the organism. Using the data on whole fish arginase activity, accompanied by information on hatching and mortality, the authors demonstrated adverse effects of some environmental samples on developing zebrafish. Using transgenic technology to create "reporter" fish for environmental monitoring might allow rapid assessment of pollution monitoring. The development and use of these fluorescent sentinels became quite common in the last 10–15 years (Carvan et al., 2000; Hung et al., 2012). The fish can be engineered to respond to various classes of toxicants using fluorescent probes coupled to various response elements. These include the aromatic hydrocarbon response element, electrophile response element, metal response element, estrogen response element, retinoic acid, and retinoid X response elements, among others (reviewed in Carvan et al., 2000).

EXAMPLES OF BIOMARKERS OF FISH TOXICITY

The majority of biomarker development in zebrafish is devoted to biomarkers of toxicological effect. These biomarkers indicate whether a specific chemical or class of chemicals has perturbed some aspect of fish development or fitness. There are many of these biomarkers of toxicity advanced in the literature, but, for the most part, they lack demonstrated specificity. It is also often unclear how sensitive the biomarker actually is because many of the studies are conducted at concentrations that produce overt toxicity. Indicators of overt toxicity include mortality, nonhatching of embryos, or classical morphological signs (e.g., edema, curved spine, trunk shortening). Table 5.1 shows a sampling of the many different types of biomarkers and biomarker approaches in zebrafish studies. The table includes studies in developing animals, adult animals, acute and long-term treatment scenarios, biomarkers in various organ systems, and some uses of reporter fish. Heat shock protein 70, for example, was employed as a biomarker of chemical stress in many of the studies. Heat shock protein 70, highly conserved across phyla, is a protein chaperone that, during periods of temperature or chemical stress, will help maintain protein integrity within the cell and also may inhibit apoptosis. There are six examples of studies that used heat shock protein 70 as a biomarker of toxicity in zebrafish embryos or larvae exposed to a variety of chemical stressors (Table 5.1). In some cases, the investigators assessed heat shock protein message (Kreiling et al., 2007); in others, protein expression was assessed (Blechinger et al., 2002; Hu et al., 2008; Osterauer et al., 2010); and in others, green fluorescent protein (GFP) expression tethered to human heat shock protein promoter was assessed (Seok et al., 2006, 2007). In most cases, an increase in heat shock protein biomarker was noted in the presence of the chemical stressor; however, there was one exception where a decrease was noted (Kreiling et al., 2007). In some instances, heat shock protein appears to be a sensitive biomarker of toxicity (showing a significant change at doses below those that elicit overt toxicity) (e.g., Blechinger et al., 2002; Hu et al., 2008). In other instances, changes in the heat shock protein 70 biomarker were only noted at overtly toxic doses (Seok et al., 2006; Osterauer et al., 2010). The specificity of heat shock protein 70 as a biomarker of toxic effect is unknown, but it appears to be relatively nonspecific, which might be desirable for a general biomarker of toxicity. So few chemicals, however, have been tested in zebrafish according to which usefulness of heat shock protein 70 as a general biomarker of toxicity for many types of chemical classes is unknown. In fact, many of the biomarkers identified in zebrafish suffer from this shortcoming: so few chemicals have been tested that it is impossible to determine how predictive a biomarker is for any type of toxic insult and/or how diagnostic it is for a certain class of chemicals. Thus, to ascertain either predictive or diagnostic power, a wide chemical space (many different

Biomarker	Reporter Fish?	Adults or Larvae?	Chemical(s) Tested	Duration	Results	References
ATP, ADP, or AMP hydrolysis	No	Adults	$HgCl_2$, $Pb(CH_3COO)_2$	1, 4, or 30 days	In general, with both heavy metals, decreased hydrolysis with increasing exposure duration, but with exceptions	Senger et al. (2006)
Arginase	No	Embryos	Malathion	6 days	Dose-related decrease	Fuentealba González et al. (2011)
Catalase	No	Adults	Paclobutrazol	96 h	Increased at nonlethal concentrations	Ding et al. (2009)
Catalase	No	Adults	Cadmium	21 days	Decreased in both liver and ovary	Banni et al. (2011)
Carboxylesterase	No	Embryos	Methyl paraoxon	48 h	Dose—response decrease at nonovertly toxic doses	Küster and Altenburger (2006)
Cholinesterase	No	Embryos	Methyl paraoxon	48 h	Dose—response decrease at nonovertly toxic doses	Küster and Altenburger (2006)
Cholinesterase	No	Embryos and adults	Chromium (V1)	6 days (embryos); 4 days (adults)	Decreased only in embryos, but at an overtly toxic dose	Domingues et al. (2010)
Copper transporters (message)	No	Larvae (5 dpf)	$CuCl_2$, Cu_2O nanoparticles	96 h (?)	Both chemicals increased expression at low doses	Chen et al. (2011)
Cytochrome P450 (CYP1A1)	Yes	Larvae (7 dpf)	PCBs	24 h	Dose—response change in fluorescence	Hung et al. (2012)
Glutathione peroxidase	No	Adults	Cadmium	21 days	Decreased activity in both liver and ovary	Banni et al. (2011)
Glutathione peroxidase	No	Adults	Microcystin-LR, Microcystin-RR	4, 7, 15 days	Duration-, dose-, tissue-, and chemical-dependent increases and decreases	Pavagadhi et al. (2012)
Glutathione reductase	No	Adults	Microcystin-LR, Microcystin-RR	4, 7, 15 days	Duration-, dose-, tissue-, and chemical-dependent increases and decreases	Pavagadhi et al. (2012)
Glutathione-S-transferase	No	Adults	Microcystin-LR, Microcystin-RR	4, 7, 15 days	Duration-, dose-, and tissue-dependent increases and decreases	Pavagadhi et al. (2012)
Glutathione-S-transferase	No	Embryos and adults	Chromium (V1)	6 days (embryos); 4 days (adults)	Decreased in both embryos and adults at and below overtly toxic doses	Domingues et al. (2010)

Continued

TABLE 5.1 A Sampling of the Different Types of Biomarkers and Biomarker Approaches in Zebrafish Studies—cont'd

Biomarker	Reporter Fish?	Adults or Larvae?	Chemical(s) Tested	Duration	Results	References
Glutathione-S-transferase (message)	No	Larvae (5 dpf)	CuCl$_2$, Cu$_2$O nanoparticles	96 h (?)	CuCl$_2$ decreased expression below overtly toxic doses; Cu$_2$O nanoparticles only decreased expression at overtly toxic doses	Chen et al. (2011)
Heat shock protein 70 expression	No	Embryos	PtCl$_2$	7 days	Increased expression, but at a dose above those which demonstrated histological changes	Osterauer et al. (2010)
Heat shock protein 70 expression	No	Embryos	Tetrabromobisphenol A; hexabromocyclododecane	96 h	Both chemicals caused increases at doses that did not produce overt toxicity	Hu et al. (2008)
Heat shock protein message (hsc70)	No	Embryos	PCBs (Aroclor 1254)	24 h	Decreased expression	Kreiling et al. (2007)
Heat shock protein 70-4	Yes	Larvae (72 h)	Cadmium	96 h	Increased expression at nonovertly toxic doses	Blechinger et al. (2002)
Human heat shock protein promoter	Transiently transfected; EGFP reporter	Larvae (72 hpf)	Arsenite	96 h	Dose–response increased fluorescence	Seok et al. (2007)
Human heat shock protein promoter	Transiently transfected; EGFP reporter	Larvae (72 hpf)	Copper sulfate	3 h	Increased fluorescence, but also overt toxicity	Seok et al. (2006)
Lactate dehydrogenase	No	Embryos and adults	Chromium (V1)	6 days (embryos); 4 days (adults)	Only altered in embryos: increases at low doses; decreased at overtly toxic doses	Domingues et al. (2010)
Lipid peroxidation	No	Embryos	Tetrabromobisphenol A; hexabromocyclododecane	96 h	Both chemicals caused increases at doses that did not produce overt toxicity	Hu et al. (2008)
Lipid peroxidation	No	Embryos	Diclofenac	90 min	Decreased peroxidation at lowest dose only; at higher doses, no differences from control	Feito et al. (2012)
Malondialdehyde accumulation	No	Adults	Cadmium	21 days	Increased accumulation in both liver and ovary	Banni et al. (2011)
Metallothionein (message)	No	Larvae (5 dpf)	CuCl$_2$, Cu$_2$O nanoparticles	96 h (?)	Both chemicals increased expression at nonovertly toxic doses	Chen et al. (2011)
MicroRNAs	No	Embryos	Perfluorooctane sulfonate	24 or 120 h	Up- and downregulation, but only an overtly toxic dose used	Zhang et al. (2011)

Superoxide dismutase (SOD)	No	Adults	Paclobutrazol	96 h	Increased at nonlethal concentrations	Ding et al. (2009)
SOD	No	Embryos	Tetrabromobisphenol A; hexabromocyclododecane	96 h	Both chemicals caused changes at doses that did not produce overt toxicity, but with dissimilar dose—response relationships	Hu et al. (2008)
SOD	No	Adults (3 months)	Methyl parathion, Cadmium chloride, Zinc sulfate	96 h	All three chemicals caused an initial increase (24 h) followed by a decrease in activity	Ling et al. (2011)

? representing uncertainity

types of chemicals) needs to be tested with a given biomarker of toxicity.

The gene expression surveys that have also been used to uncover possible biomarkers of toxicity in zebrafish are not included in Table 5.1. In general, these have been used with very few toxic compounds to instead identify a large number of possible genetic biomarkers. In addition, there is rarely any follow-up to validate the biomarkers by determining the universality and specificity of the proposed biomarkers. An example of a common approach (and the common shortcomings) is a recent study (Park et al., 2012) that assessed gene expression using the Affymetrix GeneChip Zebrafish Array. They studied responses in larval zebrafish aged 3 days (72 h) to 7 days postfertilization after exposure to two different dose levels of two serotonin reuptake inhibitors (fluoxetine hydrochloride or sertraline hydrochloride). Having more than one compound to study and including two doses and two time points are positive aspects that should allow the investigators to identify strongly associated gene expression changes. The authors, however, concluded that they had identified biomarkers of serotonin reuptake inhibitors, but without additional compounds (both predicted actives and non-actives) it is impossible to assess the specificity of their proposed biomarkers. In another very detailed study that investigated sublethal methyl mercury toxicity in embryo/larval zebrafish using many different approaches, Ho et al. (2013) not only performed DNA microarrays to identify changed genes but also confirmed those using quantitative reverse transcription polymerase chain reaction (RT-qPCR) and then followed with in situ expression analyses to delineate the tissue- and region-specific responses. In doing so they found that even within the central nervous system, the in situ expression changes varied across regions, reinforcing some of the negative aspects of performing whole-animal analysis of any biochemical change. In other words, if the entire animal is analyzed for expression changes, a very focused change in one small area may be missed because of the "dilution" effect of the rest of the animal. Instead of individual genes, another approach is to assess gene network perturbation. Using reverse transcription polymerase chain reaction (RT-PCR), Liu et al. (2013) related the toxicity of two organophosphate ester flame retardants on six gene networks that involved aryl hydrocarbon receptors, peroxisome proliferator–activated receptor alpha, estrogenic receptors, thyroid hormone receptor alpha, glucocorticoid receptor, and mineralocorticoid receptor–centered gene networks. An especially important control in the study was defining what network perturbation looked like using chemicals that would be considered positive controls for each of the networks. In one of the few papers to assess the toxicity of multiple chemicals,

Weil et al. (2009) analyzed the expression of a few ($n = 7$) sentinel genes, correlating gene expression changes with the chronic toxicity of 14 different chemicals. In general, there was a very good correlation between the two endpoints and, interestingly, expressions of *cyp1a*, *hmox1* (heme oxygenase [decycling] 1) were two of the most sensitive biomarkers of toxicity. In this case, however, *hsp70* was not a sensitive biomarker. This approach of maximizing the number of chemicals while limiting the number of genes appears to be a viable avenue for biomarker identification.

Realizing that developing biomarkers of toxicity in zebrafish appears to still be in its infancy, it may be worthwhile to ponder exactly what would be needed to establish an accepted and useful biomarker of toxicity in zebrafish. As mentioned above, one of the most important aspects of developing a biomarker would be to test a large chemical space to determine the diagnostic and predictive values of any given biomarker. In addition, combining biomarker development to mechanism discovery is also an attractive approach. An interesting example of this type of approach is a recent investigation of the toxicity of cholinesterase inhibition in developing zebrafish (Klüver et al., 2011). In this study, the investigators assessed gene expression changes in young zebrafish larvae exposed to one acetylcholinesterase inhibitor (azinphos-methyl) and two noninhibitors (1,4-dimethoxybenzene and 2,4-nitrophenol). They found that small heat shock protein (*hspb11*) expression was the most sensitive biomarker of exposure to an acetylcholinesterase inhibitor. They followed this observation with other studies that allowed them to conclude that *hspb11* may not only be a sensitive biomarker of developmental exposure to acetylcholinesterase inhibitors but also that it is involved in muscle development in zebrafish. Although this is a powerful study because it employed both positive and negative compounds, follow-up investigations assessing many more chemicals (both inhibitors and noninhibitors) would provide more convincing evidence of the utility of *hspb11* as a biomarker of anticholinesterase toxicity. Moreover, it must be noted that, at least in this case, cholinesterase inhibition was also a sensitive biomarker of exposure to azinphos-methyl.

AN EXAMPLE OF AN ESTABLISHED BIOMARKER: VITELLOGENIN

Are there any examples of moderately well-established biomarkers of toxicity in zebrafish and biomarkers that are relatively specific and predictive? A review of the literature (e.g., Marin and Matozzo, 2004; Scholz and Mayer, 2008) indicates that vitellogenin may be a predictive and specific biomarker for endocrine disruption.

Vitellogenin(s) is a family of glycolipoproteins that are precursors to the egg yolk protein found in a mature egg. Under hormonal control, vitellogenin is normally produced in the female liver and then transported via the blood to the maturing oocytes for packaging in the yolk (Lubzens et al., 2010). Changes in vitellogenin protein expression, message, or even DNA methylation status have been associated with exposure to endocrine-disrupting chemicals (Nilsen et al., 2004; Tong et al., 2004; Hoffmann et al., 2006; Kausch et al., 2008; Strömqvist et al., 2010; Dang et al., 2011). In their extensive review (Dang et al., 2011) comparing various endpoints (including vitellogenin changes) and biomarkers of endocrine disruption, it was concluded that vitellogenin was one of the three most sensitive endpoints in zebrafish tests for endocrine disruptors; the other two were measures of fecundity and gonad histology. In most of these assays, male zebrafish are exposed to putative endocrine-disrupting chemical(s) with assessment of vitellogenin induction in the liver. Given that the levels of vitellogenin are close to nothing in the normal male liver, this assay for endocrine disruption has a wide range of sensitivity. There has also been an effort in the last 5−10 years to use induced vitellogenin expression at much younger ages to assess endocrine disruption. In this manner, endocrine disruption may be incorporated into commonly used, short-term developmental assessments of toxicity in zebrafish. An example of this type of study (Muncke and Eggen, 2006) assessed *vitellogenin 1* mRNA expression in control and 17α-ethinylestradiol (EE2; 100, 1000, or 2000 ng/L; 0.34, 3.37, or 6.75 nM)−treated embryos at 24, 48, 72, 96, and 120 hours postfertilization (hpf) normalized to

the expression of a housekeeping gene (β-actin) over time. Through the use of important additional controls, the authors found that the expression of β-actin was stable from 24 to 120 hpf and also noted that the 17α-ethinylestradiol treatment did not change the levels of β-actin. 17α-Ethinylestradiol treatment, however, did change *vitellogenin 1* mRNA expression levels (Fig. 5.1) at all ages except the youngest (24 hpf). Moreover, even larvae as young as 72 h were capable of mounting significant induction of *vitellogenin 1* at the lowest nominal concentration of 17α-ethinylestradiol tested, and it appears that the 120-h-old larvae would be capable of responding to even lower concentrations of this endocrine active chemical. This pattern of response supports the use of young embryos as sentinels for some endocrine-disrupting chemicals.

In an example that illustrates the specificity of vitellogenin as a biomarker and also demonstrates how increasing the chemical space for an assay focuses the biomarker universe, Kausch et al. (2008) surveyed the gene expression overlap for three estrogenic compounds: 17β-estradiol (E2), bisphenol A, and genistein. Interestingly, although all three compounds are known to be estrogenic, there was very little overlap in their gene expression profiles (Fig. 5.2). In fact, only five genes were altered by all three compounds, and all of them encode vitellogenin in zebrafish, prompting the authors to conclude that "these genes are the only suitable markers for exposure to different estrogenic compounds," meaning that the only biomarker that was reliably changed by all three estrogenic compounds was vitellogenin. If the authors had only used two instead of three chemicals to assess the overlap and
FIGURE 5.1 Expression of *vitellogenin 1* (*vtg1*) relative to β-actin in zebrafish embryos of different ages (hours postfertilization; hpf) treated with 17α-ethinylestradiol (EE2). * Indicates significant difference from the concurrent control. *Data are redrawn from Figure 4 of Muncke, J., Eggen, R.I., 2006. Vitellogenin 1 mRNA as an early molecular biomarker for endocrine disruption in developing zebrafish* (Danio rerio)*. Environ. Toxicol. Chem. 25, 2734−2741.*
FIGURE 5.2 Venn diagram of the up- and downregulated ETs (i.e., expressed transcripts: open reading frames that are part of known genes) and TCs (i.e., tentative consensus sequences; open reading frames that show homologies to genes) in animals treated with the E2 (17β-estradiol), bisphenol A, or genistein. The first number indicates all regulated ETs and TCs. The numbers in brackets indicate the number of ETs. The overlapping areas represent the number of TCs and ETs that are regulated by two or all three chemicals. *Reproduced with permission from Figure 3 of Kausch, U., Alberti, M., Haindl, S., Budczies, J., Hock, B., 2008. identify possible biomarkers of estrogenicity, their conclusions would have been very different as 17β-estradiol and genistein perturbed 45 common genes.

CAUTIONS

A review of the zebrafish biomarker literature reveals that there are many variables that influence the expression of any given biomarker, and the investigator must be aware of these variables and understand how they can affect the changes in a biomarker of toxicity.

1. Time: The time after dosing or the duration of dosing can affect whether a biomarker is different from control and in some cases the direction of change. It has been demonstrated that different biomarkers show different time courses of change, so one biomarker of toxicity does not predict the time course of other biomarkers (Hoffmann et al., 2006; Senger et al., 2006; Sancho et al., 2010; Pavagadhi et al., 2012).
2. Dose (Concentration): Dose has a powerful influence on biomarker expression, and, interestingly, there are many exceptions to a linear dose–response relationship. Nonmonotonic dose–response relationships are often reported. Both inverted

U- (Hoffmann et al., 2006; Chen et al., 2011; Feito et al., 2012; Gündel et al., 2012; Hung et al., 2012; Pavagadhi et al., 2012) and U (Chen et al., 2011)-shaped dose–response relationships have been noted. In many (but not all) cases, an inverted U pattern in dose and response is noted as overt toxicity is approached. Under these circumstances, an increase in the biomarker is noted at the nonovertly toxic concentrations, but as overtly toxic doses are reached, biomarker expression decreases as the animal becomes moribund.

3. Tissue: In some instances, the tissue of origin for the biomarker also determines the pattern and degree of biomarker expression. For example, the expression pattern of vitellogenin or estrogen receptor genes (Islinger et al., 2003) or the degree of DNA methylation of the *vitellogenin 1* gene (Strömqvist et al., 2010) after 17α-ethinylestradiol exposure is highly tissue-specific. In their in situ hybridization analysis of the gene expression changes of zebrafish treated with methyl mercury, Ho et al. (2013) provide an elegant visual demonstration of the marked differences in tissue biomarker responses. To complicate the issue further, the shape of the dose–response relationship, the time course, and the lowest effective dose may vary among tissues (Pavagadhi et al., 2012).
4. Sex and Age: Investigators should be cautioned not to extrapolate automatically biomarker patterns from one sex to another or from one age to another. It has been demonstrated that the protein expression patterns of adult male and female zebrafish treated with prochloraz (imidazole fungicide) are markedly different, with very little overlap between the sexes (Biales et al., 2011). In assessing the effects of chromium exposure on three biomarkers (cholinesterase, glutathione-S-transferase, and lactate dehydrogenase) in larval and adult zebrafish, it was noted that, in general, larval zebrafish showed more biomarker perturbation at lower nominal concentrations of chromium (IV) (Domingues et al., 2010) (Table 5.1) than adults. The same general pattern was noted in a study (Jin et al., 2009b) of genes coding for vitellogenin and estrogen receptors in four different ages of zebrafish (embryo, larval, juvenile, and adult) exposed to 17β-estradiol or nonylphenol: the younger animals showed increased sensitivity (i.e., lowest effective concentration), whereas the older animals tended to show a higher magnitude of induction. One very important variable that was not controlled for or even assessed in any of these studies was bioavailability of the compound—differences in internal dose due to sex or age may help explain some of the differences.
5. Animal Husbandry: Jin et al. (2009a) provide data demonstrating that photoperiod and ambient

temperature influenced the transcription levels of estrogen-responsive genes in adult male zebrafish. In general, longer photoperiods and higher temperatures produced increased levels of induction, but shorter photoperiods and lower temperatures produced more sensitive responses (i.e., lowest effect concentrations). Animal husbandry variables are generally not recognized for the power they may exert over the results of investigations into biomarkers of toxicity or exposure.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Current efforts to develop biomarkers of toxicity in zebrafish appear to be disorganized and incomplete. The only biomarker that appears to have been tested with multiple compounds in multiple laboratories is vitellogenin, and vitellogenin induction can be regarded as a biomarker for estrogenic compounds. As the zebrafish toxicological community moves forward with the identification of other biomarkers of toxicity, there is a need for rigorous testing to establish the sensitivity and specificity of all proposed biomarkers.

Cincinnati Medical School, Cincinnati, OH, United States

INTRODUCTION

Biomarkers are important clinical and diagnostic tools for determining and staging human disease or exposure to toxic substances. Monitoring changes in biomarkers also provides a way to determine if dietary or pharmacological interventions are also improving (or worsening) pathology progression. It is often challenging, however, to both develop and assess how experimentally induced changes in their levels may positively or negatively affect general human physiology. The difficulty is partially due to the complexity of human organ systems. Thus, much simpler organisms are routinely used to develop and evaluate the significance of important potential biomarkers. Although the transparent nematode *Caenorhabditis elegans (C. elegans)* has been used for decades in the field of developmental biology (Brenner, 1974), it is only within the last 10–15 years that its use has gained prominence across other disciplines (Leung et al., 2008). For example, *C. elegans* has been used to screen neurotoxic compounds (Avila et al., 2012), assess cellular respiration (Koopman et al., 2016), and investigate the efficacy of potential therapeutic drugs (Ma et al., 2018).

The growing popularity of *C. elegans* partially relates to the fact that their simple anatomical and physiological organization, as well as their genome, is closely related to that of humans (Silverman et al., 2009; Varshney et al., 2011). In fact, between 40% and 75% of human genes identified as important in disease progression or etiology (Calahorro and Ruiz-Rubio, 2011; Corsi, 2006) or those related to aging (Sutphin et al., 2017) have analogs in *C. elegans*. In addition, data suggest that even stem cell populations in these worms are similar to those found in humans and other, more evolutionarily advanced, organisms (Joshi et al., 2011; Morgan et al., 2011). Along with the ease with which their genome can be manipulated (Fay, 2006), *C. elegans* possesses several characteristics that make this worm an exceptionally versatile and useful model organism. These characteristics include the following: small size, short life span, transparent bodies, and self-fertilizations (Blaxter, 2011; Brenner, 1974).

As clinical medicine and drug development move toward genetic classification of disease subtypes, and both personalized medicine and pharmaceutical therapies, the need for a robust model organism in which potential biomarkers can be assessed is pressing. The focus of this chapter is to demonstrate how markers of oxidative stress and mitochondrial inhibition, found in a number of human diseases, can be monitored *in vivo* in *C. elegans*. While not meant to be exhaustive in nature, the goal is to provide information regarding how *C. elegans* can be and is being used to elucidate biochemical pathways involved in diseases, what the potential physiological roles for these biomarkers are, and how further insight may benefit research and clinical communities.

C. *ELEGANS* AND BIOMARKERS

In the 1970s, Dr. Sydney Brenner proposed to the scientific community that *C. elegans* be used as a model organism to study genetics associated with development (Brenner, 1974; Sulston and Brenner, 1974). Many reasons for proposing these worms as a new model organism were very pragmatic: huge quantities could be

grown in a short period of time; multiple generations could be produced within days or weeks; a suitable food source (*Escherichia coli*) was easy to obtain and maintain; they could be grown in Petri dishes at a variety of temperatures; the total number of cells in the organism (959 cells, of which 302 are neurons, in the hermaphrodite) made it easy to determine cellular etiology and fate; its transparency facilitated light microscopy of gross internal structures and physiological processes; transparency also rendered it ideal for labeling endogenous proteins with fluorometric tags (e.g., green fluorescent protein [GFP]); the nervous system was quickly mapped (Ward et al., 1975; White et al., 1976); and many homologs and orthologs are evolutionarily conserved through humans (Shaye and Greenwald, 2011).

As work with *C. elegans* progressed, the developmental etiology of each individual cell was mapped and published (Sulston, 1988). Later, complete neural circuitry and connectivity was determined (Chalfie and White, 1988). In more recent years, as genetic information became increasingly important for understanding development and disease risk or disease progression, it was a momentous step forward when the worm's entire genome was determined and published (Consortium, 1998). This latter achievement alone permitted the research community to begin to easily manipulate its genome (*i.e.*, formation of *gfp* constructs, development of knockout animals, and insertion of human genes). More recently, it was in *C. elegans* that microRNAs were discovered (Sharp, 1999). As such, it became plausible to generate "conditional knockout" animals by feeding them small interfering RNA (siRNA) sequences, via specifically engineered *E. coli*, to target individual genes at precise times during the life cycle. More recently, protocols have been developed that enable researchers to easily modify the genome of *C. elegans* using clustered regularly interspaced short palindromic repeats (CRISPRs)/CRISPR-associated protein-9 (Cas-9) technologies (Farboud, 2017; Prior et al., 2017).

Once the human genome was sequenced, it then became possible to align genetic sequences from both species to expand our knowledge of homologous and orthologous genes in these worms. Thus it was feasible to search for and compare gene sequences (and by extension, protein function) common in both humans, worms, and other model organisms. For example, much of the work associated with cellular apoptotic mechanisms was originally conducted and completed in *C. elegans* (Hengartner and Horvitz, 1994). It was later confirmed that similar pathways existed in higher organisms, including humans.

Perhaps not surprisingly, many laboratories began to work diligently on producing *gene::gfp* constructs,

developing unique knockout strains, and engineering worms with human disease—associated genes. Remarkably, much of the genetic information associated with *C. elegans* is not only published but also readily available. Many of the mutant strains produced by laboratories around the world are archived at the University of Minnesota at the *Caenorhabditis* Genetics Center (http://www.cbs.umn.edu/cgc), a program partially funded by the National Institutes of Health—Office of Research Infrastructure Programs. Here, thousands of strains of *C. elegans* are archived and frozen so that laboratories from around the world can request them for a fee. This provides the opportunity for numerous researchers to benefit from the work of others without duplicating the production of identical strains. In addition, a public database (http://www.wormbase.org) dedicated to proteins and genes of known structure and function is also available through the collaborative work of the "Worm Community." Finally, the Worm Community was one of the first to provide "open access" material through the publication of *WormBook* (http://www.wormbook.org). Each of these valuable resources encourages open exchange of information, protocols, mutant worm and *E. coli* strains, siRNA sequences, and other materials to facilitate research in numerous fields.

As the popularity of this model organism has grown, many high-throughput assays have also been developed that allow researchers to monitor differences in gene and protein regulation and expression as well as document changes in stereotypical movements (Swierczek et al., 2011) following exposure to toxicants. High-throughput screening using complex object parametric analysis and sorting (COPAS) technology and instrumentation allows researchers to analyze and sort large numbers of worms over a short period of time (10—50 worms/s) based on size (Boyd et al., 2010). In addition, many different hybridization gene plates are available to determine whether genes associated with distinct pathways (cellular respiration, detoxication, metabolism, cell cycle, etc.) are altered following xenobiotic treatment. These technologies not only provide the opportunity to assess whether toxicants induce changes associated with a specific disease but also the ability to determine whether pharmacological intervention successfully targets and modulates molecules associated with these diseases.

Although many of the genes and proteins in *C. elegans* are analogous to those found in higher organisms, including humans, it is important to emphasize that the function and/or location of the proteins may not be identical. Furthermore, many of the organs and organ systems found in humans are absent in this model organism. On the other hand, the structural and functional similarities are such that vast insight can be gleaned

from studying human biomarkers in *C. elegans* related to transcriptional and translational regulation, cellular targets, and effects of various xenobiotics on these molecules. As such, this organism can function as a unique model system for mechanistic and high-throughput studies related to biomarkers associated with human disease and toxic exposure.

MECHANISTIC BIOMARKERS

Oxidative Stress Markers

Increased oxidative stress is a nonspecific marker associated with numerous diseases and toxic insults. It is often accompanied by mitochondrial inhibition because of the increased production of reactive oxygen species (ROS) resulting from inhibition of electron transport chain enzyme complexes. Oxidative stress is often associated with metal toxicity, particularly Fe, Mn, Cu, Co, and Ni, due to the fact that they can participate in the Fenton reaction (Fig. 6.1).

Pesticide toxicity (e.g., organophosphates, rotenone, paraquat, mancozeb) and numerous diseases (Parkinson's disease [PD], amyotrophic lateral sclerosis, cardiovascular disease, stroke) are other factors associated with increased oxidative stress. It is fairly common to use fluorometric and colorimetric probes in cell culture and other *in vivo* model systems to measure the presence of ROS and/or reactive nitrogen species (RNS). In humans and other animals, however, protein adducts (Mseddi et al., 2017), DNA adducts (Mazlumoglu et al., 2017), and lipid peroxidation products (Tsikas, 2017) are frequently measured in blood, urine, cerebrospinal fluid, and other biological samples. Fortunately, all of these products can also be measured in *C. elegans*. As such, this can facilitate moving from *C. elegans* to other, more complex, organisms and then back to worms. For example, dihydroethidium (DHE) has been successfully used to assess increased oxidative stress (Chikka et al., 2016). Other laboratories have combined results from multiple assays using DHE, 10-acetyl-3,7-dihydroxyphenoxazine, and hydroxyphenyl fluorescein (Fig. 6.2) to try to delineate the principal ROS formed in *C. elegans* following exposure to various pesticides (Bailey et al., 2017). Data from these probes

can also be generated quite rapidly and simply because *C. elegans* is transparent. Results, then, can be used to directly guide studies in higher organisms regarding ROS and/or RNS production.

Oxidative stress, however, is typically accompanied by increased transcription and translation of antioxidant genes. Because antioxidant and detoxication proteins have different affinities for various oxidative stress molecules, it is often important to determine the genes and proteins involved in detoxication and repair following a toxic insult. To assess this, many laboratories have created transgenic worms with a gene::fluorescent protein construct. Thus, studies designed to determine whether *superoxide dismutase* (*sod*) transcription is upregulated could treat transgenic worms with *sod::gfp* instead of wild-type (N2) worms. In the presence of increased superoxide production, requiring *sod::gfp* transcription and translation to aid in detoxication, treated worms would have greater green fluorescence than that of controls. But *C. elegans* also have other antioxidant proteins—catalase, peroxidase, glutathione-*S*-peroxidase, and heat shock proteins. All of these can be tagged with GFP to monitor differential expression of the various protective genes. Other laboratories have developed transgenic worms with GFP-labeled proteins that are responsible for regulating entire oxidative stress pathways. For example, the nuclear respiratory factor (NRF), designated SKN (**skin**head) in worms, is upstream of many proteins involved in regulating and extending life span. This regulation is thought to be partially related to the ability of NRF (SKN) to increase transcription and translation pathways of other proteins involved in oxidative/general stress responses (An and Blackwell, 2003; Benedetto et al., 2010). Finally, fluorescently labeled worm strains are even available to monitor the *in vivo* production of cytochrome P450 proteins (Table 6.1).

For studies involving toxicant exposure, the aforementioned techniques can be combined to determine (1) whether oxidative stress is increased, (2) which biomolecules are the primary targets (proteins, nucleic acids, or lipids), and (3) the identity of proteins involved in detoxication. On the other hand, numerous deletion mutants, RNA interference sequences, or CRISPR/Cas 9 target sequences are also available (or can be synthesized) to assess what happens to ROS or RNS production in the absence of detoxication enzymes. Conversely, if therapeutic compounds are being screened to determine efficacy, these same endpoints can be used to assess whether pharmacological intervention was successful. Furthermore, worms mature from egg to egg-laying adults in 2 to 3 days, depending on the temperature, and live for an average of 20–24 days. Therefore, it is possible to assess how exposure to toxicants at different life stages may adversely affect oxidative stress,

$$Fe^{3+} + O_2^{\bullet-} \rightarrow Fe^{2+} + O_2$$
$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + {}^{\bullet}OH$$
$$\overline{O_2^{\bullet-} + H_2O_2 \rightarrow OH^- + {}^{\bullet}OH + O_2}$$
$$Fe^{3+}$$

FIGURE 6.2   Structure of common fluorescent oxidative stress probes that can be used in *Caenorhabditis elegans*. (A) Dihydroethidium; (B) 10-acetyl-3,7-dihydroxyphenoxazine; and (C) hydroxyphenyl fluorescein. *(A–C) Photo by Unknown Author is licensed under CC BY-SA.*

antioxidant gene response, or detoxication (P450) gene response. While the results should be confirmed in higher model organisms, this approach permits a much faster screening, potentially over multiple generations, than is currently possible with more traditional animal models.

Mitochondrial Markers

As is the case with oxidative stress, many environmental toxicants and human diseases result in, or are marked by, mitochondrial inhibition. The target could be one of the electron transport chain complexes, as in the case of rotenone (Hoglinger et al., 2003), or enzymes in the citric acid cycle, as with Mn (Crooks et al., 2007). On the other hand, it is well-documented that mitochondrial inhibition is associated with numerous diseases, from glaucoma (He et al., 2008) and PD (Betarbet et al., 2006) to nonalcoholic fatty liver disease (Berge et al., 2016). As such, many researchers are concerned about whether exposure to their compounds of interest also promotes mitochondrial inhibition.

As with oxidative stress, many probes and markers used in cell culture can also be valuable in assessing endpoints in *C. elegans*. For example, tetramethylrhodamine ethyl ester (TMRE) and similar fluorophores have long been used to assess the integrity of the mitochondrial transmembrane proton gradient ($\Delta\Psi$). This positively charged dye crosses the mitochondrial membranes and accumulates within mitochondria. Although TMRE is predominantly used as a marker of $\Delta\Psi$, some have shown that its accumulation also correlates to mitochondrial fusion and fission events (Twig et al., 2008), cytochrome *c* release, and apoptosis (Crowley et al., 2016). In addition to using fluorescent probes, protocols exist that permit researchers to assess how well individual complexes in the electron transport chain are able to accept electrons. In these studies, colorimetric compounds that function as electron carriers and change color following oxidation or reduction can be used to determine whether complex II or complex IV is fully functional and able to participate in redox reactions (Grad et al., 2007). These protocols require that worms are permeabilized and fixed before incubation with the

TABLE 6.1   *Caenorhabditis elegans* Strains With GFP-Labeled Proteins Associated With Antioxidants and Detoxication Enzymes

Human Gene	Strain	Genotype
Superoxide dismutase	SD1746	muIs84 [sod-3p::GFP + rol-6(su1006)]. GFP should be visible at low magnification.
Superoxide dismutase	CF1580	muIs84 [(pAD76) sod-3p::GFP + rol-6(su1006)]. Green expression in head, tail, and around vulva.
Catalase	GA800	wuIs151 [ctl-1(+) + ctl-2(+) + ctl-3(+) + myo-2p::GFP].
Glutathione-*S*-transferase	CL2166	dvIs19 [(pAF15)gst-4p::GFP::NLS] III. Oxidative stress-inducible GFP.
Glutathione-*S*-transferase	CL691	dvIs19 [(pAF15) gst-4p::GFP::NLS] III. Oxidative stress-inducible GFP.
Heat shock protein	AGD926	zcIs4 [hsp-4::GFP] V. uthIs269 [sur5p::hsf-1::unc-54 3′UTR + myo-2p::tdTomato::unc-54 3′ UTR]. ER stress resistance.
Heat shock protein	CF2962	muEx420 [hsp-12.6p::RFP(NLS) + odr-1p::RFP].
Nuclear respiratory factor (nrf)	GR2198	mgTi1 [rpl-28p::skn-1a::GFP::tbb-2 3′UTR + unc-119(+)] I. Expresses SKN-1A with C-terminal GFP tag.
CYP3A4	SRU1	unc-119(ed3) III; jrsIs1 [cyp-13A7p::GFP + unc-119(+)].

All strains in the table are available from the *Caenorhabditis* Genetics Center (CGC). *GFP*, green fluorescent protein.

respective reagents, which would preclude intervention with putative therapeutics and further analysis. Other methods for determining mitochondrial inhibition that easily lend themselves to real-time and longitudinal studies involve using traditional oxygen consumption studies with Clark's electrode (Bailey et al., 2017), or using the Seahorse metabolic analyzer (Luz et al., 2016). One advantage to the latter two methods is that extensive data exist in isolated mitochondria, cells, and tissues, which makes it easier to compare results in *C. elegans* and facilitate translation into other model organisms.

Closely associated with mitochondrial dysfunction is mitophagy, or the process of removing damaged mitochondria from the cytoplasm through the proteasome. Although mitophagy, as well as proteasomal elimination of other damaged organelles and proteins, is part of normal cellular "housekeeping," dysregulation can lead to increased cell death. Conversely, maintenance of mitophagy is required to extend the life span in many model organisms, including *C. elegans* (Lionaki et al., 2013). As more is understood about this important process, its regulation, and how it contributes to neurodegeneration and aging, researchers are looking for ways to assess this in vivo during both normal aging and disease states following toxicant exposure. Again, various fluorescent probes originally designed for cell culture have found their way into *C. elegans* research. For example, worms can be incubated in MitoTracker Green to facilitate the mitochondrial visualization (Dingley et al., 2010). Alternatively, fluorescent-tagged proteins associated with mitophagy have been labeled

in transgenic worm strains (Table 6.2). This latter approach allows researchers to treat worms with toxicants suspected of modulating mitophagy and then visually determining whether the respective treatment had any effect on this process. On the other hand, these strains could also be used to assess whether potential therapeutic interventions reversed abnormal mitophagy.

NEURODEGENERATIVE DISEASES AND GENE–ENVIRONMENT INTERACTIONS

Recent advances in the fields of genome sequencing and bioinformatics have enabled the scientific community to more easily examine gene–environment interactions in the context of major diseases. This approach is particularly attractive to those studying chronic neurodegenerative diseases that lack obvious Mendelian inheritance, or consistent links to toxicant exposures. Thus, many researchers now consider the possibility that these diseases result from "multiple hits" (Fig. 6.3). These "hits" could be the (1) presence of a "susceptibility gene" that renders a person more vulnerable to an environmental exposure, (2) exposure to two (or more) chemicals that target the same organelle (i.e., mitochondria) or work via the same mechanism (i.e., oxidative stress), or (3) multiple genes working in concert with each other to adversely affect a specific cellular process (i.e., autophagy). The literature linking environmental toxicants to neurodegenerative diseases is rather compelling in the cases of mitochondrial inhibition

TABLE 6.2 *Caenorhabditis elegans* Strains With Fluorescence-Labeled Proteins Associated With Autophagy

Human Gene	Strain	Genotype
Microtubule-associated protein 1 light chain 3 (MAP-LC3)	DLM1	uwaEx1 [eft-3p::CERULEAN-VENUS::lgg-1 + unc-119(+)]. Labeled autophagy marker (LGG-1 in worms) is expressed with protein required for embryogenesis and the germline development.
Microtubule-associated protein 1 light chain 3 (MAP-LC3)	DLM10	uwaSi5 [myo-3p::CERULEAN-VENUS::lgg-1 + unc-119(+)] II. LGG-1 tagged with oxCerulean–oxVenus double fluorescent protein (dFP) for monitoring autophagy in body wall muscle.
Microtubule-associated protein 1 light chain 3 (MAP-LC3)	DLM11	uwaEx6 [rab-3p::CERULEAN-VENUS::lgg-1 + unc-119(+)]. Lgg-1 tagged with oxCerulean–oxVenus double fluorescent protein (dFP) for monitoring autophagy in neurons.
Microtubule-associated protein 1 light chain 3 (MAP-LC3)	MAH215	sqIs11 [lgg-1p::mCherry::GFP::lgg-1 + rol-6]. Tandem-tagged autophagy reporter strain.
Microtubule-associated protein 1 light chain 3 (MAP-LC3)	YQ243	wfIs232 [app-1p::mCherry::H2B::unc-54 + unc-119(+)]. mCherry::H2B expression in the nuclei of intestinal cells.
Phosphatase and tensin homolog (PTEN)–induced kinase 1 (PINK1)	AGD926	byEx655 [pink-1p::pink-1::GFP + myo-2p::mCherry + herring sperm DNA]. Pink-1 translational GFP fusion generated by cloning the complete pink-1 genomic fragment.

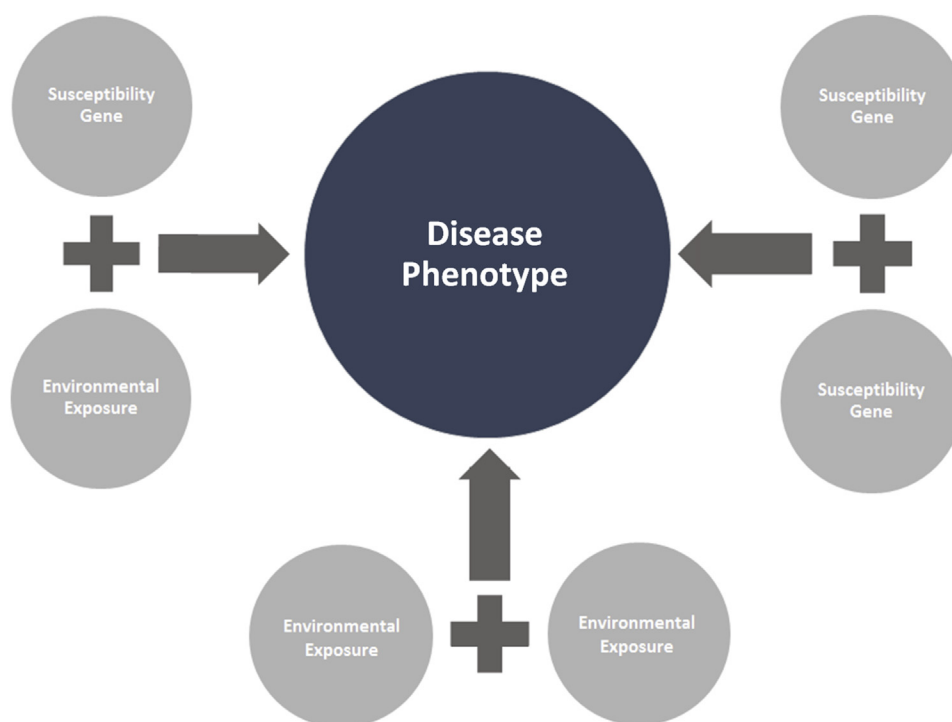
All strains in the table are available from the *Caenorhabditis* Genetics Center (CGC).


FIGURE 6.3　Multi-hit hypothesis. This figure depicts various ways, based on a multi-hit hypothesis, that a person could ultimately manifest a disease phenotype.

and increased oxidative stress, which are not unique, however, to neurodegeneration. Because *C. elegans* (1) have many genes that are homologous or orthologous to human genes, (2) are easily manipulated to create deletion mutants, (3) can have human disease—related genes inserted, and/or (4) can be assessed with methods routinely used in cell cultures and mammals, these worms provide a unique high-throughput opportunity to determine how genes, toxicants, or potential therapeutics alter biomolecules or cellular pathways.

Alzheimer's Disease

Alzheimer's disease (AD) is the most common neurodegenerative disease in the United States, affecting almost six million people. Despite being multifaceted, the disease is most commonly associated with memory loss and a diminished ability to engage in complex thought processing and analysis. Because AD is highly correlated with aging, it is likely that the number of cases of AD will continue to increase substantially as people live longer. The causes of AD are not well understood, but some studies suggest that people who engage in abundant social, physical, and mental activities are less likely to be diagnosed with or suffer from AD (or even age-related dementia) than those who do not (Qiu et al., 2009). Unfortunately, current treatments focus predominantly on slowing the disease progression. Tragically, there is no known cure.

The pathology of AD is well documented (Calderon-Garciduenas and Duyckaerts, 2017). At autopsy, neurons, particularly those in the prefrontal cortex, frontal cortex, and temporal lobe, show an increase in intracellular β-amyloid plaques (Aβ) and phosphorylated tau (p-tau). This results in intraneuronal tangles that compromise the neuron's anatomical and physiological integrity (Mattsson et al., 2012; Revett et al., 2013). The Aβ responsible for plaque formation results from abnormal cleavage of amyloid precursor protein (APP). Tangles, another pathological hallmark of AD, are formed when hyperphosphorylated tau aberrantly interacts with microtubule proteins. Both Aβ plaques and tau tangles are thought to ultimately lead to neuronal death. Although mutations in APP, presenilin 1 (PSEN1), and PSEN2 account for 6%—8% of early-onset AD diagnoses, the etiology of the vast majority of AD cases is unknown (Patterson et al., 2008). Increased plasma levels of Aβ have been observed in families with AD, people with mutations in APP, PSEN, or those who have Down's syndrome (Irizarry, 2004). Although work is rapidly progressing to bring AD-specific biomarkers to the clinic (Henriques et al., 2018; Scarano et al., 2016), longitudinal studies are required to determine how these biomarkers change over time in the presence and absence of pharmacological intervention.

Fortunately, the simplicity of the nervous system of *C. elegans* has been able to help researchers identify

mechanisms and protein interactions involved in AD. Biomarkers with a demonstrated link to this disease, such as Aβ accumulation, are present in worms. In other cases, the worms can be easily manipulated to include or produce these markers. In addition, many genes associated with AD have orthologs in *C. elegans* (Table 6.3). For example, *C. elegans* express cytoplasmic Aβ$_{3-42}$, which elicits a toxic effect similar to that observed in humans who express Aβ$_{1-42}$ (McColl et al., 2012). Furthermore, incorporating endpoints mentioned in previous sections with AD-specific transgenic worms can increase the screening power available to those in the scientific community. But using *C. elegans* has also resulted in more rapid data generation time (weeks) due to both the short life span and availability of the worm's sequenced genome. Furthermore, 60%–80% of human genes associated with disease phenotypes have been identified in *C. elegans* (Keowkase, 2010). As a result of this sequence knowledge, scientists can more easily target AD genes and proteins of interest in the nematode.

Parkinson's Disease

PD is the second most common neurodegenerative disease in the United States, next to AD. The characteristic

bradykinesia, resting tremor, rigidity, and postural instability typically result when 70%–80% of the dopaminergic neurons in the *substantia nigra, pars compacta*, die. Although PD is predominantly associated with aging, approximately 5%–10% of the cases, many of which are classified as "early-onset," can be attributed to genetic mutations (Rousseaux et al., 2012). On the other hand, head trauma, chronic exposure to various heavy metals (i.e., Fe, Mn), living and/or working in an agricultural environment, and acute exposure to high concentrations of various pesticides (i.e., rotenone, maneb, paraquat) also increase a person's risk of PD or parkinsonism. In general, however, most incidents of PD do not have a clear etiology and are thus referred to as "idiopathic" (Fritsch et al., 2012). As with most neurodegenerative diseases, treatment typically focuses on reducing disease symptoms rather than halting or reversing the actual disease progression. Thus, identification of biomarkers of this disease that would aid early diagnosis would be of benefit to patients and their family members.

Many biomarkers are associated with mutations in both autosomal dominant and recessive genes (Lesage and Brice, 2009). In general, Lewy bodies, predominantly composed of α-synuclein deposits, are seen in

TABLE 6.3 Genes Altered in Alzheimer's Disease and *Caenorhabditis elegans* Analog

Human Gene	Function in Humans	*C. elegans* Genes	Function in *C. elegans*	Location
Tau	Neurofibrils structure	*Ptl-1*	Microtubule-binding protein required for intracellular transportation and stabilization	Microtubules
Dynein, light chain, LC8-type 1 (DYNLL1)	Dynein light chain	*dlc-1*	Cellular transportation	Adult body wall muscle, pharynx, posterior intestine, and nervous system
Kinesin-1	Kinesin heavy chain	*unc-116*, *unc104*	Transportation and localization of vesicles	Neurons
Amyloid-like protein 1/2 (APLP1/2)	Memory	*Ard-1*, *Apl-1*	Molting, morphogenesis, pharyngeal pumping, and progression past L1 larva stage	Neurons, muscles, hypodermis, and supporting cells of larva and adults
Presenilins	Aβ cleavage	*Sel-12*, *Spr-1*, *Spr-5*, *Spe-4*, *Hop-1*	Influential in gonadal, germline, and vulval formation	Within receiving cells, fibrous body-membranous organelles and tubulin in spermatocytes
Amyloid beta (A4) precursor protein-binding, family B, member (2APBB2)	APP signal transduction	*Feh-1*	Embryonic and larval viability; pharyngeal pumping	Pharynx and neuronal subpopulations
Eukaryotic translation initiation factor 6 (Eif6)	Translation initiation factor that prevents association of the 40S and 60S ribosomal subunits	*Eif-6*	Normal growth and cell division, ribosome assembly	Ubiquitous expression in somatic larval and adult tissues

Comparison of genes associated with Alzheimer's disease in humans and their corresponding family members in *C. elegans*. Where possible, putative function is included for the *C. elegans* gene product (Bayer et al., 1999; Blanco et al., 1998; Corneveaux et al., 2010; Grundke-Iqbal et al., 1986; Lazarov et al., 2005; Putney, 2000).

multiple brain regions of PD patients at autopsy. Recessive mutations in *parkin*, *phosphatase and tensin homolog* (*PTEN*)—*induced putative kinase 1* (*pink1*), or *Parkinson disease 7* (*PARK-7* or *DJ-1*) are thought to confer abnormalities in the ubiquitin—proteosome complex and autophagy (Coppede, 2012). Mutations identified in the *leucine-rich repeat kinase 2* (*LRRK2*) gene and parkin result in defective oxidative stress sensors and mitochondrial dysfunction (Fig. 6.4). Fortunately, not only are many of these genes found in *C. elegans*, but, in most cases, they are also actually expressed in the nervous system of the worm (Table 6.4). In addition, like their human homologs and orthologs, they are associated with mitochondria, oxidative pathways, and neuronal integrity (Harrington et al., 2010; Saha et al., 2009). Identifying and characterizing these genes and their protein products is important, and in many cases knocking down or knocking out genes of interest helps determine what effect loss-of-function mutations have on the associated biochemical pathways. Again, by

coupling the genetic tractability of *C. elegans* with endpoints already identified in cell culture, rodents, and humans, the ability to screen for PD-related toxicants and potential therapeutics dramatically increases relative to screening only in mammals.

CONCERNS UNIQUE TO C. *ELEGANS*

For researches who have never used *C. elegans*, there are several husbandry-related issues that are somewhat unique to this model organism. Thus, it is important to maintain good laboratory records, provide detailed protocols in manuscripts, and pay attention to the worm strains and bacterial strains used throughout each study. In this respect, using worms is partially analogous to using cell culture; conversely, worms are intact organisms with all of the complex physiology that accompanies *in vivo* work. Thus, as researchers choose *C. elegans* to complement or inform their work in more traditional organisms, it is important to keep in mind the following: (1) life stage at both the time of treatment and endpoint assessment, (2) data obtained from unique synchronizations, (3) strain characteristics, and (4) environmental control and stability.

As with almost all other organisms, the physiology of worms changes during their various life stages. Furthermore, during the early larval stages, *C. elegans* rely primarily on glycolysis and the glyoxylate cycle for energy production but shift to oxidative phosphorylation during later larval stages and early adulthood (Braeckman et al., 2008). In addition to respiration, control of transcription and translation, apoptosis regulation, and expression of antioxidant and other protective genes also change throughout development and with age. To minimize data variation, worms should be "synchronized," so they are all in the same life cycle. This is often accomplished by lysing gravid worms and isolating eggs for studies requiring large numbers. On the other hand, if relatively few worms are needed, worms in the same life cycle can by physically picked from one plate and moved to a new treatment plate. Synchronization via bleaching to lyse the worms can also minimize any fungal contamination that may be on the plates. Following synchronization, however, care must be taken to ensure adherence to the determined time point when worms will be treated, particularly if they are treated during larval stages. Because they grow and mature so rapidly, changing treatment timing by even an hour may mean that worms have progressed to a different life stage. The same is true for assessing endpoints: a strict time table must be followed and documented in published materials/methods sections to aid in data reproducibility. If longitudinal studies are required, 5′-fluorodeoxyuridine (FUdR) can be
FIGURE 6.4   Genetic mutations leading to mitochondrial damage. (A) Depiction of genes relevant to PD that help protect cells from mitochondrial damage and oxidative stress. (B) When these gene products (proteins) no longer function in familial or early-onset PD, oxidative stress can increase, and mitochondria can be damaged. *PD*, Parkinson disease; *ROS*, reactive oxygen species.

Human Gene	Function in Humans	*C. elegans* Gene	Function in *C. elegans*	Location
Microtubule-associated protein tau (Tau)	Microtubule stabilization	*Pgrn-1*	Regulates clearance of apoptotic cells	Intestinal organelles
Parkinson protein 7 (PARK7/DJ-1)	Speculated to be a redox sensitive molecular chaperone	*Djr-1.1*	May promote stability of the transcription factors SKN-1 or SKNR-1 (homologs of mammalian NFE2L2)	Primarily in the intestine and localizes to the nucleus and the cytoplasm
ATPase type 13A2 (ATP13A2/PARK9)	Inorganic cation transport	*Catp-6, Lagr-1, Ymel-1*	Embryo development; fertility	Pharyngeal muscles
PTEN-induced putative kinase 1 (PINK1/PARK6)	Serine/threonine protein kinase localized to mitochondria	*Pink-1*	Normal response to ROS, mitochondria homeostasis, neurite outgrowth, and brood size	Neurons, musculature, and vulvar tissues in larvae and adults
Leucine-rich repeat kinase 1 (LRRK1)	Unknown, however in mice seem to aid in organogenesis and mutations	*Lrk-1*	Presynaptic vesicles protein	Golgi apparatus
NADH–Ubiquinone oxidoreductase flavoprotein 2	Reducing agent	*F53F4.10*	Facilitates electron transport in the electron transport chain	Predicted to be a mitochondrial protein
PARKIN	Component of a multiprotein E3 ubiquitin ligase complex	*Pdr-1*	Proteasome-dependent degradation of proteins in response to cytosolic and ER stress	Predicted to be cytosolic
Ubiquitin carboxyl-terminal esterase L1 (UCHL1)	Recycling polymeric chains of ubiquitin	*Ubh-1*	Cellular senescence and aging	Predicted to be cytosolic

Comparison of genes associated with Parkinson's disease in humans and their corresponding family members in *C. elegans*. Where possible, putative function is included for the *C. elegans* gene product (Birkmayer et al., 1993; Biskup et al., 2007; Maraganore et al., 2004; Mollenhauer et al., 2006; Weihofen et al., 2008; Zhang et al., 2005).

used to sterilize *C. elegans* and prevent additional egg hatching, which would introduce mixed-aged populations (Lionaki and Tavernarakis, 2013). It is also the case that one unique synchronization is usually considered an interexperimental replicate in *C. elegans* research and should be noted as such in published protocols.

As with most vertebrate model organisms, differences in strains will often lead to differences in results as well. The same is true for *C. elegans*. Although the research strains are derived from the canonical wild-type (Bristol or N2) strain, genetic mutations that make these worms so useful can also change some phenotypes. This should not be surprising, however. In addition, although the vast majority of reproduction in *C. elegans* involves hermaphrodite self-fertilization, which minimizes genetic variability, genetic drift has still been noted (Cutter et al., 2009). To minimize the effect this may have on results, it is good practice to order new stocks from the CGC on a regular basis or to pull up new stocks from those frozen in the research laboratory. This latter process is similar to what is done with cell culture stocks. This process is also important for the bacterial cultures that are used to feed the *C. elegans* because

genetic variation (e.g., gene knockdown via iRNA sequences) can be introduced by feeding worms genetically modified *E. coli*. Maintaining good notes and observing changes in behavior or endpoints will help researchers identify possible changes in the genetics of a strain.

Finally, these worms are very sensitive to changes in their environment. For example, in about 50 h, worms raised at 25°C can move from eggs laid on a plate to adults capable of laying their own eggs (Fig. 6.5). If the temperature is reduced to 16°C, worms will not be mature enough to lay eggs until about 90 h after laying egg (Altun et al., 2002—2010). This means that temperatures must be kept steady throughout a study, so times for treatment and endpoint assessment will take place at the same life stage each time. In a similar manner, the tonicity of the plates, the treatment solutions, and washing solutions should also be carefully monitored. Although the protective cuticle surrounding worms can provide some protection from lysing (in a hypotonic solution) or undergoing crenation (in a hypertonic solution), these osmotic changes will still induce stress in the animal. This stress can adversely affect gene
FIGURE 6.5 Life cycle of *Caenorhabditis elegans* at 25°C. The rate at which *C. elegans* proceed through its life cycle is temperature-dependent, and worms progress faster at higher temperatures. Each stage is shown, along with the corresponding size and cartoon depiction of the way the worm looks under a microscope. *Photo by Unknown Author is licensed under CC BY-SA.*

transcription and translation, which can alter experimental results. With careful monitoring, however, almost all of these confounders can be controlled or even eliminated.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Although humans and *C. elegans* are far removed from each other on the evolutionary tree, they still share remarkable genetic homology and orthology. As such, they are a valuable model organism for studying biomarkers of human disease. Not only does their transparency make it relatively easy to follow protein production using fluorescent tags, but the ease with which their genes can be manipulated through siRNA, CRISPR/Cas 9, the ability to insert relevant human genes, and the rapid production of traditional knockout animals makes them an attractive model organism. Furthermore, their ability to reproduce both hermaphroditically and through male-hermaphrodite fertilization allows for greater control over the introduction of genetic variation than what is available with more commonly used organisms.

C. elegans also has a much shorter life span than other model organisms. This makes it an ideal model for studying diseases associated with aging. On the other hand, it also means that more unique replicates of experiments can also be completed in a shorter period of time, even in studies that do not require "aged" animals. Using *C. elegans* to further characterize and explore the potential usefulness of biomarkers linked to these pathologies, one can significantly reduce the amount of time needed to study the effects of aging. It is also possible to determine if and/or how the expression of those proteins or the regulation of specific genes used as biomarkers may change over the life span of the organism. Such information is important to verify that alterations in biomarker levels or activities are not strictly age related, but predominantly disease related.

Finally, *C. elegans* offers a unique opportunity to study protein and gene regulation in an *in vivo* environment that rivals the ease of use, cost, and genetic manipulation of many *in vitro* systems. As such, these worms can be used to determine whether various pharmaceutical interventions have any positive effect on the concentration or activity of the various biomarkers of interest. This provides a unique opportunity to explore the role of treatments, to a first approximation, in an animal model that has relevance to human disease. Taken together, these examples suggest that *C. elegans* is a useful model organism that should be utilized to a greater extent in the context of biomarkers and human diseases.

INTRODUCTION

Rapid industrialization, unsafe use of agrochemicals, and various anthropogenic activities can introduce several chemicals into the environment. In general, the chemicals can be categorized as pesticides, polychlorinated biphenyls, metals, polycyclic aromatic hydrocarbons, volatile organic compounds, organic solvents, dioxins, complex chemical mixtures, food additives, etc (Martin et al., 2010; Nesatyy and Suter, 2007; Sutton et al., 2012). The production and use of these chemicals are part of the industrial and agricultural revolutions. These chemical—biological interactions produce serious risk to the environment and to human health (Asgari et al., 2017; Cao et al., 2016; Gupta et al., 2017; Jayaraj et al., 2016).

The major chemical hazards share three common features: (1) environmental persistence, (2) tendency of accumulation in living systems, and (3) serious health adversities. Chemicals released into the environment pose hazards to the ecosystem by interacting at population, community, cellular, and molecular levels (del Carmen and Fuiman, 2005; Houlahan et al., 2000). Therefore, assessing the effects of these toxicants on the environment and on humans is one of major biomedical concern. Research in the field of exposure assessment and hazardous identification is undergoing fundamental change due to scientific and technical advancements.

The last two decades have seen interest on the rapid detection of cellular and organismal toxicity for better predictability. Moreover, chronic exposure of environmental chemicals leads to serious health hazards, such as neurological disorders, hepatic and renal problems, and cancer. Therefore, biomarker-based exposure assessment can be used to monitor the toxic effects of chemicals. Biomarkers are the variations at the biochemical, cellular, molecular, and structural level that are measurable in biological samples (Hook et al., 2014). Apart from early and specific chemical toxic assessment, biomarkers also allow a ranking of different exposures in the laboratory and in the field. In addition, the absolute measured effects through biomarkers can be applied to regulatory environmental agencies.

The use of model organisms has always been at the core of toxicology testing to ensure environmental safety. The resultant information forms the hub of our biological knowledge to date. However, relating such laboratory assessment to the ecosystem can only be achieved by investigation with an appropriate group of organisms. Due to similar developmental pathways and gene homology, mammalian or higher models are the "gold standard" in toxicology research. However, due to regulatory, scientific, and ethical concern, an emphasis has been placed on reducing the use of higher mammals for toxicological research and testing (Badyal and Desai, 2014; Doke and Dhawale, 2015). Moreover, toxicology research needs alternative, rapid, and cost-effective methods to improve prediction of human outcomes. The focus has been given to use and develop alternative animal models and techniques in relation to the principles of the 3Rs, *Reduction*: reducing the use of animals for experiments; *Replacement*: developing alternative methods and models for experiments; and *Refinement*: improving the research and testing methods to

preclude pain and discomfort to the organisms wherever possible in biological research (Beekhuijzen, 2017; Festing et al., 1998).

Within the last two decades, various small/nonmammalian/in vitro models have been developed and designed to replace mammalian models to investigate the effects of toxicants. Due to the availability of genomic and proteomic information, short life span, high reproductive capacity, cost-effectiveness, and technical advancement, these models have become more popular. These animals have been employed for toxicity testing at the molecular, cellular, organism, and population levels (Table 7.1 and Fig. 7.1). A number of chemicals have been tested using these organisms (Table 7.2). The focus of this chapter is to discuss the contribution of three major experimental small animal models (*Drosophila melanogaster*, *Daphnia magna*, and *Eisenia fetida*) in toxicity assessment of environmental chemicals.

TABLE 7.1   Biomarkers Used for Toxicity Testing in Small Organisms

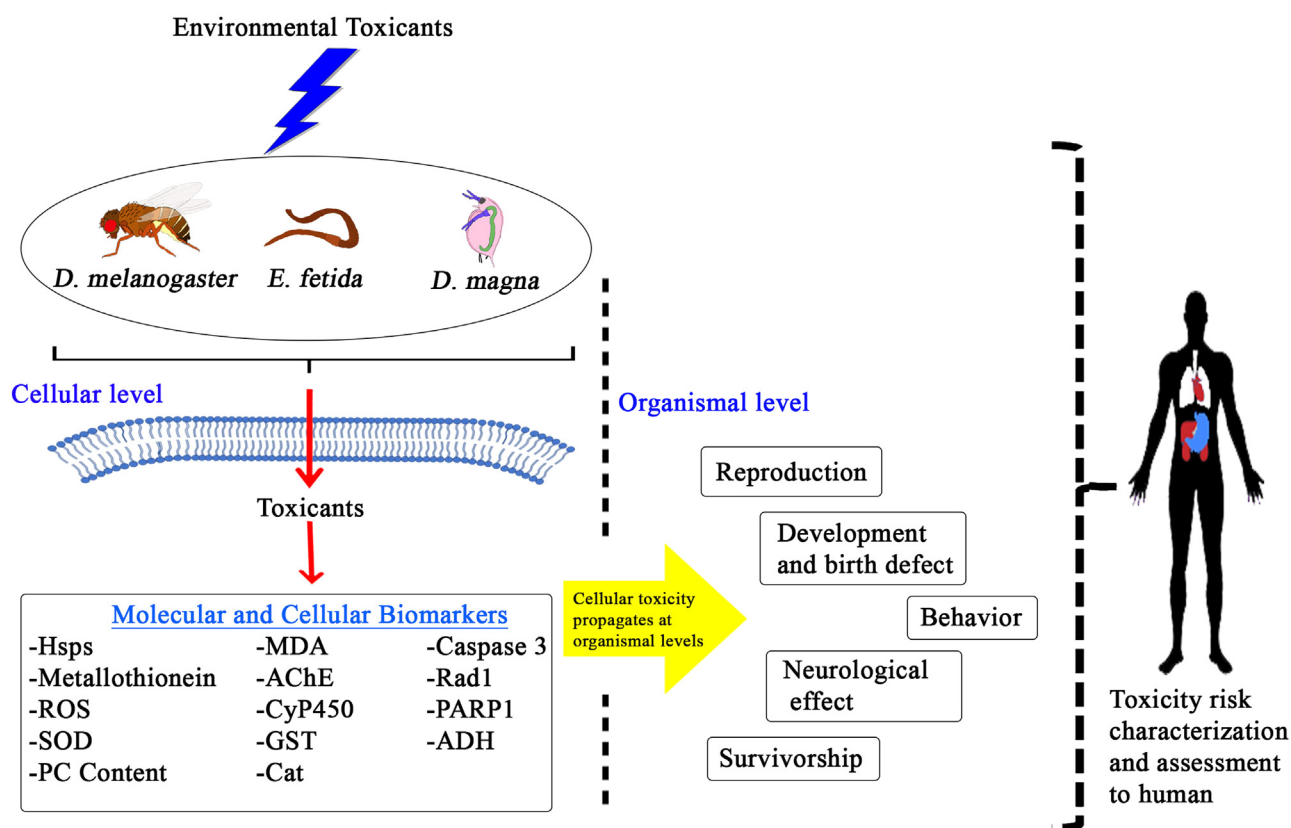
Drosophila melanogaster	*Eisenia fetida*	*Daphnia magna*
MOLECULAR AND CELLULAR BIOMARKER		
Heat shock protein 22, 23, 26, 27, 60, 70, 83	Heat shock protein 60, 70, 72, 90	Heat shock protein 60, 70, 90
Methuselah	Calreticulin	—
Reactive oxygen species	Reactive oxygen species	Reactive oxygen species
Malondialdehyde	Malondialdehyde	Malondialdehyde
Protein carbonyl	Protein carbonyl	Protein concentration
Superoxide dismutase	Superoxide dismutase	Superoxide dismutase
Catalase	Catalase	Catalase
Glutathione	Glutathione	Glutathione
Glutathione peroxidase	Guaiacol peroxidase	Selenium-dependent glutathione-peroxidase
Glutathione S-transferase	Glutathione S-transferase	Glutathione S-transferase
DNA damage check point: *Rad1*, recombination repair protein 1 (*Rrp1*)	DNA repair: poly(ADP-ribose) polymerase	DNA repair (*REV1*)
Dcp1 (caspase 3)	Caspase 8	—
Cytochrome P450: *CYP6d5*, *CYP6a8*, and *CYP12d1*, alcohol dehydrogenase, metallothionein	Calcium hemostasis, metallothionein-2	Linoleic acid, prostaglandins, thromboxanes, metallothionein
Accessory gland proteins	Ecdysone receptor, membrane-associated progesterone receptor, and adiponectin receptor	Methylfarnesoate, estrogen receptor, androgen receptor, and aryl-hydrocarbon receptor
Diptericin, drosomycin, AMP, TOLL, PGRP-LC	AMP, lectins	Lip, Ltb4dh
DEVELOPMENTAL TOXICITY PARAMETERS		
Emergence assay	Growth and mortality	Assessing motility
REPRODUCTIVE PARAMETERS		
Fecundity, fertility, and hatchability	Fertility, cocoon production, and hatching pattern	Fecundity and fertility
NEUROTOXICITY PARAMETERS		
Acetyl-cholinesterase	Acetyl-cholinesterase	Cholinesterase
Jumping and climbing assay	—	Swimming assay
IMMUNOTOXICITY PARAMETERS		
Hemocyte viability and count	Coelomocytes cell viability and count	Hemocyte viability and count
Melanization assay and phagocytosis assay	Phagocytosis assay	Melanization assay


FIGURE 7.1   Schematic diagram showing utility of small organisms in toxicity testing.

TOXICITY TESTING USING SMALL ANIMALS

Drosophila melanogaster

Due to its well-defined developmental biology and genetics, *D. melanogaster* has been used as an in vivo tool in biomedical research. This model has been instrumental in deciphering the pathogenesis of human diseases including aging, cancer, immunity, and some neurodegenerative diseases (Buchon et al., 2014; He and Jasper, 2014; McGurk et al., 2015; Richardson & Kumar, 2002; Rudrapatna et al., 2012; Yadav et al., 2016). Because of its short life span, small size, low maintenance cost, high reproductive capacity, highly conserved genetic architecture, and ease of availability of mutants and transgenic lines, this model has great potential in the assessment of human relevant toxicological pathways. FlyBase (http://flybase.org) is a freely available online database for the biological information of *Drosophila*. *Drosophila* strains (mutants, transgenic, RNAi, Gal4) are also available from four major *Drosophila* stock centers (Bloomington Drosophila Stock Center, Kyoto Stock Center, NIG-FLY, and Vienna *Drosophila* RNAi Center) with nominal charges.

Drosophila *Model in the Prediction of Cellular Toxicity*

Depicting the effect of environmental toxicants at the cellular level is crucial for human risk assessment. Environmental toxicants are different in nature; therefore cellular toxicity could be assessed at varied forms of regulation on different levels. Among the multiple cellular responses, upregulation of heat shock proteins (Hsps) is considered an early toxicity biomarker (Mahmood et al., 2014). Increased Hsps level in the cell prevents protein aggregation and other protein modification (Takalo et al., 2013). However, initially Hsps was discovered by observing puffing in the *Drosophila* salivary gland chromosome due to the elevated temperature (Ritossa, 1962). Apart from an elevated temperature, it is now clear that Hsps can be induced by other stressors including environmental chemicals (Eder et al., 2007; Kim et al., 2014; Mahmood et al., 2014). Hsps are classified into high (90, 70, and 60 kDa) and low molecular (15—30 kDa) weight families, and the Hsp70 family appears most likely to be induced following environmental exposure (Gupta et al., 2010).

Within the last two decades, transgenic *Drosophila* construct containing a lacZ reporter gene fused with a Hsp70 promoter (*hsp70-lacZ*) have been used for quantification of *hsp70* expression in *Drosophila* larvae exposed to

TABLE 7.2   Environmental Chemicals Tested Using Small Organisms

Chemicals	*Drosophila melanogaster*	*Eisenia fetida*	*Daphnia magna*
Heavy metals	Cadmium, chromium, Iron, copper, nickel, lead, zinc, manganese	Nickel, cadmium, zinc, copper, lead	Cadmium, mercury, copper, zinc, chromium
Organochlorine	Endosulfan, dieldrin, lindane, DDT, β-hexachlorocyclohexane	α-endosulfan	Endosulfan
Organophosphate	Acephate, chlorpyrifos, dichlorvos, malathion, fenitrothion, monocrotophos, methyl parathion, azamethiphos, prothiofos, diazinon	Chlorpyrifos, malathion, fenitrothion	Paraoxon, parathion, chlorpyrifos glyphosate and glyphosate-copper complexes, diazinon, dichlorvos
Triazine	Atrazine	Terbuthylazine	Atrazine
Carbamates	Methomyl, carbofuran	—	Carbendazim
Pyrethroids	Cypermethrin, permethrin, deltamethrin	Cyfluthrin, deltamethrin	Deltamethrin
Organic compound	4-vinylcyclohexene, alcohol formaldehyde, acetaldehyde benzene, toluene perchloroethylene, methyl methanesulfonate xylene, bromobenzene, n-butylbenzene, ethylbenzene, p-isopropyltoluene, naphthalene, styrene, 1,2,3- trichlorobenzene, 1,2,4-trichlorobenzene, 1,2,4-trimethylbenzene, and 1,3,5-trimethylbenzene, benzo(a) pyrene,bisphenol, polycyclic aromatic hydrocarbons	Octane, undecane, decane, 3-methyl heptane, 2,4-dimethyl heptane, 3,3-dimethyl octane, 2,2,4,6,6-pentamethyl heptane, 2,4-di tert buyl phenol, benzo(a) pyrene, bisphenol, polycyclic aromatic hydrocarbons, perfluorooctanoic acid, metaldehyde, chloroacetamide, 3,4-dichloroaniline, pentachlorophenol	3,4-dichloroaniline, chlorothalonil, nitrofen
Inorganic compound	Sodium fluoride	—	Ferric oxide
Nanoparticles	Silica nanoparticle, sliver nanoparticle, titanium dioxide nanoparticle	Silver nanoparticle	Diamond nanoparticle, titanium dioxide
Phthalates	Di-(2-ethylhexyl) phthalate	Di-(2-ethylhexyl) phthalate	—
Herbicides	Glyphosate, atrazine, rotenone	Glyphosate, butachlor, clomazone	Glyphosate, atrazine, rotenone
Fungicide	Mercurial fungicide, agallol	—	

various environmental chemicals, such as heavy metals, pesticides, volatile organic compounds, and industrial and municipal waste (Bhargav et al., 2008; Gupta et al., 2005; Kumar et al., 2011; Mukhopadhyay et al., 2003; Nazir et al., 2003; Siddique et al., 2008; Singh et al., 2009).

In addition to *Hsp*70, other members of the *Hsp* family have also been proposed for toxicity testing. Only one class of gene/protein cannot accurately assess the toxicity of a wide range of pollutants (de Pomerai, 1996; Gupta et al., 2010). Significant induction in the other classes of *hsps* such as *hsp83*, *hsp26*, *hsp23*, and *hsp22* in *Drosophila* larvae after exposure to silica nanoparticles, endosulfan, and volatile organic compounds has also been observed (Pandey et al., 2013; Sharma et al., 2012; Singh et al., 2009).

Parallel to Hsps induction, generation of reactive oxygen species (ROS) and modulation in antioxidant capacity of an organism have been used as indicators of cellular toxicity (Birben et al., 2012; Magder, 2006). Excess ROS levels due to toxicants may cause protein, lipid, and DNA damage in the cell, and eventually various disease emergencies (Fulda et al., 2010). As a protective mechanism, organisms have developed enzymatic antioxidants [e.g., catalase (CAT), glutathione peroxidase (GPx), glutathione reductase (GR), superoxide dismutase (SOD)] and nonenzymatic antioxidants [e.g., glutathione (GSH), vitamins C and D] that detoxify ROS (El Golli-Bennour and Bacha, 2011). The *Drosophila* model has been used successfully to assess ROS along with alteration in oxidative stress markers. These

markers include antioxidant enzyme activity (SOD, CAT), GSH-content, lipid peroxidation (LPO), and protein carbonyl (PC) content after exposure to a range of environmental toxicants, such as silica nanoparticles, organophosphate and organochlorine insecticides, industrial and municipal waste, and monocyclic aromatic hydrocarbons (Bhargav et al., 2008; Gupta et al., 2010; Gupta et al., 2007; Pandey et al., 2013; Siddique et al., 2008; Singh et al., 2009).

The immune system is considered the first line of defense against pathogenic organisms. This is a very sensitive system which may be altered by stress factors present in the environment. To investigate Cr(VI)-induced immunotoxicity and its possible mechanism, Pragya et al. (2014) used a Drosophila model system. Exposure to Cr(VI) led to an extreme reduction in hemocyte population due to ROS-induced cell death, which could be rescued by the overexpression of SOD. In addition, Gao et al. (2014) also observed that paraquat-induced oxidative stress led to aberrant differentiation of hemocytes in the lymph gland (Drosophila hematopoietic organ), which could be rescued by overexpression of E-cadherin. Singh et al. (2011) showed the protective effects of curcumin supplementation against benzene-, toluene-, and xylene-induced oxidative stress-mediated cell death in third instar Drosophila larvae.

Cytochrome P450 and GST activities are associated with the detoxification process of xenobiotics and play a vital role in resistance development in the exposed organism (Omiecinski et al., 2011). In Drosophila, the gut, malpighian tubules, and the fat body are major sites for cytochrome P450-mediated detoxifications. Several reports have underlined the upregulation in cytochrome P450 and GST activities in Drosophila exposed to toxicants (Rajak et al., 2017; Sharma et al., 2012; Terhzaz et al., 2015). The metabolic enzymes (CYP6d5, CYP6a8, and CYP12d1) have been involved in the degradation of caffeine (Coelho et al. (2015).

Genotoxicity testing represents an essential component of hazardous assessment of environmental toxicants and the comet assay has been widely used as a genotoxic testing method (Martins and Costa, 2015). Recently, the comet assay has been developed in Drosophila midgut, brain cells, and hemocytes and used to asses genotoxicity of toxicants ranging from industrial and municipal waste, insecticides, volatile organic compounds, food additives, and heavy metals (Carmona et al., 2011; Sharma et al., 2011, 2012; Siddique et al., 2005a; b; 2008, 2009; Gupta et al., 2005; Singh et al., 2011). In addition, DNA repair pathways/enzymes are considered biomarkers for human biomonitoring (Collins and Azqueta, 2012). In this context, the comet assay has been applied to different Drosophila repair-deficient strains to find out affected DNA repair pathways against genotoxic agents such as industrial waste leachates, chromium, and dichlorvos (Mishra et al., 2011, 2014; Siddique et al., 2008).

Prediction of Developmental, Reproductive, and Behavioral Toxicity Using Drosophila melanogaster

Usually acute toxicity tests of short duration are used to extrapolate the safety levels of anthropogenic chemicals (Gormley and Teather, 2003). However, assessing long-term effects on organisms on the basis of these acute tests may be complex and will differ in nature (Roex et al., 2001). Therefore, systematic studies with environmentally relevant exposures of chemicals are required to provide essential information to understand their potential long-term impacts i.e., on development, behavior, and reproduction of the exposed organisms. Developmental toxicity is the study of unwanted effects on the development of an organism which may be the result of exposure to a chemical before conception, during prenatal development, or postnatally. The principal manifestations of developmental toxicity include the following: (1) embryolethality, (2) malformation, (3) growth retardation, and (4) functional deficit (O'Bryant et al., 2011; Sabra et al., 2017; Thompson and Bannigan, 2008; Ueker et al., 2016). A number of studies have shown reduced and delayed emergence pattern, reduced body size, and weight in Drosophila when exposed to environmental contaminants such as organophosphates, organochlorines, herbicides, industrial and municipal solid wastes, and heavy metals during early life stage (Abnoos et al., 2013; Al-Momani and Massadeh, 2005; Bhargav et al., 2008; Gupta et al., 2007; Marcus and Fiumera, 2016; Sharma et al., 2011, 2012 Siddique et al., 2009).

Developmental exposure of Drosophila larvae to endosulfan has been shown to cause hind leg deformities such as truncation and/or fusion of tarsal segments (tarsomeres) in newly emerged flies (Sharma et al., 2012). Interestingly, these leg deformities are reminiscent of those observed in vertebrates (Mobarak and Al-Asmari, 2011). Ranganathan et al. (1987) observed malformation in legs and wings in the ethanol-exposed Drosophila. In another study, methyl-mercury inhibited alcohol dehydrogenase activity, when co-administrated with alcohol to Drosophila during the developmental period (Chauhan and Chauhan, 2016). This result advocates that alcohol consumption by methylmercury-exposed pregnant mothers may have a negative effect on the developing fetus. It has been well established that exposure to environmental chemicals during critical developmental periods leads to serious reproductive, neurological, and behavioral abnormalities (Grandjean and Landrigan, 2014; Heindel et al., 1994; Tiwari et al., 2011).

Researchers have used the Drosophila model to evaluate environmental toxicant—induced reproductive

emergency. Reproductive toxicity includes the analysis of reproductive ability (reproductive performance), courtship behavior, and molecular analysis. In flies, the male *Drosophila* initiates courtship behavior in response to various sensory inputs including auditory, visual, and olfactory signals to achieve reproductive success (Pan et al., 2012).

Accumulating evidence indicates the susceptibility of courtship behavior to exposure to environment chemicals. Chauhan et al. (2017) observed altered courtship behavior in male *Drosophila* exposed to mercury due to the reduced wing extension. Similar altered courtship was observed in flies in response to lead (Hirsch et al., 2003). Gayathri and Krishnamurthy (1983) developed a method to assess the reproductive performance. In this method, first instar *Drosophila* larvae are exposed to toxicant and allowed to grow throughout the development phase. Virgin male and female flies from exposed and normal larvae are collected and pair mating is established (control male X control female, treated male X treated female, control male X treated female, control female X treated female). These mating pairs are transferred to fresh vials every day for 10 days. To analyze reproductive performance (fecundity, fertility, and hatchability), the number of eggs laid is counted each day. Several studies explored this method to evaluate reproductive adversities induced by an environmental chemical.

Bhargav et al. (2008) and Siddique et al. (2009) showed that exposure of *Drosophila* larvae to industrial/municipal effluent posed negative effect on reproductive performance. Similarly, reduced fecundity and hatchability were recorded when first instar *Drosophila* larvae were exposed to dichlorvos, chlorpyrifos, cypermethrin, and volatile organic compounds (Gupta et al., 2007; Mukhopadhyay et al., 2006; Singh et al., 2009).

Recently, Khatun et al. (2017) observed a reduction in reproductive performance along with morphological alteration in the ovary after developmental exposure *Drosophila* to sodium fluoride. Epidemiological studies have underlined that approximately 50% of infertility cases are associated with male-related factors. Two recent studies are of particular relevance to male reproductive toxicity. In one study, exposure of male *Drosophila* to dibutyl phthalate (DBP), a known reproductive toxicant, caused reduced sperm quality, seminal protein, increased oxidative stress, and altered activity of estrogen receptors (Misra et al., 2014a; b). Sperm competition is the mating process between spermatozoa of two or more separate males to fertilize the same egg. Misra et al. (2014a,b) showed that the exposure of adult *Drosophila* to endosulfan leads to poor sperm competition and hampered reproductive output even at a low level of exposure. Expression analysis of gene encoding reproductive proteins in accessary gland (Acps) in exposed *Drosophila* provides a key link between environmental chemicals and reproductive outputs. Siddique et al. (2009) found downregulation of some seminal protein encoding genes (Acp70A and Acp36DE) in *Drosophila* exposed to tannery waste leachate. Additionally, Gupta et al. (2007) observed dysregulation in the expression of Acps in *Drosophila* males emerging from food contaminated with organophosphate compounds. Collectively, these findings prove *Drosophila* a quick, reliable genetic model to evaluate reproductive toxicity. The normal physiological activity of an organism determines its behavior. Furthermore, behavior changes are an integrated output of chemical toxicity (Pan et al., 2017; Wang and Xing, 2008). In this context, the *Drosophila* model has been used to study various environmental toxicant-induced behavioral changes that are quite similar to those of mammals (Kaun et al., 2012).

The developmental exposure of flies to endosulfan, acephate, atrazine, and silver nanoparticles showed reduced jumping and climbing behavior, along with reduced acetylcholinesterase (AChE) activity (Figueira et al., 2017; Raj et al., 2017; Rajak et al., 2017; Sharma et al., 2012). These authors concluded that the effects of these toxicants on climbing and jumping activity are mostly due to the disturbance in the dopaminergic system and induction of oxidative stress. Similarly, interrupted climbing activity was observed when adult *Drosophila* were exposed to rotenone, 4-vinylcyclohexene, and paraquat (Abolaji et al., 2015; Shukla et al., 2014; Sudati et al., 2013). To further understand the protective mechanism associated with behavioral toxicity, Pandey et al. (2016) demonstrated the protective role of Hsp27 in *Drosophila* against prolonged dichlorvos exposure at organismal level, including locomotor performance. Moreover, subsequent studies demonstrated that mutation in the *methuselah* gene (an aging-associated gene) confers resistance to locomotory defects in paraquat and dichlorvos exposure (Pandey et al., 2015; Shukla et al., 2014). St Laurent et al. (2013) observed amelioration in rotenone-induced locomotor impairment following administration of sodium butyrate (fatty acid derivative). Apart from developmental, reproductive, and behavioral toxicity, assessment of the chronic influence of environmental chemicals on life expectancy is one of the major concerns in toxicological science. The *Drosophila* model has been used in assessing life expectancy. Nazir et al. (2001) and Sharma et al. (2012) have shown that chlorpyrifos (an organophosphate compound) and endosulfan (an organochlorine compound) can reduce the survivorship of exposed adult *Drosophila* by 19% and 29%, respectively.

Toxicomics Profiling Using Drosophila

The application of an omics field to study the totality of toxic chemicals in cells is called Toxicomics. Toxicomics aim to examine the effect of toxic chemicals in cells

through high-throughput experiments such as microarray and molecular interactions. The use of omics technology in toxicology has been increased in recent years. Global analysis of gene, protein, and metabolic expression changes associated with chemical exposure helped environmental toxicologists to better predict adverse response to toxicants (Joseph, 2017; Ramirez et al., 2013; Singh et al., 2010). In this context, transcriptomic data revealed the modulation of genes associated with the developmental process, stress and immune response, and metabolic process in third instar *Drosophila* larvae exposed to endosulfan (Sharma et al., 2011). Transcriptomic data derived from third instar *Drosophila* larvae exposed to Cr (VI) revealed the presence of a double strand DNA damage-triggered repair response (Mishra et al., 2013). Eom et al. (2017) studied a transcriptomic response of *Drosophila* that inhaled toluene and formaldehyde. Severe inhalation toxicity was accompanied with dysregulation of genes associated with important biological processes such as oxidative stress, immunity, and behavioral response. A similar cellular response was reported by Gu et al. (2008) in a murine model after long-term exposure of toluene and formaldehyde. Moskalev et al. (2015) studied the transcriptional response of ionizing radiation in *Drosophila* and observed misregulated genes involved in DNA damage response, aging, oxidative stress, immunity, and the metabolic process. Likewise, Xue et al. (2017) demonstrated that misregulated genes are involved in different cellular and molecular process in male *Drosophila* exposed to ethylparaben (an endocrine disruptor). Insects and mammals deploy similar mechanisms of toxicant detoxification. In this context, Mitchell et al. (2015) conducted a microarray study against α-amanitin (principal toxin of deadly poisonous mushroom) and found several genes/mechanisms that seem to provide α-amanitin resistance.

Changes in the expression profiling of miRNAs has also been explored in toxicology (Yu and Cho, 2015). Chandra et al. (2015) identified critical miRNAs in Cr(VI)-exposed *Drosophila* larvae. These miRNAs were involved in development and differentiation, DNA damage repair, and oxidation−reduction processes. Shukla et al. (2016) reported paraquat toxicity in *Drosophila* brain by metabolic profiling. Paraquat toxicity was associated with changes in energy metabolism, amino acids metabolism, lipid metabolism, and nucleotide metabolism. In conclusion, *Drosophila* helps in assessing the toxicological impact of several chemicals. Because of the conservation of the genome, observations from *Drosophila* can be extrapolated with humans.

Predication of Toxicity Using *Eisenia fetida*

E. fetida (common name: earthworm) is the major fraction of soil fauna communities in most ecosystems and represents a major biomass (>80%) in soil. Darwin's research established a keystone role of earthworms within terrestrial ecosystems and an understanding of how environmental change impacts survival and reproduction. This model has been widely used for ecotoxicological studies. The Organization for Economic Cooperation and Development (OECD) provides a number of protocols to test environmental chemical-induced cellular and organ toxicity using the earthworm. Over the years, a significant shift has been recorded in the development of end point toxicological parameters using the earthworm, i.e., from mortality analysis as the only end point to biomarker analysis at cellular, molecular, and behavioral levels (OECD, 1984). *E. fetida* is the most commonly used earthworm species in terrestrial ecotoxicology due to its (1) importance in soil structure, (2) easy breeding and rapid propagation, (3) elementary position in the food chain, and (4) its continuous exposure to pollutants present in the soil.

Biomarker research focuses on understanding the effects of environmental pollutants on different levels of biological organization, i.e., from cell to population. Studies conducted to analyze the impact of varied pollutants showed that *E. fetida* is a standard testing organism to assess toxicity at all biological organizational levels. During the last decade, changes in stress gene expression (Hsps and metallothioneine), enzyme-based parameters, and DNA damage have been used as a biomarker in *E. fetida* to assess the impact of environmental pollutants. Upregulation in the expression of *hsp70* and metallothionein was reported after exposure to imidacloprid (Dittbrenner et al., 2012), cadmium and siduron (Uwizeyimana et al., 2017), copper sulfate (Xiong et al., 2014), di-(2-ethylhexyl) phthalate (Ma et al., 2017), triclosan (Lin et al., 2014), α-endosulfan (Nam et al., 2017) zinc, copper, and lead (Homa et al., 2015).

Apart from Hsp and metallothionein, oxidative stress appears to be an important element in regulation of the response triggered by environmental stressors. A number of studies highlight the modulation in ROS, MDA levels, SOD, CAT, and lipid peroxidation activities when *E. fetida* are exposed to cyfluthrin (type II pyrethroids), silver nanoparticle, and imidacloprid (Li et al., 2017; Patricia et al., 2017; Zhang et al., 2014). Apart from oxidative stress biomarkers, changes in digestive enzyme activity directly determine the physiological status of the organism. Cellulase is one of the crucial digestive enzymes in the earthworm. Zhang et al. (2014) reported decreased activity of cellulase with prolonged exposure of *E. fetida* to imidacloprid. Similar results were obtained when *E. fetida* was exposed to the herbicide acetochlor (Xiao et al., 2006).

Recently, Ma et al. (2017) exposed *E. fetida* to sublethal concentrations of di-(2-ethylhexyl) phthalate for 14 days

and observed an increase in tail DNA ratio (through Comet assay) in their coelomocytes (immune cells). Other parameters, like total cell number and viability of coelomocytes, have been also developed as biomarkers of exposure (Homa et al., 2015). Garcia-Velasco et al. (2016) used cell number and viability as a biomarker in the coelomocytes of earthworms exposed to silver nanoparticles and demonstrated its severe effect at higher biological complexity levels. Very recently, Martínez-Guitartea and his team investigated the molecular biomarker against *E. fetida* exposed to bisphenol (endocrine disruptors). The group observed changes in the expression of genes associated with endocrine function (membrane-associated progesterone receptor, ecdysone receptor), epigenetic mechanisms [DNA (cytosine-5)-methyltransferases 1], DNA damage (PARP1), and stress pathway (HSC70 4) (Novo et al., 2018). Mayilswami et al. (2016) performed differential gene expression study in perfluorooctanoic acid exposed *E. fetida*. The group observed dysregulated genes involved predominantly in the apoptotic process, calcium signaling, lipid metabolism, neuronal development, and reproduction. Similarly, a transcriptomic study by Srinithi et al. (2017) in benzo(a)pyrene-exposed *E. fetida* revealed altered mRNA expression involved in various biological processes, i.e., protein transport, calcium homeostasis, lipid metabolism, and development. Moreover, Wang et al. (2010) identified differentially regulated proteins involved in transcription, translation, the tricarboxylic acid cycle, amino acid metabolic process, protein phosphorylation, and the glucose metabolic process during cadmium exposure of *E. fetida*.

In earthworms, the body wall muscles resemble vertebrate-like cholinergic neuromuscular junctions (Rosenbluth, 1972), which contain the enzyme AChE. A number of studies have provided evidence that inhibition in AChE activity in *E. fetida* could be used as potential biomarker of behavior (Nam et al., 2015; Wang et al., 2015; Zhiqun et al., 2017). Mortality, growth, and reproduction are the most commonly used population health measurement to evaluate chemical toxicity. A number of studies have shown that growth and mortality of the earthworm could be used as a sensitive marker to assess the toxicity of environmental toxicants. Milanović et al. (2014) found galition G-5, terbis, and gardene exposures significantly increased mortality and reduced the weight and growth of the *E. fetida*. A similar decline in growth was also observed when *E. fetida* was exposed to bisphenol, chlorpyrifos, cadmium, and lead, which had long-term negative effects on the organism (Jūratė Žaltauskaitė and Sodienė, 2010; Verdu et al., 2018; Zhou et al., 2007). The growth of earthworms is more severely affected at the juvenile stage than the adult stage (Dasgupta et al., 2012; Zhou et al., 2007).

The earthworm has also been used to evaluate reproductive toxicity. The reproductive biomarkers include cocoon production and hatching pattern, viability of the worms, and sexual maturation (De Silva et al., 2009; Gestel and Dis, 1988; Robidoux et al., 1999). Earthworms produce cocoons in which their embryos develop. Accumulating evidence suggests that cocoon production can be used as a sensitive reproductive parameter for exposure to nickel (Yan et al., 2011), perchlorate (Landrum et al., 2006), zinc (Spurgeon and Hopkin, 1996), and silver nanoparticles (Makama et al., 2016). Similarly, hatchability of the cocoon has been proposed as a sensitive reproductive parameter for endosulfan carbaryl and chlorpyrifos exposure (Dasgupta et al., 2012). In addition, a single dose of malathion given to *E. fetida* was found to reduce the spermatic viability in spermatheca, sperm count, and quality, altering the cell proliferation and modifying the DNA structure of spermatogonia (Espinoza-Navarro and Bustos-Obregon, 2005). In conclusion, growth, mortality, and reproductive performance of earthworms are useful bioindicators for ecotoxicity studies.

Prediction of Toxicity Using *Daphnia magna*

The *Daphnia* species, commonly called "water flea", are common planktonic (1−5 mm long) invertebrate organisms which inhabit freshwater ecosystems and are an important food source for fish. For a long time, *Daphnia* has been considered a key member of the aquatic food chain as an intermediate link between primary and secondary productivity and its development as an alternative and sensitive model for ecotoxicological assessments (Taipale et al., 2016; Tatarazako and Oda, 2007). *D. magna* is one of the oldest models for ecotoxicology and evolutionary biology. The factors that make *D. magna* popular for experimental work include the following: 1) sensitivity toward toxic substance, 2) short life cycle, 3) small size, 4) high fecundity, 5) wide spatial distribution, and 6) availability of omics-based tools (Abe et al., 2014; Guilhermino et al., 2000). Furthermore, *D. magna* is recommended for aquatic environmental studies in OECD chemical testing guidelines (OECD, 2004).

The use of *Daphnia* for toxicological evaluation began in the early 1900s when Ernest Warren introduced *D. magna* to study the toxicity of sodium chloride (Warren, 1900). In addition, the widespread use of *D. magna* as a bioindicator is due to the fact that acute toxicity is considered a primary and sensitive test for the assessment of chemicals. During the last two decades, a number of biochemical, cellular, and molecular markers have been established in *D. magna* along with traditional ecotoxicity parameters. *Daphnia* swimming performance is considered a sensitive biomarker of toxicity. For

example, when *D. magna* was exposed to copper, chromium, and titanium dioxide, the average swimming duration and speed of the organism was reduced in a concentration-dependent manner (Nikitin et al., 2018; Noss et al., 2013; Untersteiner et al., 2003). Dichlorvos, malathion, and parathion are also known to alter behavioral strength of the organism (Ren et al., 2009a,b). Travel distance is another swimming parameter for the locomotor activity of *Daphnia*. A reduction in travel distance was found in *D. manga* when the organism was exposed to a glyphosate copper mixture (Hansen and Roslev, 2016).

Assessment of fecundity and survivorship are the traditional biomarkers of ecotoxicity. Mendonca et al. (2011) reported the adverse effect of diamond nanoparticle on survival and reproduction of *D. manga*. The group also observed that the diamond nanoparticles adhere to the exoskeleton surface and accumulate within the gastrointestinal tract, leading to the blockage of food absorption by the gut cells. A similar observation (reduction in life span, growth, reproduction, and accumulation and persistence of nanoparticles) was reported by chronic exposure of *D. magna* ZnSO4 and ZnO nanoparticles (Bacchetta et al., 2016). The reproduction and survival of *D. magna* is affected by its exposure to chlorpyrifos, diazinon, cadmium, and triphenylphosphate (Geffard et al., 2008; Jemec et al., 2007; Yuan et al., 2018; Yuzhi et al., 2017). In arthropods, ecdysone signaling regulates molting and embryonic development. Palma et al. (2009) reported that endosulfan sulfate can decrease the molting process and produce embryonic toxicity, due to an anti-ecdysteroid activity of the chemical. Similarly, Toumi et al. (2013) assessed the acute and chronic toxicity of deltamethrin through analyzing longevity, molting, day of first brood, number of broods, embryotoxicity, and sex determination. The authors concluded that deltamethrin acts as an endocrine disruptor, which leads to decreasing juvenile number and growth, abnormalities in development, and interference in sex determination.

The *D. magna* model has also been used to assess the toxicity of chemicals using biomarkers at the cellular and molecular levels. For example, modulation in Hsps and metallothionine, GST, AChE activity, and ROS levels has been reported when the organism is exposed to toxicants (Dominguez et al., 2015; Ferrario et al., 2018; Haap et al., 2016; Oliveira et al., 2015; Oropesa et al., 2017; Parolini et al., 2018). Water quality has also been assessed employing the Comet assay in *D. magna* (Pellegri et al., 2014). For example, multigenerational exposure of carbendazim significantly increases DNA damage (Silva et al., 2017). In addition, coexposure of carbendazim with triclosan showed synergetic DNA damage in the exposed *D. magna* (Silva et al., 2015). Poynton et al. (2007) compared the distinct expression profiles in *D. magna* subjected to Cu, Cd, and Zn exposures and identified known biomarkers, i.e., metallothioneins and a ferritin (iron-response element). Transcriptomics analysis of nickel-exposed *D. magna* revealed an alteration in mRNA expression involved in metabolic processes, transport, and cell signaling. Moreover, in the same study mRNA profiling of a nickel and cadmium mixture pointed out the interactive molecular responses and the complex nature of mixture toxicity (Vandenbrouck et al., 2009). Collectively, *Daphnia* can be used as a simple platform to understand the impact of environmental chemicals on an ecological system.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

As discussed in this chapter, *Drosophila*, the earthworm, and *Daphnia* represent an excellent alternative to a higher model organism for toxicity testing. These organisms can be used for toxicity testing at the molecular, cellular, and animal levels. The advent of advanced molecular and genetic tools has provided a basis for examining the potential of small organisms in toxicity testing by using multiple readouts. The most commonly used biomarker at the molecular level are the Hsps. Additionally, other biomarkers such as antioxidant enzymes, DNA damage response genes, metabolic enzymes, and behavioral and reproductive parameters have also been used for toxicity testing. The lower genetic redundancy, short life cycle, high conservation of signaling pathways, and ease in genetic manipulation are major advantages associated with these organisms. A number of toxicants such as heavy metals, pesticides, nanoparticles, volatile organic compounds, and additives have been tested using small organisms. In spite of several examples provided in this chapter, small organisms have not been recommended for routine toxicity testing due to the complex biological architecture of the human being. We hope that ongoing studies across the world will help in placing these animals in the forefront of biomarkers for toxicity testing.

Alternative Animal Toxicity Testing and Biomarkers

Gopala Krishna[1] , Priya A. Krishna[1] , Saryu Goel[2] , Kavya A. Krishna[1]

[1]Nonclinical Consultants, Ellicott City, MD, United States; [2]Nonclinical Expert, Leesburg, VA, United States

INTRODUCTION

The subject of animal testing is highly controversial and has become an emotional issue in recent years. Therefore, it is important to recognize the growing impact on alternatives to animal testing, such as, in vitro toxicity, metabolism, and efficacy testing. It is evident that animal testing is an essential part of basic research, new product discovery, and the improvement process. In this regard, animal testing is defined as the use of nonhumans, such as vertebrate and nonvertebrate animals or organisms, in scientific experimentation in search of answers for the good of mankind and the pursuit of basic knowledge. It is estimated that up to 100 million vertebrate animals ranging from zebrafish to nonhuman primates are used annually worldwide. Likewise, invertebrates such as fruit flies (*Drosophila*) and earthworms are also commonly used in research. While the uses of vertebrates are heavily regulated, invertebrates are excluded from such regulations. Much of the animal testing around the world is conducted under the strict global regulatory guidelines and/or guidelines of respective countries, which set fundamental standards for the humane use of animals for training, experimentation, biological testing, research, or for other related purposes. These regulations and guidelines require minimizing harm to animals through 3Rs: reduction, refinement, and replacement (Russell and Burch, 1959), by searching for alternatives, including consideration for hierarchical use of species and in vitro methods.

In product discovery and development, "preclinical studies" is the term that encompasses all activities in nonhuman species. This scientific discipline includes everything that is not purely chemical or formulation-oriented nor involves humans. These studies are conducted using cells, organs, unique animal models, and multiple animal species in large numbers with an objective to obtain data on the mechanism of product's action, adverse effects (toxicity to genetic material, reproductive system, and ability to cause cancer) over a range of doses, pharmacokinetics, and metabolism of the substance that is being tested. For pharmaceuticals, these studies define safety margins for human clinical trials. The process of drug development from bench to bedside is illustrated in Fig. 8.1.

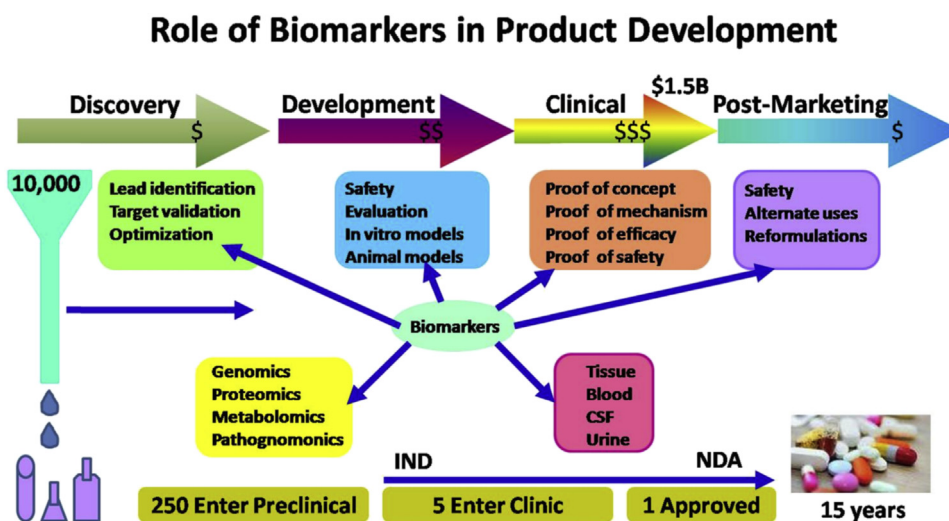
With the advancement of science and technology, particularly in biomarkers, in vitro testing, and instrumentation, tremendous progress has been made to achieve 3Rs. Biomarkers are defined as parameters such as pharmacological, physiological, pharmacokinetic, molecular markers such as genes, proteins, metabolites, and clinical chemistry, which can be used to predict a toxic event in an individual animal and/or biological system (in vitro). These markers are used to extrapolate to a similar toxic endpoint across species, including humans. An ideal biomarker is described as accessible, noninvasive, sensitive, specific, inexpensive, translational (able to cross the bridge between basic and clinical research), predictive of the extent of injury, and accurate. Generally, biomarkers are utilized in three forms: (1) biomarkers of effect—quantifiable health impairment, such as, in the form of change of liver enzymes in blood, DNA/chromosomal changes, clinical signs; (2) biomarkers of exposure—concentration over time of an agent or its metabolite that can be measured in body fluids; and (3) biomarkers of susceptibility—inherent susceptibility of an organism to toxic insult, such as polymorphisms in cytochrome P450 enzymes. Advancements in instrumentation leading to technologies such as functional/pharmacological magnetic resonance imaging (fMRI/phMRI), mass spectrometry, and flow cytometry


FIGURE 8.1   Use of biomarkers in product development from discovery to approval and postmarketing.

have accelerated such efforts leading to achieve the goal of 3Rs. The objective of this chapter is to provide a brief overview of the reasons for animal surrogate strategies, descriptions of select systems used for toxicity, metabolism, efficacy testing, and the role of biomarkers in the form of toxicity endpoints used in product development (Benford et al., 2000; Blaauboer et al., 2012; Bradlaw, 1989; Doke and Dhawale, 2015; Goldberg and Frazier, 1989; Hartung, 2014; McKeehan et al., 1990; Schaeffer, 1990; Tainsky, 2009; Smith, 2012; Vaidya and Mendrick, 2012).

USE OF ALTERNATIVES TO ANIMAL TESTING AND BIOMARKERS

To deal with the concerns of animal testing, alternatives have been sought. Most scientists in academia, industry, and government around the globe agree that animal testing should be ethical and cause as little suffering as possible, and that alternatives to animal testing need to be developed. The "3Rs," first described by Russell and Burch (1959), are guiding principles for the use of animals in research around the globe:

- **Reduction** refers to strategies that enable researchers to obtain comparable levels of information from fewer animals, or to obtain more information from the same number of animals.
- **Refinement** refers to strategies that alleviate or minimize potential pain, suffering or distress, and enhance animal welfare for the animals still used.
- **Replacement** refers to the preferred use of nonanimal methods over animal methods whenever it is possible to achieve the same objective(s).

These guiding principles are the fundamental reasons for the development of alternative procedures, a rationale for involving animals and appropriateness of the species, the number of animals to be used in research, and product development and training.

REASONS FOR DEVELOPING ALTERNATIVES TO ANIMAL TESTS AND BIOMARKERS

There are multiple reasons to develop and practice alternatives to animal testing of which two key reasons are described. First, economy and efficiency play a key role. In vitro tests, once developed and validated, provide toxicity and efficacy information in a cost-effective and time-saving manner. Such information can also increase the efficiency of whole-animal studies and decrease the number of animals required for toxicity, metabolism, and efficacy testing. The relative simplicity, space, and time-saving characteristics of in vitro methods are considered advantageous, albeit with some concerns that in vitro methods do not recapitulate the in vivo microenvironment and homeostasis.

Second, in vitro testing using human cell lines has been useful in securing relevant information for human risk assessment and understanding molecular mechanisms, sensitivity, and resistance to targeted therapy, thereby opening up opportunities to explore responses to existing and emerging therapies. Human cells, ethically obtained and successfully established in vitro, may provide information about a toxicant or therapeutic agent that is relevant to human risk and/or efficacy, such as mechanism of action and metabolism in human cells, and can provide the basis for selecting a suitable

animal model for repeat-dose toxicity testing. This can be illustrated as an operating concept of in vitro toxicology where manifestations of changes at the molecular level can be studied at the organ level (Fig. 8.2). It is proposed that the endpoints used in the 3Rs be considered as biomarkers, where appropriate. It is also known that test substances interact with various cells, organelles, and organ systems pharmacologically and toxicologically to produce their effects (Fig. 8.3), which can be used for efficacy and safety assessment (Lee et al., 2013). Likewise, human cell lines have been used in search of effective emerging and existing therapies for certain diseases. For example, it is known that there are over 50 types of breast cell lines, which originated from about 150 human breast tumors (Neve et al., 2006). These cell lines retain most of the genetic information for autonomous growth. These cell lines have been successfully used to understand molecular mechanisms of sensitivity/resistance to inhibitors with exquisite sensitivity for the EGFR (epidermal growth factor receptor), HER2 (human epidermal growth factor receptor 2), MET (hepatocyte growth factor receptor), and BRAF kinase inhibitors (McDermott et al., 2007). These cell lines indeed paved the way for the use of trastuzumab (Herceptin) as an adjuvant therapy in the treatment of breast cancer in some individuals. Another example would be the increased BCR-ABL expression, which is an excellent biomarker of Gleevec resistance, leading to personalized medicine—meaning treating the patient with a drug that works with minimal to no adverse effect (Tainsky, 2009; Khalil et al., 2010).

EXAMPLES OF ORGANIZATIONS' RESEARCHING AND FUNDING ALTERNATIVES TO ANIMAL TESTING AND BIOMARKER DEVELOPMENT

- **Johns Hopkins University Center for Alternatives to Animal Testing (CAAT-a, 2013)**

  The Johns Hopkins University Center for Alternatives to Animal Testing (CAAT-a, 2013) has worked with scientists since 1981 to find new methods to replace the use of laboratory animals in experiments, reduce the number of animals tested, and refine necessary tests to eliminate pain and distress to test animals. The CAAT promotes humane science by supporting the creation, development, validation, and use of alternatives to animals in research, product safety testing, and education. It is not an activist group; rather, it seeks to effect change by working with scientists in industry, government, and academia.

- **Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM, 2013)**

  Traditionally, consumer products, medical devices, chemicals, and new drugs are tested on animals to predict toxicity, metabolism, and efficacy in humans. Scientists in ICCVAM are working to promote the development and validation of alternative test methods. Alternative test methods are those that accomplish one or more of the 3Rs principles.

Operating Concept of *In Vitro* Toxicity and Biomarkers

Drugs/Agents cause changes in molecular expression or activity

Which changes cellular physiology or morphology

- Result in target organ toxicity
- Biomarkers are used to detect changes

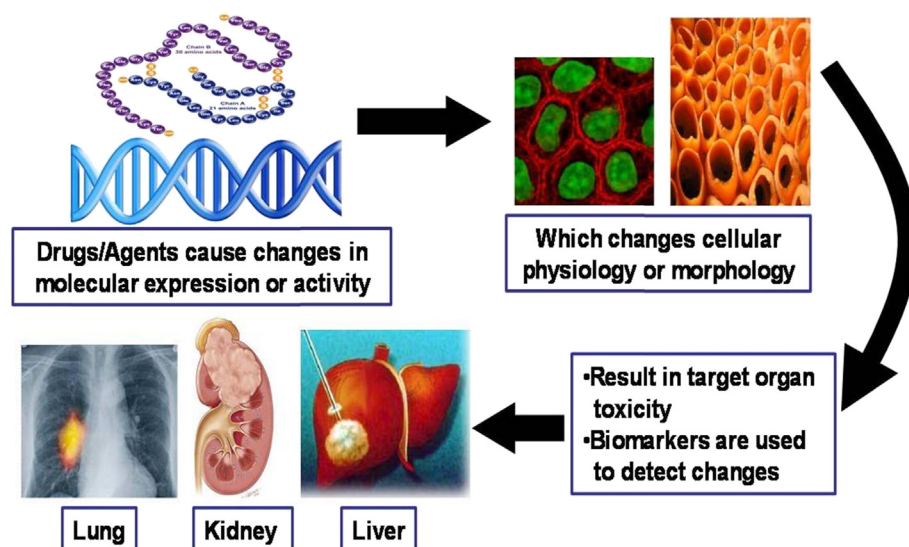
Lung   Kidney   Liver


FIGURE 8.2 Toxic test substances cause changes at the molecular level (DNA or protein), which are expressed at the cellular level. This in turn results in target organ toxicity (e.g., liver, kidney), which can be studied and extrapolated to whole animals or humans based on in vitro studies.
FIGURE 8.3   Drugs or agents interact with various cells, organelles, and organ systems to produce their pharmacological and/or toxicological effects. These effects can now be studied using various in silico or in vitro tools, minimizing the use of animal testing.

- **University of California–Davis, Center for Animal Alternatives (CAAT-b, 2013)**

    The UC Davis Center for Animal Alternatives disseminates information on alternatives to animal experiments with information on the most current methods for improving all aspects of animal care.

- **Dr. Hadwen Trust**

    The Dr. Hadwen Trust for Humane Research is a British biomedical research charity, founded in 1970 (Dr. Hadwen Trust, 2013). It funds peer-reviewed alternatives to animal testing in relation to health issues such as cancer, heart disease, meningitis, and Alzheimer's disease. Trust researchers have cultured human cartilage, which has helped to show how arthritis drugs work; developed a three-dimensional model of human teeth and jawbone for dental research; created a computer model of a human fetus; and used mathematical modeling to create drug treatment for non–Hodgkin's lymphoma and neuroblastoma. Over 200 papers about the Trust's work have been published in scientific journals.

- **National Centre for the Replacement, Refinement, and Reduction of Animals in Research**

    The European Centre for the Validation of Alternative Methods (ECVAM) launched an online database on toxicology of nonanimal alternative test methods in 2006 (NC3R, 2013). Categories at present include in vitro methods, quantitative

structure–activity relationship (QSAR) models, and a bibliographic section, aiming to develop alternatives to animal testing. This describes general guidance to researchers and associated veterinary and animal care staff using vertebrates (live animals or animal products) in bioscience research funded by various agencies. It sets out the expectations of the funding bodies for the use of such animals in research and is therefore useful to ethics committees, referees, and members involved in reviewing research proposals. Implementation of the principles in this guidance is a condition of receiving funds from the funding bodies.

- **REACH (Registration, Evaluation, Authorization, and Restriction of Chemicals)**

    This organization is the European Community Regulation on chemicals and their safe use (EC, 1907/2006). The aim of REACH (2013) is to improve the protection of human health and the environment through better and earlier identification of the intrinsic properties of chemical substances. At the same time, REACH aims to enhance innovation and competitiveness of the EU chemicals industry, thus enhancing information sharing and minimizing unnecessary experimentation in animals. REACH is executed through a public database in which consumers and professionals can find hazard information.

ACHIEVING 3RS WITH MINIMAL TO NO ANIMAL TESTING BY USING BIOMARKERS

Over the years, several methods have been identified and practiced where possible, in achieving the 3Rs. For example,

1. In silico computer simulation
2. In vitro cell culture techniques
3. Integrated toxicity testing using fewer animals and collecting the most information by selecting different experimental endpoints, improved use of anesthetics, analgesics, and replacing open surgery with minimally invasive endoscopic surgeries, and procedures related to animals and a myriad of other things, which will minimize potential pain and distress
4. Microdosing, in which the basic behavior of the drug is assessed using human volunteers receiving doses well below those expected to produce whole-body effects (FDA, 2006)
5. Epidemiologic and clinical studies and genetic monitoring, in which studies of human populations have provided important information about the causes of many diseases, such as the relationships between cholesterol and heart disease, the mechanism of transmission of HIV, and chemical exposures and birth defects. Scientists can "see" abnormalities and track treatment progress in the brains of victims of Alzheimer's and Parkinson's diseases, schizophrenia, epilepsy, and brain injury using sophisticated scanning technologies (CT, PET, and MRI). All drugs must undergo clinical testing before being approved; carefully crafted clinical research is the best way to determine human reactions to new drugs.

Some of these strategies are described below.

In Silico Computer Simulation

There are a variety of in silico computer simulation software programs available in the public domain and on a fee-based service. Computers can often predict the toxicity of chemicals, including their potential to cause cancer or birth defects, based on their molecular structure. Computer simulations can also predict the metabolism and distribution of chemicals in human tissues.

Lhasa (2013) Limited is a not-for-profit organization that promotes the sharing of data and knowledge in chemistry and life sciences. It has developed software tools such as DEREK (**D**eductive **E**stimation of **R**isk based on **E**xisting **K**nowledge) for Windows, Meteor, and Vitic to facilitate such sharing. DEREK for Windows and Meteor are knowledge-based expert systems that predict the toxicity and metabolism of a chemical, respectively. Vitic is a chemically intelligent toxicity database. These software tools include illustrations on (1) the use of data entry and editing tools for the sharing of data and knowledge within organizations; (2) the use of proprietary data to develop nonconfidential knowledge that can be shared between organizations; (3) the use of shared expert knowledge to refine predictions; (4) the sharing of proprietary data between organizations through the formation of data-sharing groups; and (5) the use of proprietary data to validate predictions. Sharing of chemical toxicity and metabolism data and knowledge in this way offers a number of benefits, including the possibilities of rapid scientific progress and reductions in the use of animals in testing. Maximizing the accessibility of data also becomes increasingly crucial as in silico systems move toward the prediction of more complex phenomena for which limited data are available. Recently, it has been shown that the use of in silico methods is the way forward for assessing the genotoxicity and potential carcinogenicity/repeat-dose general toxicology of large numbers of chemicals (Hayashi et al., 2005). More importantly, it is expected that these methods will contribute to the reduction of animal use.

There are several other in silico methods that have been developed and validated, for example, Leadscope, MCase, Topkat, Toxtree, and Osiris software, as well as QSAR models developed by the FDA with proprietary databases (Contrera et al., 2007). It is proposed that, depending on the type of molecule being tested and the type of safety information being sought, one or more software programs may be used to understand the structural alteration alters for the endpoint desired (Krishna et al., 2014). As the data outputs are reviewed, a consensus and reproducibility of alerts in at least two or more databases may be considered as significant alerts.

Structure Activity Relationship (SAR) software, such as, DEREK, Toxtree, Ecostar, OECD QSAR Toolbox, can perform predictions for multiple toxicity endpoints and species for new drugs and agents. This software utilized either the knowledge base or rules to make determination using data from previously tested compounds and algorithms that consider a multitude of factors, including physical, chemical, and biological properties of compounds and substituent's groups. The predications are used to prioritize and determine urgency for further testing in animals, as needed (Fig. 8.4).

In Vitro Cell Culture Techniques

In vitro cell culture is currently the most successful and promising alternative to animal use. Isolated cells, tissues, and organs can be prepared and maintained in culture by methods that preserve properties and characteristics of the same cells, tissues, and organs in vivo (Krishna et al., 1984, 1985, 1986; Wilcox and Bruner, 1990; Krishna, 2010). Using such in vitro systems will permit data to be generated under controlled experimental conditions that are, in the absence of many complicating factors, characteristics of experiments in whole animals. For example, cultured cells have also been developed to create monoclonal antibodies thereby replacing the use of animals required to undergo a procedure likely to cause pain and distress. An enormous amount of valuable in vitro cell culture research is conducted today. The National Disease Research Interchange provides more than 130 types of human tissues to scientists investigating more than 50 diseases, including cancer, diabetes, and glaucoma (NDRI, 2013). Cell and tissue cultures are used to screen new therapies and to test for product safety. Genetic microarrays are being used to predict liver toxicity by measuring gene expression in human liver cells (Lipp, 2007; Tainsky, 2009).

Several in vitro tests have been validated and/or are currently being evaluated to replace the in vivo tests that cause pain and suffering to animals. These tests are used to determine, for example, phototoxicity, skin and/or eye irritation and corrosivity, immunotoxicity, bone marrow toxicity, phospholipidosis, kidney toxicity, and genotoxicity. Most frequently used in vitro tests are listed in Table 8.1.

Toxicity biomarkers in the in vitro context are defined as quantitative measurable characteristics that serve as indicators of a pathologic process or related biochemical or molecular events. There is great value in developing preclinical assays that are predictive of human clinical outcomes and in vitro methods to test for drug-induced liver injury, for example, are well recognized. High-throughput screening and high-content screening have enabled the scientific community to efficiently screen large new chemical entity (NCE) libraries. Continued advancement in the development of instrumentation and biomarkers has strengthened researchers' ability to deliver suitable and predictable assays. The combination of both methods and biomarkers may elucidate mechanisms of hepatocyte damage and significantly improve the understanding of drug safety and efficacy profile. When such methods and biomarkers are shown to have in vitro—in vivo correlation, the risk—benefit ratio for a particular drug's development can be more effectively managed, leading to safer and more successful outcomes for patients and pharmaceutical companies (Moeller, 2010).

TABLE 8.1   Most Frequently Used In Vitro Tests in Achieving 3Rs

Test	Targets	Benefits
3T3 NRU Phototoxicity Test	In vitro identification of a phototoxicity	Partial replacement of in vivo studies for the investigation of phototoxic effects.
Bovine Corneal Opacity/Permeability Assay (BOCP)	In vitro alternative to in vivo rabbit Draize test for eye irritation and corrosivity	Replacement of in vivo studies to test eye irritation or severe damage.
Human Corneal Epithelium (HCE Test)	In vitro alternative to in vivo rabbit Draize test	Same as above
3D Human Skin Model	In vitro alternative to in vivo rabbit Draize test for skin irritation and corrosivity	Same as above for skin irritation or corrosion. Can detect photoreactive chemicals if applied in UV light.
Mishell–Dutton Culture	In vitro alternative to immunotoxicity assay in the rodent (plaque assay). The immune reaction occurs in vitro	Assay done in blood cell cultures, no animal sacrifice. Blood of different species can be tested, compared, enable better prediction for humans
CFU-GM Assay	In vitro screen for bone marrow toxicity mainly for indication oncology	Early detection of bone marrow toxicity
Phospholipidosis Assay	In vitro screen for phospholipidosis-inducing drug	Early identification of drugs with unfavorable properties
Biomarkers for nephrotoxicity	Earlier and sensitive prediction of kidney toxicity	More sensitive biomarkers
Integration of genotoxicity tests into repeat-dose toxicity studies (IWGT working group)	Rat micronucleus test and comet assay included in repeat-dose studies	Better correlation to overall assessment

Limitations of Alternative In Vitro Tests

A variety of limitations of in vitro tests have been described. Briefly, the in vitro test systems are not available for all tissues and organs. Furthermore, normal systemic mechanism of absorption, distribution, metabolism, and excretion systems is absent under culture conditions. In vitro systems lack the complex, interactive effects of the immune, blood, endocrine systems, nervous system, and other integrated elements of the whole animal. Therefore, in vitro tests cannot be used to study the complex nature of systemic toxicity. Finally, validation of new methods is time consuming and expensive. Acceptance of in vitro tests as alternatives to traditional toxicity testing in whole animals is expected to be slow. However, a significant amount of progress has been made toward regulatory acceptance of such methods. The REACH program by the European Union, for example, has implemented acceptance of in vitro data for regulatory purposes.

APPLICATIONS OF IN VITRO TESTS AND BIOMARKERS

Genetic Toxicology Testing, In Vitro

A battery of in vitro genetic toxicology tests has been routinely used for over 30 years to predict the carcinogenicity of substances that are of safety concern. Such assays include, for example, bacterial assays and in vitro cell culture assays for chromosomal aberration assessment and cytotoxicity assessment. The effects on DNA and cells caused by test agents are indirectly observed and enumerated using multiple genetic and cytotoxicity endpoints as biomarkers (Sankaranarayanan et al., 2000; Gollapudi and Krishna, 2000; Hancock et al., 2004; Kirkland et al., 2005).

Bacterial Mutation Assay (Ames Assay)

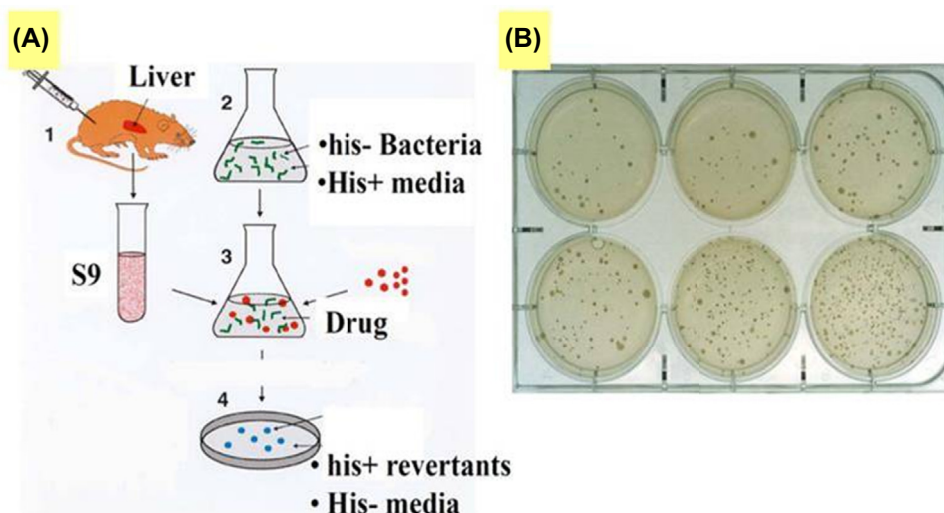
This assay measures genetic damage at the single base level in DNA by using five or more test strains of bacteria. Each of the *Salmonella typhimurium* and *Escherichia coli* strains used in the assay have a unique mutation that turns off histidine biosynthesis in *Salmonella* or tryptophan biosynthesis in *E. coli*. Because of these original mutations, the bacteria require exogenous histidine or tryptophan to survive and will starve to death if grown without these essential nutrients (auxotrophy). The key to the assay is that the bacteria can undergo a reverse mutation turning the essential gene back on and permitting the cell to grow in the absence of either histidine or tryptophan (prototrophy). A specific type of mutation, either a base-pair substitution or frameshift mutation, creates each bacterial strain. The standard Ames assay designs include preliminary


FIGURE 8.5   The in vitro Ames assay in specially constructed strains of bacteria is used to evaluate the mutagenicity of drugs or chemicals. (A) Principle: (1) S9 liver microsomal fraction is prepared from rats pretreated with a liver enzyme inducer; (2) Histidine mutant bacteria are grown in the presence of histidine media; (3) S9, bacteria, and the drug are mixed in top agar containing trace amounts of histidine to allow several DNA replications and poured on to agar plates with minimal media without the histidine and incubated; (4) If the test substance and/or its metabolite(s) causes mutations, and then it would reverse the his⁻ gene into his⁺ gene, which can grow in minimal media and form colonies, thus, considered a mutagen. (B) The results of an Ames test are shown in a 6-well plate: from the top left each well represents control, dose 1, 2, 3, 4, and positive control, showing an increasing number of colonies with dose, suggesting the test article as a positive Ames mutagen.

toxicology tests or combined toxicity and mutation tests followed by a definitive mutation assay. In both toxicity and mutation tests, test strains are combined with S9 mix (prepared from the livers of Aroclor-treated rats) buffer, a test or control article, a trace of histidine or tryptophan, and molten agar. The bacteria use the trace of histidine or tryptophan to undergo several cell divisions but will stop growing once they have run out, leaving a characteristic "background lawn" that decreases in density with increasing toxicity. After 48 h, only those cells that have undergone a reverse mutation turning the essential gene back on have survived, producing mutant colonies. The background lawn density is scored followed by counting the number of revertant colonies. Mutation results are reported as revertants per plate. These assays are performed in the presence and absence of exogenous metabolic activation systems (S9 mix) (Fig. 8.5).

In Vitro Micronucleus and Chromosome Aberration Assays in Cultured Cells (Cytogenetic Assays)

In vitro cytogenetic analysis provides a valuable technique for evaluation of damage to chromosomes on the basis of direct observation and classification of chromosomal aberrations. Cells arrested in the metaphase are examined microscopically for both numerical and structural chromosome aberrations. An alternate cytogenetic approach is the observation of micronuclei, which represent chromosomal-breakage fragments or lagging chromosomes in the cell cytoplasm (Fig. 8.6; Krishna et al., 1989, 1992). The cytogenetic assays may be performed either in vivo or in vitro (Fig. 8.7). In vitro cytogenetic assays are performed in the presence and absence of S9 mix. These assays are also used in human biomonitoring in clinical research and/or in occupational exposures (Fig. 8.8).

Comet or Single-Cell Gel Electrophoresis Assay

The comet assay is a microgel electrophoresis technique that detects DNA damage and repair in individual cells (Fig. 8.7). The damage is represented by an increase of DNA fragments that have migrated out of the cell nucleus in the form of a characteristic streak similar to the tail of a comet. The DNA fragments are generated by DNA double strand breaks, single strand breaks, and/or strand breaks induced by alkali-labile sites in the alkaline version of the assay. The length and fragment content of the tail is directly proportional to the amount of DNA damage. Comet assay can be conducted in both in vitro and in vivo test systems and are increasingly used in genotoxic testing of industrial chemicals, agrochemicals, and pharmaceuticals. Comet assay is rapid (results are available in days), simple to perform, requires small amounts of the test substance (25–50 mg), and can be performed in almost any eukaryotic cell (different animal target organs). The comet assay serves as an important tool in early drug development as a mechanistic and genotoxic predictor (Tice et al., 2000).
FIGURE 8.6   The in vitro and/or in vivo/in vitro micronucleus assay determines the clastogenic effects of chemicals on the chromosomes. This can be evaluated in vitro using human peripheral blood lymphocytes cultured in the presence of drug. (A) Normal mononucleate cells (not divided in culture) and binucleate cells that have undergone 1 division, (B) micronuclei in binucleate cells, (C) tetranucleate cell that has undergone two divisions, and (D) cell with 8 nuclei that have undergone 3 divisions. This assay is used to evaluate clastogenicity (chromosome breakage), aneugenicity (chromosome lagging due to spindle dysfunction), and cytotoxicity (delay in cell cycling) with appropriate staining techniques.

Integrated Genotoxicity Testing Using Fewer Animals and Collecting Most Information

The concept of integrating toxicity assessment employs fewer animals, but a variety of relevant toxicity data can be collected and evaluated (Krishna et al., 1994, 1995a,b; 1998, 2000; Fig. 8.7). As an example, an integrated in vivo genotoxicity testing philosophy and a practical approach, as applied to pharmaceuticals, is currently practiced and is recommended by the International Conference on Harmonization (ICH) guidance (ICH, 2006). In this case, a rodent (primarily rat) micronucleus assay is integrated with routine 2- to 4-week repeat-dose toxicity and toxicokinetic studies. This approach has several advantages: (1) it utilizes the general principles of toxicology that govern the overall toxicity profile of a test substance; (2) factors such as the dose and/or route of drug administration, drug metabolism, principles of toxicokinetics, and saturation of defense mechanisms are considered in evaluating genotoxicity; (3) it uses the concept of administering multiple tolerable doses aiding in achieving steady-state plasma drug levels, which is more relevant for risk assessment when compared with high acute doses; and (4) it helps minimize the amount of drug, the number of animals used, and other resources. This integration approach can be extended to other toxicology studies, and other relevant genotoxicity endpoints may be assessed. Based on experiences reported in the literature, integrating micronucleus assessment in routine toxicology testing is promising and should be utilized when practical. A number of genotoxicity endpoints can be easily evaluated in peripheral blood lymphocytes of subjects exposed by genetic monitoring during clinical trials and/or while on medication (Fig. 8.7).

Unique Zebrafish Model

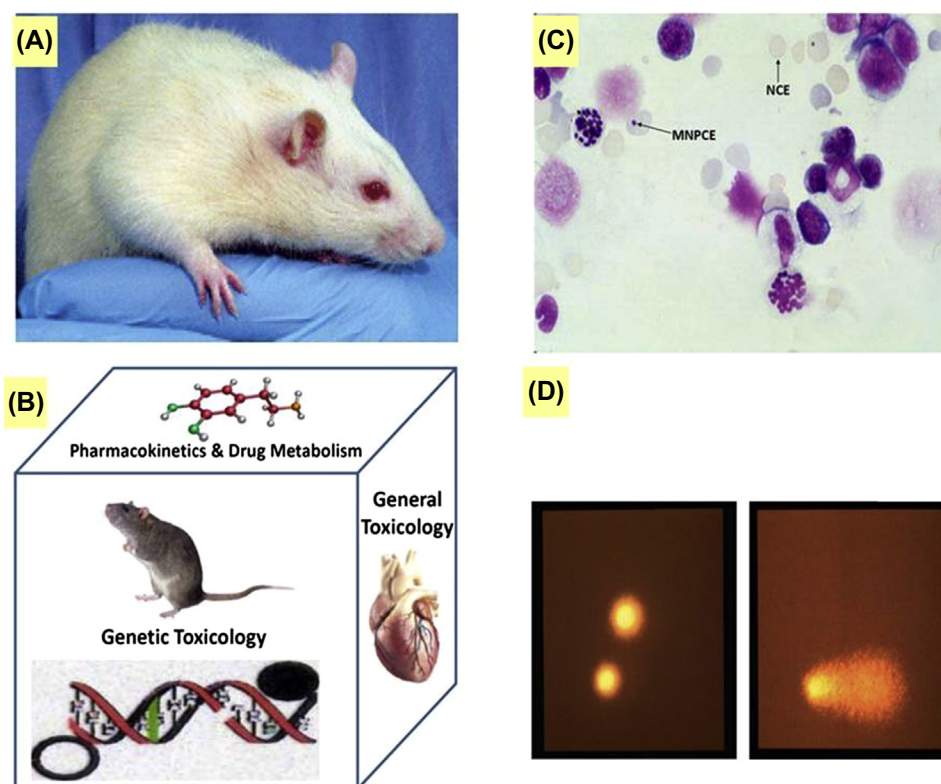
For years, mouse models have been used for testing new drugs, despite their high cost. More recently, the zebrafish has been identified as an important vertebrate model for studying the development of embryos and pathogenesis of human diseases (Lieschke and Currie, 2007). When compared with mammalian models, experimental results show that zebrafish embryos exhibit similar responses to drugs for cardiovascular diseases, and antiangiogenesis and anticancer drugs (Hill et al., 2005). This suggests that the zebrafish model can be used as a bridge between the in vitro model and the in vivo model in the drug


FIGURE 8.7 Integrated in vivo genotoxicity of drugs or agents can be evaluated using samples obtained during the general toxicity study, (A) The samples are obtained from an animal (e.g., rat). (B) The drug is exposed to in vivo biochemical processes, including metabolism and opportunity to interact with the DNA, thereby providing an intact animal with homeostatic assessment of the genotoxic potential of a drug; and (C) the blood sample/bone marrow is obtained and stained to detect the presence of micronuclei in polychromatic erythrocytes (PCE); if positive, then the drug is considered as clastogenic. (D) Cells, particularly from liver, are processed and tested for DNA strand breaks in the comet assay. The breaks in the DNA are observed as a comet-shaped migration of DNA from the nucleus of the cell following gel electrophoresis in treated compared with the intact round nucleus suggesting unaffected DNA (control).

discovery and screening processes. In addition, pollutants induce similar pathological changes in zebrafish and other mammalians.

In Vitro Pharmacologic Activity Testing

Pharmacology is the study of drug effects in biological systems, including therapeutic or toxic effects. The field of in vitro pharmacology takes advantage of the technological advances in studying drug effects in the laboratory settings using cell culture models and isolated tissue assays and predicts such effects to in vivo models (Irwin et al., 2008). In vitro pharmacology data provide invaluable information on the compounds' chances to succeed in the clinical phase. Multiple contract research organizations offer a variety of panels of validated in vitro pharmacological assays that cover a broad range of targets. Apart from ascertaining the potency of a NCE on target, assays are also made available for selectivity screening and profiling. These assays are available either as stand-alone or as a screening platform.

Isolated Tissues

In the study of the molecular mechanism of drug action, receptors are the most important link in the chain of events. The characteristics of the receptors are studied by the observations and quantitation of some physiological response elicited by a tissue in response to a drug. This constitutes the pharmacological approach and is an indirect study of the drug–receptor interaction. Pharmacological activity of a compound can be easily, quickly, and inexpensively obtained from isolated tissue experiments. Because of this simplicity, researchers in the early 1900s were able to define the interaction between drugs and receptors, predict drug effects, and formulate mathematical models of drug receptor theory. Isolated tissue techniques revolutionized and dominated the field until the end of the 20th century. Readers are directed to excellent reviews by Kenakin (1984, 2002), where the author discusses some very important concepts in isolated tissue methods and procedures for measuring drug activity.

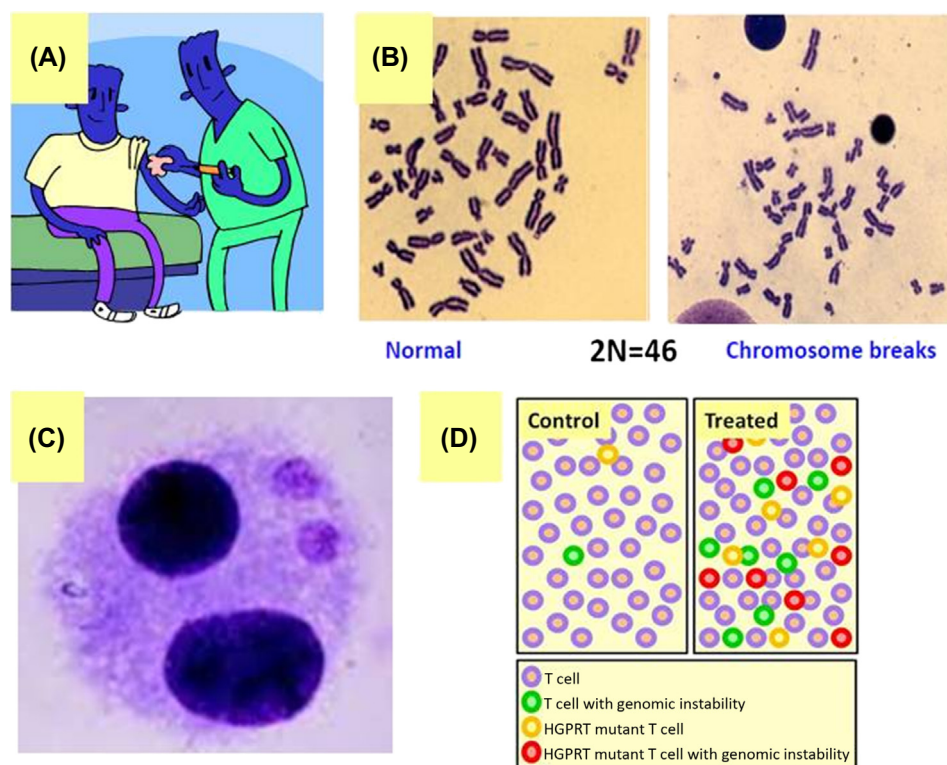
A variety of isolated tissues for each receptor class have been described in the literature. Three of the


FIGURE 8.8 Monitoring humans during clinical trials using peripheral blood lymphocytes from treated subjects can be collected and evaluated for a number of genotoxicity endpoints such as, chromosomal aberrations, micronuclei, and gene mutations. (A) Small amount of blood is collected from the subject in clinical trial to isolate peripheral blood lymphocytes for further genetic testing. (B) The normal intact chromosomes are shown from untreated subjects. (C) Breaks in chromosomes are seen in cells obtained from a subject who received treatment (if the test agent is clastogenic). (D) HGPRT gene mutation is observed in cells using various staining techniques and flow cytometry.

most widely used classes of isolated tissues are from cardiac muscle, vascular smooth muscle, gastrointestinal, and other smooth muscles.

Receptor Binding Studies

Radioligand binding studies were developed to identify and characterize receptor sites in various tissues. These studies provided insights into molecular interactions between ligands (endogenous and exogenous) and receptors and clarified the modes of drug action and the general mechanism that can lead to altered receptor function. Two principal parameters that are determined with these studies are the "density (B_{max})" of a given class of receptor sites and their "affinities (K_m)" for various ligands. The values determined from these studies are compared with those derived from in vitro and in vivo functional studies. There are subtle differences between pharmacological methods and radioligand binding procedures in regard to the characterization of receptors. Binding studies lack a functional response. However, agonists' interactions with binding sites and their sensitivity to temperature, various ions, and often to guanine nucleotides can provide some indication of efficacy. Disruption of the tissue to prepare membranes or solubilization may alter the pharmacological characteristics of receptor sites. With membrane preparations, there are few diffusional barriers, and thus the actual concentration of the drug in the receptor compartment can be fairly well estimated. In addition, radioligand binding studies identify ligand-binding sites, which may or may not represent bona fide receptors. Thus, results must be treated cautiously.

In a drug discovery program, radioligand binding studies are developed and performed for several therapeutic targets such as G protein—coupled receptors (GPCRs), ion channels (including hERG), and transporters using membranes from recombinant cells as well as native tissues.

GPCR functional assays: In addition, functional assays are used as a follow-up screen on GPCR targets. Ligand binding to GPCR promotes G protein coupling initiating signal transduction pathways, which trigger a series of cellular responses. These data can be used to substantiate the binding data.

Enzyme assays: Enzymes are increasingly recognized as potential drug targets in drug discovery. Multiple contract research organizations offer assays for several enzyme classes using different readouts like

fluorescence, luminescence, time-resolved fluorescence, and radiometry. The following are a few examples of enzymes that have been validated and are available for applications in pharmacology research. Hundreds of in vitro tests are available that utilize isolated or cloned animal and/or human receptors, ion channels, enzymes, transporters, and other components to determine the efficacy and safety of drugs or chemicals. Select examples of commonly used pharmacological assays are listed in Table 8.2.

In Vitro Drug Disposition Studies

Absorption, distribution, metabolism, and elimination (ADME) are the processes by which the body handles chemicals, referred to as drug disposition studies. The process of pharmacodynamics, however, describes how chemicals or test substances affect the living organisms at the molecular, cellular, organ, host, and population levels (Heinrich-Hirsch et al., 2001). As understanding of the molecular basis for ADME properties evolves, it is becoming possible to move beyond studying pharmacokinetics in intact people or animals. By combining data collected in vitro characterizing specific processes with computer models describing the interplay among the pharmacokinetic processes in the whole body, one can predict what would be expected to occur if intact organisms were exposed. Integrating data or predictions about chemical concentrations in different organs in the body with data or predictions about effects those chemicals would be expected to cause provides a long-term path toward predicting beneficial (therapeutic) or adverse (toxicological) effects. The success of this long-term path depends on continued research on the basic biological processes underlying pharmacokinetics, further development of in vitro systems both for ADME processes and for effects, and improved computer models. The major uses of in vitro ADME studies include the following:

1. To predict pharmacokinetics in vivo
2. To provide and/or characterize ADME processes and effects seen in vivo using in vitro assays
3. To predict drug−drug interactions

In vitro ADME studies help in optimization of pharmacokinetic characteristics of a drug candidate, identify the metabolic pathways, and provide valuable inputs for the design of in vivo studies. Multiple contract research organizations (the reader is suggested to visit these websites for additional information—e.g., MDS labs, CEREP) offer both standardized and customized assays as per sponsor's requirement for ADME parameters. These services include

- Physicochemical studies
  - pKa
  - LogD/LogP
  - Solubility (Thermodynamic/Kinetic)
  - Chemical stability at different pH
- Absorption/distribution Assays
  - PAMPA (Parallel Artificial Membrane permeability Assay)
  - Caco2 or MDCK (unidirectional/bidirectional)
  - P-gp efflux
  - Protein binding (ultrafiltration and equilibrium dialysis)
- Metabolic stability
  - Microsomal stability (rat, human, etc.)
  - Hepatocyte stability
  - Metabolite identification
  - Biological stability (plasma, serum, blood, simulating fluid)
- CYP450 Assays
  - CYP inhibition (CYP 1A2, CYP 2C9, CYP 2C19, CYP 2D6, CYP 3A4)
  - Mechanism based inhibition
  - Half-life determination/IC_{50} determination
  - CYP pathway identification
  - CYP450/metabolite identification
  - CYP induction
- Drug transporter assays
  - Identification of substrates and/or inhibitors
  - Induction of transporter (P-gp)

An illustration of drug transporters expressed in cells of various tissues and utilized to understand drug−drug interaction in vitro is shown in Fig. 8.9. Results from such studies are used in extrapolating effects on humans (FDA, 2012).

Major Challenges of In Vitro Absorption, Distribution, Metabolism, and Elimination

1. A major challenge in predicting in vivo pharmacokinetics is in characterizing the association between the in vitro conditions and the in vivo situation.
   a. For instance, measurements of glucuronyl transferase enzymatic activity using microsomes, a preparation of subcellular organelles, are highly dependent on experimental conditions, in part due to inaccessibility of the enzyme without solubilizing or pore-forming agents.
   b. Accurate quantitation of the microsomal content of liver tissue has been another concern.
   c. Similarly, there have been comparisons of the metabolic capabilities of genetically expressed enzymes, microsomes, isolated liver cells, and other systems for studying metabolism.

TABLE 8.2 List of Select Pharmacological Assays and Biomarkers Used in Research to Help Achieve Goals of 3Rs

RECEPTORS—G PROTEIN–COUPLED RECEPTORS (GPCRS)

Adenosine	Calcitonin	Endothelin	Histamine	Neuromedin U	Prokineticin
Adrenergic	Cannabinoid	GABA	Leukotrienes	Neuropeptide Y	Relaxin
Angiotensin	Chemokines	Galanin	Melanocortin	Neurotensin	Serotonin
Apelin	Cholecystokinin	Glucagon	Muscarinic	Orexin	Urotensin-II
Bombesin	Complement 5a	Glutamate	Neurokinin	Puringic	Vasopressin
Bradykinin	Dopamine	Neuropeptide W/B	Neuropeptide S	Protanoid	Somatostatin
Calcium sensing	Free fatty acids	Growth hormone	N-formyl peptide	Parathyroid hormone	Proteinase activate
Corticotropin-releasing factor	Glycoprotein hormone	Lysophospholipids	Orphan (Class A)	Thyrotropin-releasing hormone	Vasoactive intestinal peptide
Calcitonin gene–related peptide	Gonadotropin-releasing hormone	Melanin concentrating hormone	Opioid and opioid like	Platelet-activating factor	

ION CHANNELS—VOLTAGE-GATED CHANNELS

Calcium channels	Potassium channels	Sodium channels	Transient receptors potential channels

TRANSPORTERS

Adenosine transporter	Cannabinoid transporter	Serotonin	Dopamine
GABA ATP-binding cassette (ABC) transporter		Choline transporter	Norepinephrine
Solute carrier (SLC) transporters			

KINASES

Protein-tyrosine kinases	Protein-serine/threonine kinases	Atypical kinases	Other kinases

EPIGENETIC AND DNA RELATED

DNA methyltransferase	Demethylases	Histone methyltransferase	Histone acetyltransferases
DNA repair and mitotic enzymes	Topoisomerases		

OTHERS

Phosphatases	Proteases	Cyclooxygenases	HIV proteases

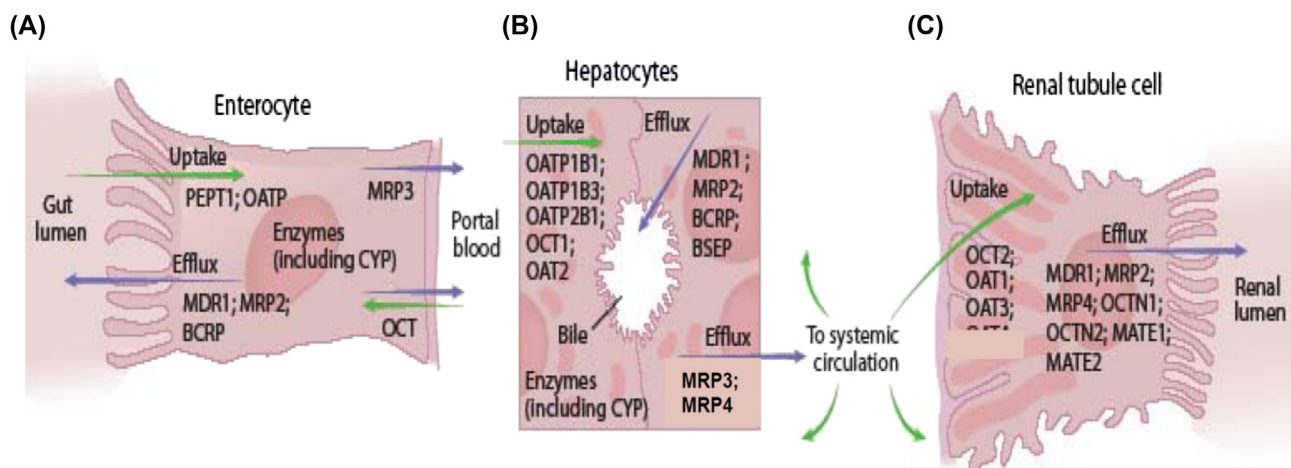
(A) **(B)** **(C)**


FIGURE 8.9 Illustration of efflux and uptake transporters in the gut wall (A), liver (B), and kidneys (C) that may be involved in a drug absorption, distribution, metabolism, and excretion (ADME).

   d. Similar issues exist for characterizing transporter activities, which are often essential to absorption, tissue distribution, and excretion.

   e. Limited in vitro methods to assess some processes, such as biliary excretion and reabsorption or urinary excretion (recent reports of sandwich cultures of hepatocytes to predict biliary excretion and expression of renal transporters in different systems like oocytes).

2. Another major challenge for predicting in vivo pharmacokinetics is developing and implementing computer simulation and modeling.

   a. A range of modeling approaches can be useful, with the long-range goal being to make predictions for the intact organism from the formula and structure of the chemicals.

   b. Considerations to link in vitro to in vivo—(1) mathematically describing selected ADME processes and (2) integrating multiple pharmacokinetic processes within physiologically based models to track chemical disposition within the "in vivo" context.

The ADME of drugs can be predicted using different in vitro assays. The data obtained from individual or a combination of assays are utilized to predict the in vivo ADME in animals or human. Select examples of ADME and PK parameters commonly used are listed in Table 8.3. For comparative purposes, an animal toxicokinetic model is shown in Fig. 8.10, and the toxicodynamics model with molecular mechanisms is shown in Fig. 8.11. These could also be considered as PK-PD modeling with allometric scaling for human risk assessment.

Advances in Technologies

With the advancement of computer science and continued improvement in instrumentation and

technologies such as fMRI, phMRI, mass spectrophotometry, and flow cytometry have become useful tools with high resolution and discrimination of biological processes (Kirshna et al., 1993; Criswell et al., 1998a,b, 2003; Chin et al., 2010; Lake, 2011; Darzynkiewicz et al., 2011; Dertinger et al., 2011; Canavan, 2013). Also, with appropriate dyes as diagnostic cell markers and imaging, these tools are able to generate valuable toxicity and efficacy data, while serving as biomarkers. Thus, they have contributed to the 3Rs and continue to make a difference in accelerating the discoveries in the fields of biomarkers, toxicity, efficacy, and overall risk assessment to humans (Andersen and Krewski, 2010). The systems' applications are briefly described in Table 8.4 and a few examples illustrating these technologies are shown in Fig. 8.12.

Systemic Toxicity Testing in Product Development

Keeping the concept of 3Rs and biomarkers in mind, significant progress has been made in the safety evaluation of substances, as this is the major area where a large
FIGURE 8.10 Toxicokinetics: an illustration of how the animal handles the drug and its metabolites.
FIGURE 8.11 Toxicodynamics: (A) An illustration of how a drug handles the animal and its relationship to human risk. (B) Molecular toxicodynamics interactions.

numbers of animals are used (Fig. 8.13). Traditional animal testing has not been a solution to current day research needs (FDA, 2018; SOT, 2013a,b, 2018). For example, it requires a lot of resources and time to test all substances in the environment, their utility in testing new substances such as nanoparticles or cell therapies is questioned, the limited predictivity of traditional tests for human health effects, and animal welfare considerations. Furthermore, the scheduled 2013 marketing ban on cosmetic ingredients tested for systemic toxicity in animals has given more impetus to use new ways of safety assessment and a critical review of alternatives was sought (Adler et al., 2011; Hartung, 2011, 2014) and integrated testing strategies for safety assessments were proposed (Hartung et al., 2013). To this end, a road-map for how to overcome the recognized scientific gaps for the full replacement of systemic toxicity testing using animals is proposed (Basketter et al., 2012). A multiprong global approach has been initiated in addressing toxicokinetics, skin sensitization, repeated-dose toxicity, carcinogenicity, and reproductive toxicity testing with deliberations among scientific experts periodically and proposed timely updates.

TABLE 8.4 Vision for Toxicity Testing for the 21st Century

Tools	Applications
High-throughput screens	Efficiently identify critical toxicity pathway perturbations across a range of doses and molecular and cellular targets
Stem cell biology	Develop in vitro toxicity pathway assays using human cells produced from directed stem cell differentiation
Functional genomics	Identify the structure of cellular circuits involved in toxicity pathway responses to assist computational dose-response modeling
Bioinformatics	Interpret complex multivariable data from HTS and genomic assays in relation to target identification and effects of sustained perturbations on organs and tissues
Systems biology	Organize information from multiple cellular response pathways to understand integrated cellular and tissue responses
Computational systems biology	Describe dose—response relationships based on perturbations of cell circuitry underlying toxicity pathway responses giving rise to thresholds, dose-dependent transitions, and other dose-related biological behaviors
PBPK models	Identify human exposure situations likely to provide tissue concentrations equivalent to in vitro activation of toxicity pathways
Structure—activity relationships	Predict toxicological responses and metabolic pathways based on the chemical properties of environmental agents and comparison to other active structures
Biomarkers	Establish biomarkers of biological change representing critical toxicity pathway perturbations

HTS, high-throughput screening.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Identification, development, and validation of biomarkers have played a significant role in achieving the goals of the reduction, refinement, and replacement (3Rs). Currently, a global effort is underway to recognize and put well-thought-out assays, instrumentation, and strategies in place for product discovery and development. Global regulatory agencies are working in collaboration with academia and industry, so the stakeholders, the thought, the talk, and the action are on the same page. Meaningful cooperation is sought, as needed, to attain a common goal of achieving the 3Rs while using biomarkers as we discover, develop, market, and cherish man-made advancements. This kind of collective and collaborative effort and efficient use of resources with funding from multiple bodies will continue to provide impetus in fully achieving the ultimate goal of reducing, refining, and replacing animal use, as applicable, in efficacy and toxicity testing and finding viable alternatives at all times.

Moving forward with continued innovations in biomarkers, instrumentation, and collaborative effort by the stakeholders is expected to deliver desired results in 3Rs. The ideas, vision, and initial promise in developing and utilizing technologies, such as "multiorgans a chip," an organ-by-organ, would become a reality. This is based on the premises that the "rat is not human" and animal models cannot fully mimic human patients, diseases, and toxicity. One such example is asthma, where the constriction of airways and all of the other characteristics of the disease are different. However, in many other situations, the human chip technology seems to be promising and serving as a closer surrogate to a human, at least in the drug discovery stages of drug development (Rockoff, 2013; Hartung, 2014; FDA, 2018). With these advancements, the concerns of excessive use of animals in product development would continue to decrease.

Adverse Outcome Pathways and Their Role in Revealing Biomarkers

Magdalini Sachana

Organization for Economic Cooperation and Development (OECD), Paris, France

INTRODUCTION

Decades of research in the field of toxicology have led to a vast amount of scientific knowledge and a correspondingly large literature that is stored in peer-reviewed journals and text books. While the literature on this particular form is suitable and useful for researchers, it is very challenging for regulators, who assess the safety of chemicals, to use this knowledge that is spread in so many sources and is not organized in a suitable and easy accessible manner. This limits the ability to apply knowledge from toxicological studies and to take advantage of mechanistic information that could be useful for enriching regulatory decisions.

Another challenge that the regulators face today is the considerable high number of untested chemicals with significant uncertainty concerning their environmental and human health safety that need to be assessed at a short time frame. To close this data gap with the current approach that relies almost completely on animal testing is not achievable because this is far too resource-intensive concerning money, time, and number of animals. In parallel, the research community and industry have been investing significant time, effort, and resources in innovation by developing cutting-edge cellular models (e.g., three-dimensional organotypic cultures, human induced pluripotent stem cells, microfluidic organs on a chip, etc.), computational methods (e.g., in silico, modeling), and technologies (e.g., omics, high-throughput, and high-content) that could advance chemical safety assessment, complement, and potentially replace animal testing in long term. A variety of sophisticated in vitro methods are now available for a number of endpoints used for different regulatory purposes, which have the potential to close this data gap by allowing targeting testing that is based on mechanistic understanding that is captured in "toxicity pathways."

In recent years, the concept of "toxicity pathways" and its use in regulatory arena gained support from both researchers and regulators. First, the International Program on Chemical Safety (IPCS) published the framework for using mode of action information to determine human relevance of animal data (Sonich-Mullin et al., 2001) that was further refined later (Boobis et al., 2006, 2008). In 2007, the United States National Academy of Science (NAS) published the Report on Toxicity Testing in the 21st Century: A Vision and a Strategy in which emphasis to the "toxicity pathways" based on similar principles was suggested as one of the tools to help the paradigm shift in toxicity testing. This paradigm shift involves the evaluation of perturbations of biological pathways by chemicals in well-designed in vitro models preferably of human origin instead of rodents to predict adverse outcomes (AOs) in humans (NRC, 2007).

In 2012, the Organization for Economic Cooperation and Development (OECD) initiated a program that aimed to evolve the concept of adverse outcome pathways (AOPs), which was first introduced by Ankley et al. (2010). An AOP is not intending to provide a comprehensive description of every aspect of the biology and toxicology; instead it is capturing only the critical steps in a toxicity pathway. A reductionist approach to biology and toxicology is followed to reveal and establish the important events at each major level of biological organization (e.g., molecular, cellular, tissue, organ, individual) that if do not occur then the downstream sequence of events does not take place, including the AO.

Although the AOP concept is reasonable new, it has its roots to a certain extent to the biomarker concept

that was initially introduced in 1990s (WHO, 1993, 2001) and it is presented in this book by Anna M. Fan in Chapter 69 (Fan, 2018). The biomarker concept is also serving regulatory purposes and makes use of mechanistic knowledge that aligns to a certain degree with the current AOP thinking.

The chapter will focus on the AOP framework, and it will provide some principles related to AOP development and assessment. It will also explore the differences and similarities between the two regulatory frameworks (i.e., biomarkers and AOPs), and it will close by presenting some relevant examples.

ADVERSE OUTCOME PATHWAYS: PRINCIPLES OF DEVELOPMENT AND ASSESSMENT

The development of AOPs is an international effort that relies on existing biological and toxicological knowledge concerning the linkage between two anchors of a toxicity pathway—the molecular initiating event (MIE), which represents the initial interaction(s) of a stressor with a biomolecule within or on the body of an organism, and an AO (Fig. 9.1). The AO is a specialized key event (KE) that represents the final step of an AOP, which should be relevant to regulatory decision-making in chemical safety (i.e., corresponding to an apical endpoint or measurements that are done in a test guideline study such as developmental neurotoxicity, carcinogenicity, reproductive toxicity etc.). On the other hand, the MIE captures the interaction (e.g., covalent binding, hydrogen bonding, electrostatic interaction, etc.) between a chemical and the biomolecules (i.e., DNA, proteins etc.) within an organism, and it is the trigger for the following steps in the pathway.

Between the MIE and the AO, there is a series of KEs that are captured. KEs represent important steps that

need to take place at different levels of biological organization that ranges from the cellular to the organ level (Fig. 9.2). The KEs need to be both measurable and essential, and so a defined biological perturbation can progress and eventually culminate with the manifestation of a specific AO. A KE can be the altered activity of an enzyme, upregulation or downregulation of a gene, increased or decreased levels of a hormone or protein, histopathological findings in a tissue, functional changes of an organ, etc.

The linkages between KEs are named key event relationships (KERs) that are described in the form of a one-way arrow relationship, linking an upstream "causing" KE to a downstream "responding" KE (Fig. 9.1). The knowledge captured in KER descriptions permits the AOP developer to collect biological and toxicological information and support the evaluation of the level of confidence in each KER and consequently in the whole AOP. Building confidence on KERs contributes to increased uptake of AOPs for regulatory application. Having confidence in data points measured at low levels of biological organization (i.e., molecular and cellular) facilitates the prediction of outcomes at higher levels of organization (i.e., organism and population level). Overall, the accurate description of KERs in an AOP provides the scientific basis for deriving the probable degree of alteration of a downstream KE from the measured state of an upstream KE.

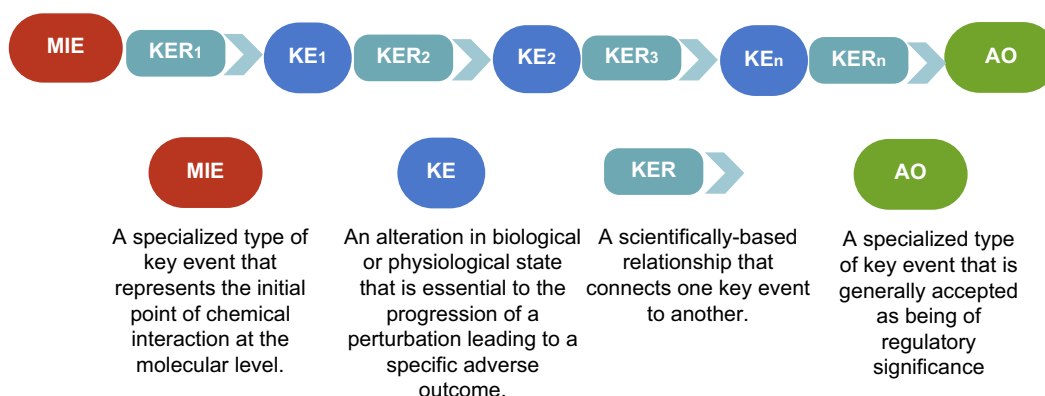
An AOP can be seen as a simplification of the biology describing a single sequence of events that begin with an MIE that moves along a series of intermediate KEs to final reach the AO. A single AOP aims to describe how one particular molecular perturbation may cause one AO and it does not aim to cover all possible AOs that the perturbation may cause nor every possible pathway through which a particular AO may occur. Since the beginning of the OECD AOP program, it was recognized that MIEs, KEs, and AOs may be shared by


FIGURE 9.1　A schematic representation of the adverse outcome pathway (AOP) framework. An AOP is triggered by a molecular initiating event (MIE), an initial interaction with a biological target that leads to a sequential cascade of key events (KEs), linked to each other by key event relationships (KERs) to result in an adverse outcome (AO) of regulatory relevance.
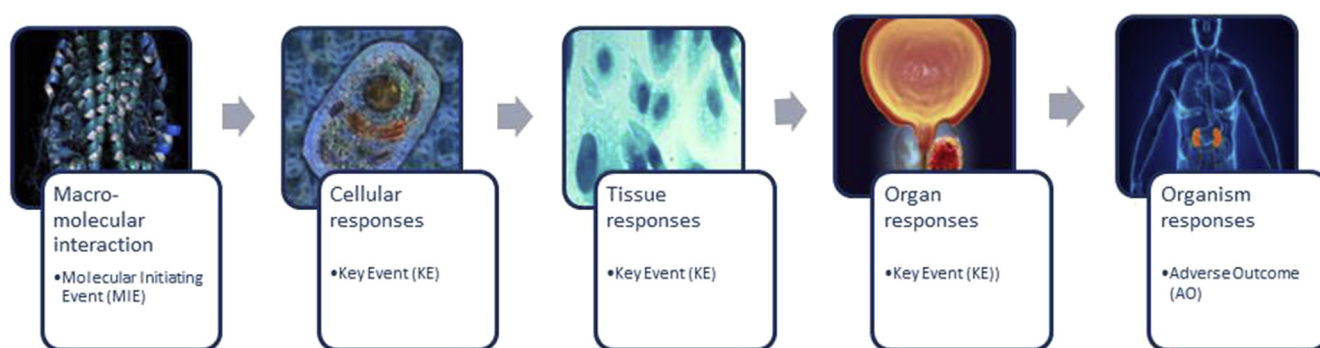

FIGURE 9.2 Graphical representation of a hypothesized adverse outcome pathway. Key events (KEs) are represented in an increasing order of biological organization starting from cellular, continuing to tissue/organ, and ending to the organism level.

more than one AOP, and that a knowledge base (KB) is required to capture this sharable information. For this reason, the AOP development process takes place making use of an IT platform named AOP-KB that permits that the described KEs and KERs are modular and independent units that can be reused by other AOP developers. By having the development of the AOPs done in an electronic platform, it also permits the building and conceptualization of AOP networks.

When two or more AOPs have one or more KEs in common, then the assembly of these AOPs in one place constructs an AOP network. The components of an AOP (KEs and KERs) are described in a modular fashion within the AOP-KB that allows the creation of AOP networks that emerge from the description of individual AOPs that share KEs. The vision is that as more AOPs are introduced to the AOP-KB, the constructed AOP networks will be able to capture gradually all the available scientific knowledge relevant to a number of possible AOs that an MIE might trigger or the range of pathways through which a particular AO may happen. AOP networks are considered the real tool that the regulators will use in the future for most of the regulatory endpoints because for the majority of AOs, a number of distinct mechanisms are involved, with the rare exception of some topical endpoints, e.g., skin sensitization. Similarly, capturing all the potential MIEs that are involved in the manifestation of an AO within a network can help regulators to assess exposure to mixtures of chemicals (Knapen et al., 2015, 2018; Villeneuve et al., 2018).

Indeed, AOPs try to partially depict what happens at the cellular level, where networks of molecular reactions occur that can be organized into higher-order interconnected pathways. Molecules are synthesized, degraded, transported from one location to another, and assembled into complexes and higher-order structures with other molecules. Intensive toxicological studies reveal the interaction and the effects of chemicals to signal transduction pathways, hormonal pathways, and other

aspects of cell biology, as well as to specific genes and their proteins. By annotating all of these pathways in a single, consistent format, the AOP-KB systematically provides mechanistic knowledge that can be used for regulatory purposes and inform about existing knowledge gaps.

It is recognized that AOP descriptions reflect current knowledge and might present some knowledge gaps. For this reason, AOP descriptions are considered "living documents" that can evolve as new scientific information becomes available. AOPs are helpful to depict knowledge gaps that can trigger targeted scientific research that involves the collaboration between experts in various areas. Once new scientific evidence becomes available, an AOP can be revised and reassessed for its completeness and the relevance to regulators.

Within the OECD program on AOPs, member countries jointly develop and review AOPs and make them available to the regulators for further use. For this reason, a guidance document and a users' handbook on AOP development and assessment have been developed (OECD, 2016a, 2016b, 2016c, 2017). AOP descriptions that are developed within the OECD AOP development program and reach a mature stage undergo peer-review as per procedures outlined by the OECD, which involve two phases, the internal and the external review (Delrue, 2016). The Extended Advisory Group on Molecular Screening and Toxicogenomics (EAGMST) that oversees the AOP development process is responsible for reviewing the AOPs for completeness (internal review) and scientific rigor (external review), and for approving the final AOPs.

The AOP framework provides a transparent and scientifically based way to depict and make available current biological and toxicological knowledge that allows the prediction of subsequent KEs and AOs, once confidence has been built on KERs. This knowledge can help assay developers to invest money and effort on KE measurements that can be made efficiently using in vitro, in silico, and in chemico approaches, which are

cost-effective and have a predictive value for adverse effects at higher levels of organization that are relevant to regulatory decision-making. AOPs are not only useful for assay development but also they can be applied in more regulatory contexts as it is discussed below.

ADVERSE OUTCOME PATHWAY FRAMEWORK: SIMILARITIES AND DIFFERENCES WITH BIOMARKERS

In response to some incidences related to chemical-induced human health adverse effects and environmental disasters that have happened in the past, there has been a continuous effort by regulatory agencies to improve the hazard assessment of the chemicals that are used and released in the environment. These efforts have led to ever-growing interest in developing and applying frameworks that rely on the understanding of the biological processes that can take place in an organism after chemical exposure. The concept of biomarkers was introduced in the 1990s (WHO, 1993, 2001) aiming to enhance hazard identification. Recently, the AOP framework came into play and is considered suitable for application in different regulatory contexts (OECD, 2016a). Both frameworks share lots of similarities and differences, and the AOP framework has a lot to learn and eventually build on the experiences gained from the implementation of the biomarkers framework.

There are three main types of biomarkers, namely biomarkers of exposure, effect, and susceptibility. However, in this occasion we compare only the biomarkers of effect with the AOPs, as a separate framework, named the aggregates exposure pathways (Teeguarden et al., 2016) deals with the exposure to chemicals. Regarding susceptibility, this is dealt within the applicability domain for each AOP and it is an additional consideration that needs to be taken into account during the risk assessment process. The taxa, life stage, and sex applicability of AOPs help to understand how available data can be extrapolated from in vitro to in vivo, including potential human relevance.

A biomarker of effect captures a biological response after exposure to a chemical that is linked to the manifestation of an AO or disease, and there are many similarities between this concept and the concept of AOPs (OECD, 2017; Ryan et al., 2007). One similarity is that biomarkers of effect and the KEs that are present in the AOPs both aim to capture responses at the molecular or cellular level that happens early in time after exposure to chemicals, so they can be used to predict AOs or diseases that manifest later in time. Because of this joint focus on predicting AOs, biomarkers of effect and KEs share common principles. First, both need to be measured in a relatively routine manner and preferably

should be easy to collect and analyze. Second, KEs and biomarkers of effects need to be supported by toxicological and biological evidence, so they can be plausible and have a potential predictive validity by establishing dose-response relationships. Finally, temporal concordance is very important to establish KEs and biomarkers of effect as their early observation before the AO or disease is key for their predictive value. AOPs and biomarkers are also linked to global efforts to advance chemical risk assessment, and they require similar level of validation.

Despite the similarities between biomarkers of effects and AOPs, these are very close but are still separate and distinct concepts. AOPs try to capture the whole pathway that leads to an AO, providing a more holistic approach and full mechanistic understanding, whereas the biomarkers seem to be only a snapshot of the AOP that resembles a nonadjacent KER that links the biomarker with the AO or the disease, without taking into account all the mechanistic knowledge that is available. Moreover, building confidence on all the KEs present in an AOP that are described through the collection of biological and toxicological information permits the extrapolation of data measured at the molecular or cellular level to predict outcomes at the organism or population level. Biomarkers of effect tend to rely and focus on the use of molecular epidemiological data, meaning that human data are evaluated without requiring any interspecies extrapolation analysis. In contrast, AOPs tend to use mainly in vitro and in silico data to support the KERs that are present at molecular and cellular levels, and both in vitro—in vivo extrapolation and interspecies extrapolation are required when data derived from nonhuman-based cellular models. However, epidemiological data can also be used in the AOP context as it allows the support of KEs that appear closer to a higher level of biological organization. Other differences are present in the way in which AOPs and biomarkers of effect are used in the regulatory decision-making. Biomarkers are tools that can be applied directly in the process of risk assessment and tends not only to assess the presence or absence of an AO or disease but also to provide, when feasible, valuable dose-response data for risk assessment (Swenberg et al., 2008). On the other hand, AOPs use dose-response data to support the confidence and their utility in the regulatory context, and consequently they play a supportive role in the process of risk assessment that is explained fully in the last section of the present chapter. Furthermore, AOPs can be a source for establishing biomarkers of effect, and it discussed in the following section of this chapter.

Given the differences and similarities in definition, methodology, tools, and application domains for AOPs and biomarkers of effect, it can be concluded that both are very useful frameworks in the field of chemical risk assessment, and AOPs can potentially support the

identification of new biomarkers that could subsequently inform chemicals and safety regulations.

ADVERSE OUTCOME PATHWAYS AS A TOOL TO RETRIEVE BIOMARKERS

The AOP-KB is an open-data resource of chemical-induced toxicity pathways. It consists of two main modules: the AOP-Wiki (https://aopwiki.org/) and the Effectopedia (https://www.effectopedia.org/), where the development of qualitative and quantitative AOPs, respectively, takes place. The eAOP portal (https://aopkb.oecd.org/) is the main entrance point for the KB, which is a search engine for AOPs and KEs that are available in both AOP-Wiki and Effectopedia.

Besides of enabling the development of AOPs by scientists, the AOP-KB can also aid regulators, who seek mechanistic information to support the chemical evaluation process. Another role for the AOP-KB would be to facilitate the identification of biomarkers that then can be further validated before their implementation for risk assessment purposes.

The KEs as they are described following the guidance provided in the OECD Users' Handbook (OECD, 2017) can be a real valuable source for retrieving biomarkers. A KE description contains information on the biological state, the biological compartment, and its general role in the biology. The description of the biological compartment in which a KE is measured can provide important information because biomarkers should be easily collected using noninvasive procedures. For example, a KE that is measured in a fluid (e.g., plasma, cerebrospinal fluid) has more potential to become a biomarker compared with a KE that can only be measured in a tissue.

In the dedicated section named "How it is Measured or Detected," more information related to KE can be obtained regarding the reliability of the methods with which a KE can be measured. These methods can be either advanced methods that underwent validation and became test guidelines or methods published in the peer-reviewed literature. Methods used to measure KEs can be found in the OECD Test Guidelines website (http://www.oecd.org/chemicalsafety/testing/oecdguidelinesforthetestingofchemicals.htm) and the EURL ECVAM Database Service on Alternative Methods to Animal Experimentation (DB-ALM) (https://ecvam-dbalm.jrc.ec.europa.eu/).

Significant information can also be obtained from a section, which is dedicated to the essentiality of the KEs within an AOP. In this section, experimental data are provided showing that by blocking a KE, the downstream KEs, including the AO, are prevented to happen. Blockage of the downstream KEs and the toxicity pathway mainly can be recorded using data from studies that are based on knockout models' specific inhibitors, induced mutants, overexpression constructs, and other single-gene perturbations. Identifying biomarkers with cause−effect relationship is highly important, and besides the essentiality of KEs, the biological plausibility of the KERs in an AOP can inform about the mechanistic (i.e., structural or functional) relationship between KEupstream and KEdownstream.

Although the biological plausibility followed by essentiality are the most influential criteria to determine the degree of confidence in an overall hypothesized AOP that will then guide its potential regulatory application (Meek et al., 2014a,b), still toxicological data using chemical stressors that define the associations between KEs within an AOP are considered important, especially for establishing biomarkers of effect. The dose-response concordance and temporal relationships between and across the series of KEs within an AOP can be retrieved from experimental studies in in vivo, in vitro, and in silico models and can inform biomarkers of effect that are applied in risk assessment.

It is recognized that a KE that occurs at lower doses and earlier time points than the following KEs of an AOP based on experimental data has better chances to become a biomarker. Furthermore, if the incidence or frequency of a KE is greater than that of the remaining KEs within an AOP, then it could satisfy most of the principles for defining biomarkers of effect.

Overall, the AOP-KB is a source for exploring KEs that have the potential to become biomarkers of effect. The AOP-KB currently contains more than one thousand KEs and is constantly increasing due to contributions from the scientific community. All the available data in the KB have not been reviewed or published yet through the OECD process. However, as the AOPs reach a maturation stage and enter the OECD review process, they can obtain OECD-approved status. This pool of KEs is worth exploring in order to identify even well-established and validated biomarkers of effect that can facilitate chemical risk assessment.

BIOMARKERS DEPICTED FROM THE ADVERSE OUTCOME PATHWAY−KNOWLEDGE BASE

Based on the AOP-KB, using the key word "biomarker," commonly recognized or emerging biomarkers that are associated with KEs of specific AOPs were identified. Information was derived mainly from the AOP-Wiki platform. Table 9.1 presents the results after conducting this search in the AOP-KB. The potential biomarkers are not presented or organized in any particular order and are

TABLE 9.1 Potential Biomarkers Revealed After Searching the Scientific Knowledge Stored in AOP-KB

Potential Biomarkers and Associated KEs	AOP
Oxidative stress (plasma protein carbonyl content)	AOP 220: Chronic Cyp2E1 activation leading to liver cancer
Increase in vascular resistance (noninvasive ultrasound-based method to evaluate flow-mediated vasodilation)	AOP 149: Peptide oxidation leading to hypertension
Decrease in tetrahydrobiopterin (tetrahydrobiopterin plasma levels)	AOP 149: Peptide oxidation leading to hypertension
Promotion of SIX-1–positive basal-type progenitor cells	AOP 167: Early-life estrogen receptor activity leading to endometrial carcinoma in the mouse
Increased induced mutations in critical genes	AOP 46: Mutagenic mode of action leading to hepatocellular carcinoma
Formation of hemoglobin adducts	AOP 31: Oxidation of iron in hemoglobin leading to hematotoxicity
Altered gene expression specific to CAR activation	AOP 107: CAR activation leading to hepatocellular adenomas and carcinomas in the mouse and the rat
Reduction in plasma vitellogenin concentrations	AOP 23: Androgen receptor agonism leading to reproductive dysfunction AOP 25: Aromatase inhibition leading to reproductive dysfunction
Inhibition of acetylcholinesterase (AChE)	AOP 16: Acetylcholinesterase inhibition leading to acute mortality
Reduced levels of brain-derived neurotrophic factor	AOP 13: Chronic binding of antagonist to NMDARs during brain development induces impairment of learning and memory abilities AOP 12: Chronic binding of antagonist to NMDARs during brain development leads to neurodegeneration with impairment in learning and memory in aging AOP 54: Inhibition of Na+/I− symporter leads to learning and memory impairment

applicable to both human health and environmental risk assessment.

The list of potential biomarkers depicted after searching the AOP-KB and shown in Table 9.1 is neither exhaustive nor definitive. This is only a first attempt aiming to illustrate how AOP-KB can be used to retrieve biomarkers of effect by using available information that can be found in KEs, KERs, and AOPs. Different strategies than the one applied here can potentially be followed to retrieve biomarkers using the AOP-KB. Depending on the AO, all the relevant AOPs can be explored, and by digging in the information that is stored in KEs and KERs, new potential biomarkers of effect can emerge.

REGULATORY USE OF ADVERSE OUTCOME PATHWAYS

In the chemical industry, mainly at the stage of research and development, different in vitro and in silico models are already being used routinely. However, alternative to animal methods are hardly used for regulatory purposes in different steps of hazard and risk assessment. An important hurdle that impedes the use of data derived from nonanimal methods is the lack of mechanistic information and the association of these data with an AO that is relevant to regulatory decision. The availability of toxicological mechanistic data depends on the published scientific knowledge and the way that is stored, so it can be accessible by regulators.

Toward this goal, the OECD program on AOPs has spearheaded the development of processes to review hypothesized AOPs and built the AOP-KB, an ontology-driven database that combines existing biological knowledge with empirical data derived from toxicological experimental studies (Delrue et al., 2016). The AOPs stored in the KB are getting gradually reviewed and published in the OECD series on AOPs (http://www.oecd-ilibrary.org/environment/oecd-series-on-adverse-outcome-pathways_2415170x). The number of AOPs with OECD-approved status, although limited at the moment, is steadily increasing, and OECD encourages the uptake of AOPs by regulators in their everyday work.

It is also important to recognize that, due to its dependence on volunteer efforts from OECD member countries, the AOP-KB currently includes a very incomplete sample of all known toxicity pathways, with coverage varying across endpoints that are linked to legal data requirements and taxonomic groups. Across the toxicological endpoints, coverage is strongest in the area of neurotoxicity,

carcinogenicity, and endocrine disruption based on data derived from the OECD workplan. Coverage is also good for both human health and environmental-related endpoints. Nonetheless, the absence of certain AOPs from the KB needs to be interpreted with care, as in most cases it does not mean that biological and toxicological knowledge is not available but that nobody until now has volunteered to develop certain AOPs and make them available through the AOP-KB.

The AOP-KB is a recently introduced tool that was launched in 2014 and allows not only the development of AOPs but also the query by users who search for mechanistic information. Indeed, it has been acknowledged that AOPs can help to progress in many areas of regulatory toxicology and, most importantly, to support integrated approaches for testing and assessment (IATA) (Tollefsen et al., 2014). AOPs can be applied as a framework to develop IATA as it can facilitate (1) the evaluation of existing information on chemical(s) undergoing assessment in a structured way and potentially conclusion and regulatory decision on the hazard based on existing information; (2) the identification and generation of certain type of data derived from nonanimal methods that might increase the confidence level concerning evidence of a particular hazard; and (3) determination if additional information is required to make a regulatory decision (OECD, 2016b; Sachana and Leinala, 2017; Sakuratani et al., 2018).

The AOP-KB allows users to query diseases, AOs, molecular markers, and reports on available AOPs and KEs ranked by semantic similarity to the query. The access to the AOPs and KEs after searching through the AOP-KB permits the visualization of networks of AOPs that provide a more complete picture of the number of mechanisms involved. This visualization can primarily inform in vitro assay development that can further help the selection of methods that can become candidates for OECD Test Guidelines. It is clear that identifying KEs that are essential to induce an AO will allow those who develop alternative methods to direct resources toward the development of testing methods derived from knowledge captured in AOPs or networks of AOPs. Significant progress has already been made in the area of skin sensitization, where the availability of an AOP, with OECD-approved status, related to this endpoint guided the advancement of in vitro testing (Delrue et al., 2016) and defined approaches (OECD, 2016c; Casati et al., 2018).

The MIE in each AOP, which is a specialized KE, captures the specific interaction of chemical(s) with biological systems and can be applied toward the development of mechanistically based structure—activity relationships (SARs). Establishing SARs by using AOPs can assist not only to predict whether a chemical with similar chemical structure can trigger an AOP but also

facilitate the chemical grouping and subsequent read-across (OECD, 2014). In case that in vitro assays are available for a number of essential KEs for a given AOP or network of AOPs, these results can be used to develop SARs or, when quantifiable, to develop Quantitative structure—activity relationship (QSARs) that can be used as stand-alone prediction or to confirm the grouping of chemicals as it happened in the case of skin sensitization (Dimitrov et al., 2016). Using mechanistic information derived from AOPs, the robustness of the data gap—filling approach information can be improved when grouping of chemicals is applied compared with grouping of chemicals approaches that are solely based on their structural similarity.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The AOP framework is useful for many regulatory purposes, including the identification of biomarkers. Developed AOPs are stored in the AOP-KB and undergo reviewing to acquire OECD-approved status. The AOP-KB is in the process to be redesigned completely to support intuitive access to the AOP browsing and data analysis tools. The new AOP-KB will retain some current features, but the aim is to make it an attractive and user-friendly application that satisfies not only the needs of the AOP developers but also the requirements of regulators that use AOPs in their risk assessment. By improving the flexibility and performance of the AOP browser and by creating a new pathway diagram visualization tool, the development and use of AOPs from the scientific and regulatory community, respectively, is expecting to increase.

Central Nervous System Toxicity Biomarkers

Lucio G. Costa[1,2]

[1]Department of Environmental and Occupational Health Sciences, University of Washington, Seattle, WA, United States;
[2]Department of Medicine & Surgery, University of Parma, Parma, Italy

INTRODUCTION

The human nervous system is the most complex organ systems in terms of structure and function. It contains billions of neurons, each forming thousands of synapses leading to a very large number of connections. It also contains perhaps 10 times more glial cells (astrocytes, oligodendrocytes, microglia) than neurons, which play important roles in the overall development and functioning of the nervous system (Barres, 2008). The central nervous system (CNS) with the help of the peripheral nervous system detects and relays sensory information inside and outside the body, directs motor functions, and integrates thought processes, learning, and memory. Such functions and their complexity, together with some intrinsic characteristics (e.g., mature neurons do not divide; they are highly dependent on oxygen and glucose), make the nervous system particularly vulnerable to toxic insults.

Neurotoxicity has been defined as "any adverse effect on the chemistry, structure or function of the nervous system, during development or at maturity, induced by chemical or physical influences" (Costa, 1998a). Morphological changes such as neuronopathy (a loss of neurons), axonopathy (a degeneration of the neuronal axon), or myelinopathy (a loss of the glial cells surrounding the axon), or other gliopathies, are considered important adverse effects, even if they are mild or partially reversible. All neurochemical changes, in the absence of structural damage, are also considered adverse effects, even if they are fully reversible.

Over 200 chemicals are known to be neurotoxic to humans (Grandjean and Landrigan, 2006), and for almost twice as many there is evidence of at least animal toxicity (Spencer et al., 2000). Neurotoxic chemicals include metals, organic solvents, pesticides, various organic substances, drugs, and natural compounds (Table 10.1). In addition to chemical exposures, head concussions leading to mild traumatic brain injury (mTBI) can also cause neurobehavioral, neurological, and neuropathological alterations (Mayer et al., 2017; Dixon, 2017; Steenerson and Starling, 2017).

The above definition of neurotoxicity also indicates that there are potential differences in susceptibility to toxicants between the developing and the mature nervous system. In most cases, the developing nervous system is more sensitive to adverse effects than the adult nervous system, as indicated, for example, by the most deleterious effects of ethanol, methylmercury, or lead when exposure occurs in utero or during childhood (Giordano and Costa, 2012). Furthermore, the blood—brain barrier (BBB), which protects the mature nervous system from the entry of a number of substances, appears to be poorly developed at birth and during the first few years of life (Jensen and Catalano, 1998).

Measuring Central Nervous System Dysfunctions

Neurotoxic effects can be detected in the course of standard toxicity testing (acute, subacute, subchronic, chronic, developmental/reproductive toxicity) required by regulatory agencies worldwide. However, specific guidelines exist to further probe the potential neurotoxicity of chemicals (USEPA, 1998a; OECD, 1997). Such tests are performed in rodents and are meant to assess specific effects of the tested chemical on the nervous system. The United States Environmental Protection Agency guidelines focus on a functional observational battery, on measurements of motor activity, and on neuropathological examinations (USEPA, 1998a). The Organization for Economic Cooperation and Development guidelines, similarly, focus on clinical observations, on functional tests (e.g., motor

TABLE 10.1 Selected Examples of Compounds From Different Chemical Classes Known to Be Neurotoxic in Humans

Chemical Class	Compound	Neurotoxic Effect
Metals	Manganese	**Extrapyramidal syndrome**
	Methylmercury	**Cerebellar syndrome, visual dysfunction, encephalopathy, CNS teratogenicity**
	Lead	Peripheral neuropathy (myelinopathy), **encephalopathy**
	Thallium	Peripheral neuropathy, **optic neuropathy**
Organic solvents	Ethanol	**Acute, chronic encephalopathy, CNS teratogenicity (fetal alcohol syndrome)**
	n-Hexane	Peripheral neuropathy
	Methanol	**Optical neuropathy**
	Toluene	**Encephalopathy, CNS teratogenicity (fetal solvent syndrome)**
Pesticides	Carbamates	**Cholinergic syndrome**
	Chlorinated cyclodienes	**Seizures**
	Methyl bromide	**Acute encephalopathy**, peripheral neuropathy, **optic neuropathy**
	Organophosphates	**Cholinergic syndrome**, delayed peripheral neuropathy (some)
Other organic substances	Acrylamide	Peripheral neuropathy
	Cyanide	**Seizures**
	Hydrogen sulfide	**Acute encephalopathy**
	Polychlorinated biphenyls	**Behavioral developmental neurotoxicity**
Drugs	Cisplatin	Peripheral neuropathy
	Chlorpromazine	**Extrapyramidal disorders, seizures**
	Thalidomide	Peripheral neuropathy, teratogenicity
	Valproic acid	**Acute encephalopathy, CNS teratogenicity**
Natural compounds	Botulinum toxin	Neuromuscular transmission syndrome
	Domoic acid	**Encephalopathy, neuronopathy, seizures**
	Ricin	**Neuronopathy**
	Tetrodotoxin	Ion channel syndrome (Na^+ channels)

CNS effects are in bold. *CNS*, central nervous system.

Selected from Spencer, P.S., Schaumburg, H.H., Ludolph, A.C. (Eds), 2000. Experimental and Clinical Neurotoxicology. Oxford University Press, Oxford, pp. 1—1310 and adapted from Costa, L.G., Giordano, G., Guizzetti, M., 2011. Predictive models for neurotoxicity assessment. In: Xu, J.J., Urban, L. (Eds.), Predictive Toxicology in Drug Safety. Cambridge University Press, pp. 135—152.

activity, sensory reactivity to stimuli), and on neuropathology (OECD, 1997). These batteries are not meant to provide a complete evaluation of neurotoxicity but to act as a Tier 1 screening for potential neurotoxicity. If no effects are seen at the appropriate dose level and if the chemical structure of the substance and/or its metabolites does not suggest concern for potential neurotoxicity, the substance may be considered as not neurotoxic. On the other hand, positive findings can be followed up by further testing (Tier 2) in case of commonly existing substances with commercial value or wide exposure; for new chemical entities, development of the molecule may instead be abandoned. The decision to carry out additional studies should be thus made on a case-by-case approach and may depend on factors such as the intended use of the chemical, the possibility for human exposure, and its potential accumulation in biological systems. Such Tier 2 studies may include specialized behavioral tests, electrophysiological and neurochemical measurements, and additional morphologic studies. Examples are tests for measuring learning and memory, measurements of nerve conduction velocity, and biochemical parameters related to neurotransmission or to indices of cell integrity and functions (Costa, 1998a,b).

As said, the nervous system undergoes gradual development that continues well after birth in both animals and humans. While, on one hand, the developing nervous system may more readily adapt to, or compensate for, functional losses as a result of a toxic insult,

damage to the nervous system during key periods of brain development may also result in long-term, irreversible damage (Costa, 1998a). Evidence that developmental exposure to chemicals and drugs may alter behavioral functions in young animals began to be described in the early 1970s. The field of developmental neurotoxicology thus evolved from the disciplines of neurotoxicology, developmental toxicology, and experimental psychology (Makris et al., 2009). In response to this issue, developmental neurotoxicity (DNT) testing guidelines were developed both in the United States and in Europe (USEPA, 1998b; OECD, 2007). Exposure to the test chemicals is from gestational day 6 to postnatal day 10 or 21 to the mother, thus ensuring exposure in utero and through maternal milk. Tests involve measurements of developmental landmarks and reflexes, motor activity, auditory startle test, learning and memory tests, and neuropathology (USEPA, 1998b; OECD, 2007). As for neurotoxicity testing, DNT testing has been proven to be useful and effective in identifying compounds with DNT potential (Makris et al., 2009). This is not to say that current DNT testing guidelines cannot be improved; indeed, it has been pointed out that they may be overly sensitive and produce a high rate of false positives (Claudio et al., 2000) or, in contrast, that they may be too insensitive and not enough comprehensive (Cory-Slechta et al., 2001).

In the past several years, the need to develop acceptable alternatives to conventional animal testing has been increasingly recognized by toxicologists to address problems related to the escalating costs and time required for toxicity assessments, the increasing number of chemicals being developed and commercialized, the need to respond to recent legislations (e.g., Registration Evaluation and Authorization of Chemicals and the Cosmetics Directive (76/768/EEC) in the European Union), and efforts aimed at reducing the number of animals used for toxicity testing (Gartlon et al., 2006; Costa et al., 2011). Hence, efforts have been directed toward the development of alternative models, utilizing either mammalian cells in vitro or nonmammalian model systems, which could serve as tools for neurotoxicity and DNT testing, particularly for screening purposes (Baumann et al., 2014; Nishimura et al., 2015; Vassallo et al., 2017; Sandström et al., 2017).

BIOMARKERS IN NEUROTOXICOLOGY

The term biomarker has acquired many meanings over the years. For example, the presence of chloracne may be considered a biomarker of exposure and of health effect of dioxin-like compounds, and behavioral alterations in children associated with lead exposure can be considered biomarkers of subtle neurotoxic effects of this metal. A decreased nerve conduction velocity can be considered a biomarker of a peripheral neuropathy, and the presences of specific lesions in the postmortem human brain are considered biomarkers of specific neurodegenerative diseases. Thus, biomarkers are often indicators of adverse health effects associated with a certain disease or toxic exposure. With regard to CNS biomarkers, such indicators can be represented by behavioral changes, which can be assessed in animals or in humans (e.g., memory deficits), by electrophysiological changes (e.g., in the electroencephalogram), by morphological changes (e.g., neuronal death in specific cell regions and/or gliosis), and by biochemical/molecular changes (e.g., decrease in the activity of an enzyme or in the level of a growth factor).

In a broad context, biomarkers of CNS toxicity can thus be defined as indicators of alterations of CNS function. As said, behavioral and/or electrophysiological alterations in an individual are indicative of potential changes in CNS function and can be considered "biomarkers" of CNS toxicity. In this chapter, however, the term biomarker is used to mean biological/biochemical/molecular markers, which can be measured by chemical, biochemical, or molecular biological techniques. This stricter definition still encompasses measurements that may be carried out in vivo in the target organ, the brain, in animals, and/or in cells (or other more complex systems, e.g., brain slice) in vitro. As such they may be useful in animal studies to identify specific alterations or in vitro for the same purpose or for developing alternative testing approaches (Costa et al., 2011). This chapter further focuses on biomarkers that can be measured in humans and must thus be present in rather easily and ethically obtainable body fluids (e.g., blood, urine, cerebrospinal fluid [CSF]). By providing information on the cellular substrates involved in behavioral changes and/or correlates of neuropathological lesions, biochemical and molecular approaches are relevant to the process of assessing the impact of human exposure to neurotoxicants (Costa, 1998b, 1992). Knowledge of the specific target of a neurotoxicant (Costa, 1997) or of a specific lesion in a neurodegenerative disorder or in other sources of neurotoxicity (e.g., traumatic brain injury) can be very useful to develop biomarkers of effect for use in animal toxicity studies, as well as in epidemiological investigations in humans, while adding an important component to the hazard characterization aspects of the risk assessment process. Finally, while all biomarkers indicated above would give indications of the effects of toxicants on the CNS, one has to recognize that biomarkers of exposure and of susceptibility also exist (NRC, 1987). In some cases, there may be some overlap, as certain markers of exposure may also represent biomarkers of effects (see Case study 1: The organophosphorus insecticides).

Biomarkers of Exposure

An ideal biomarker of exposure should be chemical-specific, available by minimally invasive techniques, detectable even at very low levels, easy to measure, and relatable quantitatively to certain prior exposures (Henderson et al., 1989). These concepts would also apply to biomarkers of exposure to neurotoxicants. The traditional biomonitoring of chemicals (and/or their metabolites) in biological fluids (urine, blood) and in other accessible tissues (hair, dentine pulp) has been widely used in neurotoxicology. Examples abound in the areas of solvents, metals, pesticides, and industrial chemicals. The metal lead (Pb) causes severe DNT (learning disabilities, low IQ) in children at low levels, peripheral neurotoxicity (myelinopathy) in adults at intermediate levels, and severe encephalopathy at even higher levels. Such levels are usually determined by measurements of Pb levels in blood, though other measurements (e.g., Pb levels in dentine pulp or in bone) have also been utilized. For other metals (e.g., arsenic or mercury), measurements of their concentrations in hair has also proven useful, as they reflect prior and/or cumulative exposure rather than the recent exposure provided by blood measurements (Costa, 1996). For solvents, measurements of their concentrations in blood or in breath, or of their metabolites in the urine, are very common methods to determine exposure. A limitation of such approaches lies in the fact that these measurements only reflect recent exposures. For chemicals that form covalent adducts to macromolecules, such adducts can be measured, and depending on the half-life of the chosen macromolecule, levels of these adducts would reflect exposure over weeks to months. Examples of neurotoxic chemicals for which this strategy has been used include n-hexane, carbon disulfide, and acrylamide (Graham et al., 1995; Valentine et al., 1993; Calleman et al., 1994).

Biomarkers of Susceptibility

Genetic factors can modulate the response to neurotoxic chemicals. Genetic polymorphisms have been identified for a number of enzymes involved in the metabolism of xenobiotics, for example, several members of the cytochrome P450 (CYP), N-acetyltransferase, and glutathione transferase (GST) families (Costa and Eaton, 2006). In addition to their major hepatic localization, such enzymatic systems are also expressed in the CNS where they can contribute to in situ activation or detoxification of neurotoxicants (Farin and Omiecinski, 1993). Organic neurotoxic compounds can be bioactivated or detoxified by these same enzymes, and genetic polymorphisms may thus play a role in differential susceptibility to CNS effects. Relevant research on the influence of genetic polymorphisms has been carried out, for example, in the context of studies on the role of environmental factors in the etiology of neurodegenerative diseases such as Parkinson's disease (PD). Investigations on familial PD have so far revealed more than a dozen autosomal dominant or autosomal recessive gene mutations responsible for variants of the disease (Houlden and Singleton, 2012; Dexter and Jenner, 2013). These include mutations of α-synuclein, parkin, DJ-1, PINK-1, and several other genes (Houlden and Singleton, 2012; Dexter and Jenner, 2013; Lill, 2016). In addition, hypotheses to explain the etiology of sporadic PD have focused on potential gene—environment interactions, namely susceptibility genes that may contribute to increased risk of PD as a result of exposure to neurotoxic agents. For example, as 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine is bioactivated to a potent dopaminergic neurotoxicant by monoamine oxidase B (MAO-B), various studies have reported of associations between MAO-B polymorphisms and PD (Costa et al., 1997). Other studies have focused on polymorphisms of enzymes involved in xenobiotic metabolism, such as CYP2D6, CYP2E1, or GSTs (BenMoyal-Segal and Soreq, 2006; Singh et al., 2008), in oxidative stress or dopaminergic neurotransmission (e.g., superoxide dismutase, dopamine receptor D2, dopamine transporter; Kelada et al., 2006; Singh et al., 2008) or in proinflammatory cytokines (e.g., interleukin 1 beta; Lee et al., 2016).

Biomarkers of Effects

Biomarkers of effects should be indicative of early modifications that precede functional or structural damage. In this context, knowledge of the mechanism(s) that lead to the ultimate neurotoxic effect is essential or at least extremely useful (Manzo et al., 1996; Costa, 1998b). Unfortunately, the exact mechanism (or mode) of action for most neurotoxicants is still unknown, and this has slowed down progress in this area. Because of the complexity of the nervous system and the diversity of manifestations of neurotoxicity, in addition to the multiplicity of cellular and biochemical targets, it is difficult to develop and validate generic markers for neurotoxicity. The scenario for neurotoxicity is indeed much more complex than that for other target organs of toxicity, e.g., the liver, where hepatotoxicity can be predicted by a few specific features (e.g., mitochondrial damage, oxidative stress, intracellular glutathione), allowing the development of potentially highly predictive screening approaches (Xu et al., 2008).

With regard to neurotoxicity, one area that has received some attention is that of neurotransmission. A number of chemicals affect various aspects of neurotransmission, including neurotransmitter synthesis,

uptake and degradation, receptor interactions, and second messenger systems (Costa, 1992; Castoldi et al., 1994; Costa and Manzo, 1995). Such changes should be measurable in an easily and ethically accessible peripheral tissue and should mirror identical changes occurring in target tissue (e.g., a certain brain region). Examples of this strategy, utilized with organophosphorus (OP) insecticides, are described in the case study below. Another example is represented by measurements of MAO-B, an enzyme involved in the metabolism of dopamine, in platelets. Exposure of rats to styrene (a neurotoxic solvent used in the production of polystyrene) causes a decrease in MAO-B in the CNS (Husain et al., 1980), and platelet MAO-B activity is significantly decreased in styrene-exposed workers (Checkoway et al., 1994; Bergamaschi et al., 1996), while the enzyme is not modified in platelets of workers exposed to perchloroethylene (Checkoway et al., 1994), suggesting a certain degree of specificity. Alterations in platelet MAO-B activity may thus reflect similar alterations occurring in the CNS and serve as a biomarker of effect in case of exposure to certain neurotoxic chemicals.

A different strategy is that of measuring in accessible tissue markers of brain injury (Roberts et al., 2015). Changes in neuronal- or glial cell−specific proteins or of certain stress proteins in the brain have been proposed as in situ biomarkers of neurotoxicity (O'Callaghan and Sriram, 2005; Petzold, 2005; Rajdev and Sharp, 2000). For example, levels of glial fibrillary acidic protein (GFAP) provide indication of gliosis and are increased on neuronal toxicity (O'Callaghan and Sriram, 2005). Neuron-specific enolase (NSE), the isoform of enolase with three $\gamma\gamma$ homodimers, and S-100β, a calcium-binding protein primarily synthesized in astrocytes, are two other examples of relatively brain-specific proteins. Some studies have investigated changes in the levels of these and other proteins in different biofluids, such as CSF and blood. For example, levels of S-100β increase in blood (and also in CSF) after traumatic brain damage, stroke, cardiac operations, and a variety of neurodegenerative diseases (Rothermundt et al., 2003; Seco et al., 2012). As CNS toxicity is often associated with increased BBB permeability, it has been suggested that increases in S-100β levels indicate BBB defects (Marchi et al., 2004). Levels of GFAP and of ubiquitin C-terminal hydrolase-1 (UCH-L1; another potential marker of neuronal injury) have been found elevated in the CSF of rats on exposure to the neurotoxicant kainic acid (Glushakova et al., 2012). Interestingly, UCH-L1 was increased at early time points, whereas GFAP increased over time, in agreement with what observed in the hippocampus (Glushakova et al., 2012). Additional biomarkers have also been investigated in relationship to PD. For example, α-synuclein

levels are decreased in the CSF of PD patients and so are levels of DJ-1 (Hong et al., 2010; Haas et al., 2012), though negative or inconclusive findings have been reported for the same biomarkers in blood (Haas et al., 2012; Lin et al., 2012).

MicroRNAs (miRNAs) are endogenous, small noncoding RNAs (approximately 22 nucleotides) that regulate gene expression, and over 60% of proteins are believed to be controlled posttranscriptionally by miRNAs (Friedman et al., 2009). Recently, miRNAs have been found to be potential targets or effectors of neurotoxicants (Tal and Tanguay, 2012; Roberts et al., 2015). Because some miRNAs are produced at high concentrations within cells in a tissue-specific manner and are reported to be remarkably stable in plasma, they may represent biomarkers to monitor tissue injury. For example, Laterza et al. (2009) showed that miR-124 can be used to monitor ischemia-related brain injury starting at 8 h and peaking at 24 h after occlusion (an approximately 150-fold increase in plasma relative to the sham surgery control group), whereas Ogata et al. (2015) found increases in blood levels of miR-9 and of miR-384, which correlated with acute neurotoxicity of trimethyltin.

The following sections present two case studies related to the use of biomarkers for neurotoxicity. The first one deals with OP compounds, an important class of insecticides whose mechanisms of toxicity have been for the most part elucidated. For these compounds biomarkers of exposure, susceptibility and effects are available. The second case study deals with mTBI caused by head concussion. In this case diffuse damage is present in the CNS, and biomarkers of effects attempt to capture its severity and time course of recovery.

CASE STUDY 1: THE ORGANOPHOSPHORUS INSECTICIDES

The OP insecticides are discussed in detail as examples of neurotoxic chemicals for which various types of biomarkers can be defined (Table 10.2).

Toxicity and Neurotoxicity of Organophosphorus

On acute exposure, OPs cause a number of central and peripheral effects, which are typical of an overstimulation of the cholinergic system (Costa, 2006). These are due to the ability of OPs to inhibit the activity of acetylcholinesterase (AChE), the enzyme which degrades the neurotransmitter acetylcholine and the only mean by which this neurotransmitter can be removed from the synaptic cleft. Inhibition of AChE leads to accumulation

TABLE 10.2   Biomarkers for Organophosphates

Type of Biomarker	Example
Biomarker of exposure	Plasma cholinesterase (BuChE) Red blood cell acetylcholinesterase OP in blood OP metabolites in urine OP adducts to blood proteins
Biomarker of susceptibility	Paraoxonase 1 status BuChE polymorphisms CYPs
Biomarker of effect	Red blood cell acetylcholinesterase Muscarinic receptors in lymphocytes Lymphocyte neuropathy target esterase

AChE, acetylcholinesterase; *BuChE,* butyrylcholinesterase; *CYP,* cytochrome P450; *OP,* organophosphorus.

of acetylcholine at cholinergic synapses, with an ensuing overstimulation of cholinergic receptors and the development of a cholinergic crisis; the latter includes increased sweating and salivation, profound bronchial secretion, bronchoconstriction, miosis, increased gastrointestinal motility, diarrhea, tremors, muscular twitching, and a number of CNS effects (dizziness, lethargy, fatigue, headache, mental confusion, depression of respiratory centers, convulsions, coma). AChE inhibition is due to phosphorylation of the active site of the enzyme, which can be followed, depending on the chemical structure of the OP, by the loss of an alkyl chain in a process known as "aging." When this occurs, AChE can be considered as being irreversibly inhibited. A few OPs may also cause another type of toxicity, known as organophosphate-induced delayed polyneuropathy (OPIDP). Signs and symptoms include tingling of the hands and feet, followed by sensory loss, progressive muscle weakness and flaccidity of the distal skeletal muscles of the lower and upper extremities, and ataxia (Lotti and Moretto, 2005). These may occur 2–3 weeks after a single exposure, when signs of the acute cholinergic syndrome have subsided. OPIDP, which can be classified as a distal sensorimotor axonopathy, is not related to AChE inhibition. Rather, the molecular target appears to be an esterase, present in nerve tissues and other tissues, named neuropathy target esterase (NTE). Phosphorylation of NTE by OPs is similar to that observed for AChE. Several OPs, depending on their chemical structure, can inhibit NTE and so can also some non-OPs, such as certain carbamates and sulfonyl fluorides. However, only OPs whose chemical structure leads to aging of phosphorylated NTE (by a process analogous to that described for AChE) can cause OPIDP. Other compounds that inhibit NTE but cannot undergo

the aging reaction are not neuropathic, indicating that inhibition of NTE catalytic activity may not be the final mechanism of axonal degeneration.

Biomarkers of Exposure

Because of the role of acetylcholine as a neurotransmitter in both the CNS and the peripheral nervous system (somatic and autonomic), AChE is widely distributed throughout the body. Moreover, AChE is also present in erythrocytes, though its physiological role in these cells, which are devoid of synaptic contacts, has not been elucidated. Another cholinesterase, known as pseudocholinesterase or butyrylcholinesterase (BuChE), coded by a gene different from that coding for AChE and with different substrate specificity, is present in several tissues including plasma, where its physiological role has not been fully elucidated. On exposure, OPs inhibit the activity of both enzymes in tissues and in blood; hence, measurements of AChE and BuChE activities in red blood cells and in plasma have been extensively used as biomarkers of exposure OPs. A lower activity of erythrocyte AChE and of plasma BuChE would indicate that exposure to an OP (or to a similarly acting compound) has occurred. Neither measurement is specific for a specific OP. Additionally, other insecticides, such as the carbamates, also inhibit AChE and BuChE, though the enzymes' activities recover within a few hours on inhibition by a carbamate compound.

When used as biomarkers of exposure in population studies, the issue of interpersonal variability in AChE and BuChE activities should be carefully considered. When possible, baseline values should be obtained for each individual, and variations below these activity levels rather than absolute levels should be used to assess exposure. In the absence of preexposure measurements, repeated postexposure measurements should be obtained at different intervals. In this case, a significant increase in enzyme activity over time would indicate recovery from an initial exposure to an OP (Coye et al., 1987). A 30% or greater decrease of plasma BuChE from preexposure baseline usually raises a red flag and requires health and workplace surveillance and removal of the worker from the exposure; however, the toxicological significance of such decrease is still much debated (Carlock et al., 1999; USEPA, 2000). Another important issue relates to which between erythrocyte AChE and plasma BuChE is a better indicator of exposure to OPs. Many OPs appear to preferentially inhibit plasma BuChE, suggesting that this enzyme may be a more sensitive indicator of exposure; however, this is not true for all OP compounds. Furthermore, plasma BuChE activity displays a higher variability because it can be

affected by other exogenous agents (e.g., drugs), physiological or pathological conditions (e.g., pregnancy or liver damage), and genetic background (Chatonnet and Lockridge, 1989; Lockridge, 1990). As AChE is the target for OP neurotoxicity, measurements of AChE activity in red blood cells are also used as a biomarker of effect for OPs (see below). NTE activity has been found in blood, namely in lymphocytes and platelets (Bertoncin et al., 1985; Maroni and Bleecker, 1986), and measurements of NTE activity in these cells may serve as indication of exposure to potentially neuropathic OPs. Such measurements may also represent markers of effects of neuropathic OPs (see below).

Several analytical methods are available to measure OPs and their metabolites in body fluids; the parent compound is measured in blood, whereas metabolites are measured in urine. These measurements are rarely carried out in the clinical setting but are extensively utilized in epidemiological studies; indeed, determination of metabolite levels in urine is the most practical method to estimate exposure to OPs (Maroni et al., 2000). Such metabolites include alkyl phosphate derivatives and chemical residues (the "leaving group") specific for each compound. The alkyl phosphates or alkyl dithiophosphates are the result of metabolism of parent compounds or their oxygen analogs by CYPs or esterases. They are not specific for a certain OP but are useful to assess exposure to (or internal dose of) several OPs. Other metabolites are specific for certain OP compounds; for example, p-nitrophenol in urine is an indicator of exposure to parathion or methyl parathion, while 3,5,6-trichloropyridinol is useful to assess exposure to chlorpyrifos or methyl chlorpyrifos. Although measurements of urinary metabolites of OPs have been widely used to assess exposure to OP from occupational, environmental, and dietary sources, caution should be exercised when interpreting results, as dialkyl phosphates, and also leaving groups, can be found in the environment, including food and drinks, as a result of OP degradation. This would lead to an overestimate of OP exposure (Lu et al., 2005).

More recently, there has been an increasing interest in the analysis of blood protein as biomarkers of OP exposure because the OP-adducted proteins have longer half-lives and are modified only by the active insecticide. Proteomics techniques (e.g., liquid chromatography—mass spectrometry [MS] and matrix-assisted laser desorption/ionization time-of-flight MS) have become important tools for the biomonitoring of OP-adducted proteins in blood, as they allow for the accurate and sensitive identification of OP-inhibited proteins based on the change in mass of the adducted active-site peptides following enzymatic digestion (Thompson et al., 2010). Among such proteins, BuChE has been extensively investigated. BuChE has a half-life of ∼10 days in plasma, whereas red blood cell AChE has a 120 days life span; however, the concentration of BuChE in blood is 10-fold higher than AChE. The critical step in this approach is the purification of the BuChE from plasma, and the use of immunoaffinity purification should be helpful (Marsillach et al., 2013). Another protein that has been proposed as a biomarker of OP exposure is acylpeptide hydrolase (APH) present in several tissues, including the brain and the erythrocytes, where it is believed to contribute to the degradation of proteins (Fujino et al., 2000). Adducts of OPs to red blood cell APH have been recently characterized (Marsillach et al., 2011), supporting its potential use as biomarker of OP exposure (Quistad et al., 2005). Additional proteins present in blood, with which OPs form adducts, are plasma albumin and monocyte carboxylesterase (Marsillach et al., 2013).

Biomarkers of Susceptibility

Genetic polymorphisms are known to affect the toxicity of several environmental chemicals, including OPs (Costa and Eaton, 2006). One of the best characterized polymorphisms is that of the enzyme paraoxonase 1 (PON1), whose name derives from its ability to detoxify paraoxon, the active metabolite of the OP parathion. Other substrates for this enzyme, which is classified as an A-esterase, are chlorpyrifos oxon, diazinon oxon and the nerve agent sarin. PON1 is secreted from the liver, and high activity levels are found in plasma. The finding that plasma PON1 activity is multimodally distributed in human populations (Geldmacher von Mallinckrodt and Diebgen, 1988) indicated the existence of polymorphisms and suggested that individuals with low activity may be more sensitive to OP toxicity. Biochemical and molecular studies led to the purification and cloning of PON1 from different species (Furlong et al., 1991; Hassett et al., 1991) and to the identification of a Q(Gln)/R(Arg) polymorphism at position 192, with the R_{192} alloform displaying a high hydrolytic activity toward chlorpyrifos oxon and paraoxon (the latter only in vitro) (Humbert et al., 1993; Li et al., 2000). In addition to these qualitative differences, there is also a large interindividual variability in the levels of protein circulating in plasma, which are likely due to polymorphisms in the promoter region of PON1 (Costa et al., 2013). Determination of the "PON1 status" of an individual by a two-dimensional assay with two substrates (Richter et al., 2004) provides information on an individual's PON1 polymorphism and the level of PON1 expression.

Administration of purified or recombinant human PON1 to rats or mice provides protection against OP toxicity (Li et al., 1993, 2000; Stevens et al., 2008). Further studies in PON1$^{-/-}$ mice and in humanized PON1 mice

(expressing either the Q192 or the R192 allele over a knockout background) (Shih et al., 1998; Cole et al., 2005) have provided additional strong evidence that PON1 is an important determinant of susceptibility for those OPs whose oxons are substrate for this enzyme. Evidence for a role of PON1 in OP toxicity in humans is still limited, though important findings have been emerging in the past few years related to exposures to OP insecticides (see Costa et al., 2013). For example, a series of studies found that low PON1 activity was associated with chronic central and/or peripheral nervous system abnormalities, at times referred to as "dippers' flu," associated with exposure of sheep dippers to diazinon (Cherry et al., 2011). In pesticide handler exposed to various OPs (most notably, chlorpyrifos), low PON1 catalytic efficiency (Q192) and low plasma PON1 activity were associated with increased degrees of plasma BuChE inhibition from baseline levels (Hoffman et al., 2009). Overall, the human studies available so far provide initial evidence that low PON1 status may increase susceptibility to adverse effects of certain OP insecticides. However, it is still uncertain whether PON1 status may play a significant role at lower dose levels of exposure (Timchalk et al., 2002; Cole et al., 2005).

CYPs are also important for the activation and detoxication of OP insecticides. Variant forms of several CYP genes have been identified, and these polymorphisms confer differences in catalytic activity or level of expression, which may result in varying rates of oxidation of xenobiotics among individuals. However, information on the role of specific CYP isozymes in the metabolism of OPs is still limited and mostly derived from in vitro studies; hence, the potential contributions of such genetic polymorphisms to OP toxicity susceptibility are still unknown, thereby limiting the usefulness of their molecular measurements (Eaton, 2000; Costa, 2001), though newer physiologically based pharmacokinetic/pharmacodynamic (PBPK/PD) modeling efforts appear promising (Foxenberg et al., 2011).

A large number of genetic polymorphisms have been also described for BuChE, with at least 39 identified genetic variants with nucleotide alterations in the coding region (Lockridge and Masson, 2000). Several of the rare variants are silent (i.e., they have <10% of normal activity), while the most common variants (e.g., atypical variants) have a reduced activity. Individuals with genetic variants of BuChE with no or low activity would be predicted to be more susceptible to OP toxicity, as suggested by a study in Brazilian farmers (Fontoura-da-Silva and Chautard-Friere-Maira, 1996), but this assumption has been challenged and appears to be valid only in the case of OP nerve agents (Lockridge et al., 2016).

Biomarkers of Effect

Changes in activity of blood cholinesterases would be reliable biomarkers of effect of OPs, if they reflect similar changes occurring in target tissues, i.e., the CNS and the muscles, particularly the diaphragm. Evidence indicates that erythrocyte AChE correlates with brain and diaphragm activity better than plasma BuChE, as observed, for example, in animals exposed to chlorpyrifos, paraoxon, or disulfoton (Padilla et al., 1994; Fitzgerald and Costa, 1993). In another study, in which rats were treated for 5 weeks with chlorpyrifos, a strong correlation between whole blood and brain cholinesterase activity was found both during dosing and also during the recovery period, though a much more reliable correlation was present during dosing, when the inhibition has reached steady state (Padilla, 1995). There is also a good correlation between the severity of signs and symptoms of poisoning and the degree of inhibition of red blood cell AChE (Lotti, 2001).

Repeated exposure to OPs has been shown to induce the development of tolerance to their toxicity, which is in part mediated by a decrease in cholinergic receptors (particularly the muscarinic ones) to compensate for the prolonged increase in acetylcholine levels (Costa et al., 1982). Such changes in muscarinic receptors may indeed serve as a protective mechanism against overstimulation by acetylcholine, but they may also result in higher brain function impairment, such as memory deficits (McDonald et al., 1988). Some subtypes of muscarinic receptors have also been identified at the protein and mRNA level in lymphocytes (Costa et al., 1988, 1994), and prolonged exposure to the OP disulfoton was shown to cause a similar decrease of muscarinic receptor density in brain areas and in lymphocytes (Costa et al., 1990; Fitzgerald and Costa, 1993).

With regard to OPIDP, there is a good correlation between lymphocytes and brain NTE (Schwab and Richardson, 1986; Makhaeva et al., 2007), suggesting that lymphocytic NTE may be used as a putative biomarker of effect of neuropathic OP compounds. A good example of its application is a case report of an attempted suicide with the insecticide chlorpyrifos where, based on the degree of lymphocyte NTE inhibition shortly after exposure, it was correctly predicted that a neuropathy would develop well after recovery from acute cholinergic poisoning had occurred (Lotti et al., 1986). However, in a study of workers exposed to the defoliant DEF, inhibition of lymphocyte NTE was observed, but no clinical or electrophysiological signs of OPIDP were detected (Lotti et al., 1983). Nevertheless, it is apparent that knowledge of the target of toxicity for organophosphates has allowed the successful use of peripheral biomarkers of effects. To date, these

represent some of the few validated effect biomarkers in neurotoxicology (Costa, 1996; Manzo et al., 1996).

CASE STUDY 2: MILD TRAUMATIC BRAIN INJURY

Sport-related brain concussions have been considered as a "public health epidemic," with 1.6–3.8 million episodes occurring annually (Steenerson and Starling, 2017). These concussions, also defined as mTBI, are often seen not only in American football or ice hockey players but also in military personnel (Dixon, 2017; Mayer et al., 2017). More severe cases can evolve in chronic traumatic encephalopathy (CTE), which can only definitely be diagnosed postmortem (Ling et al., 2017). The symptomatology of mTBI is usually divided into four domains: (1) physical (headache, dizziness), (2) cognitive (concentration, memory), (3) emotional (depression, anxiety, mood lability), and (4) sleep (hypersomnia, insomnia), of which the first two are the most commonly reported (Steenerson and Starling, 2017). Routine neuroimaging is not helpful in identifying any neuropathological change. Yet, there is evidence of massive neurotransmitter dysregulation, particularly excessive glutamate release, altered mitochondrial functions, neuroinflammation, changes in cerebral blood flow, and diffuse axonal injury (Dixon, 2017; Steenerson and Starling, 2017; Mayer et al., 2017). Of concern is that mTBI, and particularly CTE, may lead to neuropsychiatric

manifestation and to neurodegenerative diseases such as Alzheimer's disease. Also of relevance is the need of understanding the time course of recovery from the initial injury to assess the ability to return to play or service.

The diagnosis of mTBI is difficult and the medical field remains fragmented both in terms of the diagnostic (different criteria proffered by multiple medical organizations) and prognostic factors that influence patient care (Mayer et al., 2017). Hence, attention has been devoted in recent years to biomarkers of mTBI that may allow a more certain diagnosis and a follow-up during the recovery period to complement clinical approaches (Dambinova et al., 2016). Such biomarkers are present mostly in blood and reflect alterations of basic CNS cellular processes rather that specific molecular changes as in case of OPs. A summary of biomarkers utilized or proposed for use in mTBI is shown in Table 10.3. Blood biomarkers are usually divided to indicate injury to neurons or astroglial cells. Thus, for example, NSE would be a marker of neuronal damage, whereas S-100β would represent damage to astrocytes (Papa, 2016; Zettenberg and Blennow, 2016). Increases in the levels of these biomarkers in blood reflect the severity of the injury and the time course of recovery. In a study in professional ice hockey players, increases of blood tau (a marker of axonal injury) and of S-100β were found immediately after concussion, suggesting axonal and astroglial injury, and levels gradually decreased during rehabilitation; no changes in NSE

TABLE 10.3 Some Biofluid Biomarkers for Mild Traumatic Brain Injury

Type of Biomarker	Biomarker	Pros	Cons
Neuronal Injury	NSE (neuron-specific enolase)	Enriched in neuronal cell bodies.	Also present in oligodendrocytes and erythrocytes
	UCH-L1 (ubiquitin C-terminal hydrolase L1)	Enriched in neuronal cytoplasm	Not CNS specific. Useful in more severe cases
Axonal injury	Tau protein	Microtubule-associated protein (particularly unmyelinated axons)	Various forms of tau are present
	NFL-L and NFL-H (neurofilament light and heavy)	Associated with large myelinated axons	Extra-CNS contribution unknown
	Alpha-II spectrin breakdown products	Cytoskeletal protein abundant in nerve terminals	Only limited information available
Astroglial injury	S-100β	Calcium-binding protein in astrocytes. One of the most promising	Discrepancies linked to nonstandardized measurement methods. Lack of specificity
	GFAP (glial fibrillary acidic protein)	Expressed almost exclusively in astrocytes	Elevated in other conditions
Oligodendrocyte injury	MBP (myelin basic protein)	Specific to the myelin sheath	Scarcely studied
Other	MicroRNAs	May provide indication for several different damages	Still not validated

CNS, central nervous system.

were found (Shahim et al., 2014). In another study in 34 mTBI patients, increases in tau protein, GFAP, and amyloid β42 (a protein associated with Alzheimer's disease) were found 24 h after concussion and up to 30–90 days afterward (Bogolovsky et al., 2017). Elevated tau was also reported in a group of sport-related concussions, and higher initial tau was associated with more prolonged return to play time (Gill et al., 2017). Meier et al. (2017) found an increase in S-100β and of UCH-L1 in a group of 32 concussed athletes. Levels of serum neurofilament light (a protein expressed predominantly in myelinated axons) were found to be elevated in boxers and hockey players experiencing concussions (Shahim et al., 2017). Recent studies have also explored the use of blood miRNA levels for diagnosis and prognosis of mTBI. So far, a number of miRNA (e.g., miR-21, miR142-3, miR-335, miR423-3p) look promising (Mitra et al., 2017; Di Pietro et al., 2017), but much more work is needed in this area. In a recent systematic review, Papa et al. (2015) identified 13 studies exploring the use of biomarkers of mTBI in sport athletes; most studies had fewer than 100 patients and a total of 11 different biomarkers were analyzed. Their conclusion was that work is still needed to validate biomarkers for concussion, but there is a strong potential for biomarkers to provide "diagnostic, prognostic, and monitoring information postinjury" (Papa et al., 2015).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

This overview of biomarkers for CNS toxicity has evidenced how the road for developing and validating biomarkers of neurotoxic effects is still long and difficult. A variety of tools exist to measure biomarkers of exposure to CNS toxicants; this is by far the most advanced area, in which various approaches allow for assessment of recent and/or long-term exposures to neurotoxicants. The area of biomarkers of susceptibility has not been extensively investigated with regard to CNS toxicants, but many examples exist with regard to biomarkers of susceptibility in a number of CNS diseases (e.g., PD). With regard to biomarkers of effects, it appears that new opportunities will arise from increasing knowledge of the mechanisms and target of neurotoxicants (Costa, 1998b). Clearly, CNS toxicity can be manifested in very many ways, each characterized by different cellular, biochemical, and molecular substrates. The development of one or a few biomarkers of CNS toxicity appears unlikely. Rather, biomarkers may be specific for a class of chemicals (e.g., OPs) or for certain toxicological processes (e.g., neuronal death or demyelination). In this respect, the examples of biomarkers being studied and developed for mTBI may be useful and should be further explored in relationship to exposure to neurotoxic chemicals. The ultimate goal should, however, remain that of understanding the chain of events that lead to CNS toxicity, with the hope that one or more early biochemical/molecular alterations, which would precede irreversible damage, may be mirrored in changes in accessible tissues. This would thus be defined as a new biomarker for neurotoxic effects.

Peripheral Nervous System Toxicity Biomarkers

Tirupapuliyur V. Damodaran

Department of Biological and Biomedical Sciences, North Carolina Central University, Durham, NC, United States

INTRODUCTION

The great degree of complexity involved in the structural and functional aspects of vertebrate nervous system in general and the advanced capabilities of human central nervous system (CNS) and peripheral nervous system (PNS) in particular provide huge number of potential biomarkers that may be very useful in many branches of health care industry. Both CNS and PNS activities are the basis for every response involving thoughts, actions, and emotions. Along with the endocrine system, the nervous system plays a major role in the body's homeostasis in human and other vertebrates. Because of the need to be rapid and immediate, its cells communicate by electrical and chemical signals that are highly specific. The dynamic nature of responses of various organisms to their extrinsic (external environment) and other intrinsic (homeostatic) factors to ensure their survival depends on the structural and functional integrity of the nervous system. The unique status of this organ system also makes it relatively more susceptible to toxic mechanisms arising from various day-to-day life activities. These neurotoxic mechanisms can be of short-term or long-term duration, as well as either acute or chronic. The drastic outcome from these neurotoxic mechanisms can be immediate or delayed. These mechanisms may have general effects or may affect very specific parts of this multiunit hierarchical structure. Some of these neurotoxic mechanisms may get resolved quickly by the body's repair mechanisms, whereas other types may need rigorous therapeutic protocols. Because of the nervous system's omnipresent role in many other organ systems, the toxic mechanisms that affect the nervous system may have direct or indirect, mild, or profound effects on other organ systems. Thus, accurate and prompt identification of toxic mechanisms responsible for any neurological disease conditions due to known and unknown toxic mechanisms becomes imperative for effective treatment and management protocols. Although the clinical presentation of the disease condition may be useful for preliminary diagnosis for symptomatic treatment approaches, permanent cure may be possible only after disease-specific treatments. The developing nervous system may be more or less susceptible to neurotoxic insult depending on the stage of development. Biomarkers used in adults are often applicable for use during development, but developmental stage-specific and aging-related differences may be important (Slikker and Bowyer, 2005). Although both inherited and acquired PNS disorders may have common pathways that can be identified by biomarker identification and validation, there may be unknown layers of complexity that need to be understood for better treatment protocols.

Thus, PNS biomarkers (measurable end points by cell, molecular, and clinical parameters) are very important for various applications connected with the accurate diagnosis, treatment, and management of neurological and other organ systems—related disorders. These biomarkers are also useful for assessing clinical responses, identification of risks, selection of doses, and other aspects in drug development and evaluation. Positive correlation between symptoms at all levels (molecular, cellular, and phenotypical) of abnormal and/or normal presentations (both qualitatively and quantitatively) of chemicals, metabolites, and other clinical and measurable morphological features can help define the biomarker of choice. As per the National Institute of Health (NIH) biomarker working group, a biomarker is a characteristic that can be objectively measured as an indicator of normal biological processes, pathogenic processes, or a pharmacological response to a therapeutic intervention. The five phases proposed by the NIH in the evaluation of biomarkers are in sequence: (1) discovery using genomics or proteomics, (2) developing an assay that is portable and reproducible,

(3) measuring sensitivity and specificity, (4) affirming the measurement in a large cohort, and (5) determining the risks and benefits of using the new diagnostic biomarker (Raad et al., 2014).

Hence, biomarkers can be effectively used to identify (1) whether the exposure or change has occurred, (2) the route of exposure or location of the change, (3) the pathway of exposure, (4) resulting short-term or long-term effects, and (5) outcomes of therapeutic interventions to bring the organism to its original healthy status. Biomarkers can be used to identify organ system and organ-specific changes at all levels. In this chapter, emerging new developments in the broad field of PNS-related biomarkers in health and disease status, with major emphasis on humans and related animal models, are presented.

TYPES OF BIOMARKERS OF THE PERIPHERAL NERVOUS SYSTEM

The complexity of PNS structure and function makes it a daunting task to enlist the potential targets, mechanisms of neurotoxicity, valid biomarkers, and candidate biomarkers from many biological and clinical end points. The complexity and extensive nature of the PNS makes it comparatively more susceptible and at the same time more resilient for recovery from injuries (compared to the CNS). In general, the biomarkers can be identified by carefully studying various aspects of PNS structure and function.

PERIPHERAL NERVOUS SYSTEM BIOMARKER METHODOLOGY

Applying appropriate methodology is the major factor in the rapid identification and validation of biomarkers of PNS neurotoxicity. To make provisional diagnosis of the nature of toxic mechanisms in any PNS toxicity—related clinical presentation, universal methods to collect clinical data using standard methods of neurology clinic settings are essential. Biomedical informatics with its ever-increasing branches of special categories has become an important tool for collection, storage, retrieval, and dissemination of relevant information.

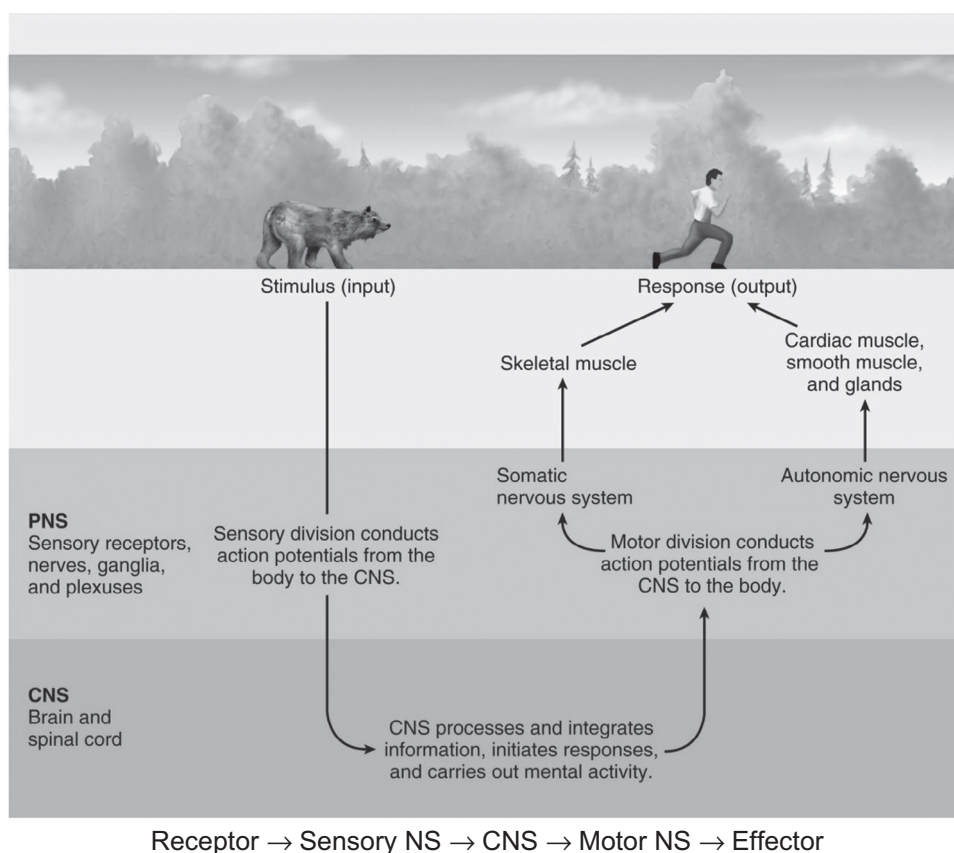
The following are the commonly employed methodologies of such categories, providing valuable clinical biomarker data sets (Fig. 11.1).


FIGURE 11.1   Organization of the nervous system: The sensory division of the peripheral nervous system (PNS) detects stimuli and conducts action potentials to the central nervous system (CNS). The CNS interprets incoming action potentials and initiates action potentials that are conducted through the motor division to produce a response. The motor division is divided into the somatic nervous system and the autonomic nervous system.

NEUROLOGICAL AND PHYSICAL EXAMINATION

Protocol

In humans, standard neurological physical examinations (NPxs) (Starks et al., 2012) include the following: Assessments of vibration perception and proprioception are generally performed on the great toes, bilaterally. Achilles deep tendon reflexes are examined bilaterally, and Romberg test performance, tandem gait, and postural tremor are routinely assessed. Clinical examination results are recorded as normal, equivocal, or abnormal. For all tests performed bilaterally (ankle reflex, toe proprioception, and toe vibration), examination results are classified as "abnormal" if ratings are abnormal or equivocal bilaterally, abnormal unilaterally and equivocal on the contralateral side, or abnormal unilaterally and missing (because of injury/amputation) on the contralateral side. For tests without laterality (postural tremor, Romberg test, and tandem gait), combined abnormal and equivocal results are used to create a dichotomized variable (normal vs. not normal) for each outcome (Starks et al., 2012). Electrophysiological measures, hand strength, sway speed, and vibrotactile threshold are also employed (Starks et al., 2012).

SAMPLE REQUIREMENTS FOR BIOMARKER TESTING

Adequate quantity of tissue (by biopsy) of investigation can be obtained for various biomarker testing procedures. The tissues include blood, cerebrospinal fluid (CSF), nerve tissue, and target (end organ) tissue. CT-guided needle biopsy and other standard blood collection procedures are used for tissue sampling. A nerve biopsy may help distinguish between demyelination (damage to the myelin sheath covering the nerve) and axon degeneration (destruction of the axonal portion of the nerve cell). It may also help to identify an inflammatory neuropathy or confirm specific diagnoses. A skin biopsy is helpful to differentiate certain disorders that might affect the small nerve fibers, as may be the case with painful sensory axonal neuropathies. A muscle or other tissue biopsy is used to diagnose and identify damage caused to muscles and organs as a result of various disorders.

Biomedical Imaging and Informatics

Various images spanning the scale from microscopic and molecular to whole body visualization, encompassing many areas of clinical medicine, are important for selecting, validating, and biomonitoring PNS disorders.

Recent years have witnessed impressive advances in the use of magnetic resonance imaging (MRI) and single-photon emission CT for the assessment of patients with PNS and CNS disorders (Poewe et al., 2017). MRI is an imaging technique used to produce high-quality images of the inside of the human body. A scanner emits a strong magnetic field inside the brain (or elsewhere in the body) and produces signals that are analyzed by a computer to produce detailed images. Complementary to the clinical evaluation, conventional MRI provides crucial pieces of information for the diagnosis of acquired and hereditary PNS and CNS disorders (Filippi and Agosta, 2010). Newer quantitative magnetic resonance (MR)—based techniques, such as magnetization transfer MRI, diffusion tensor MRI, proton MR spectroscopy, and functional MRI, are contributing to elucidate the mechanisms that underlie injury, repair, and functional adaptation in patients with nervous system disorders (Filippi and Agosta, 2010). Diffusion weighted imaging (DWI) and diffusion tensor imaging (DTI) are functional MRI techniques that are able to evaluate and quantify the movement of water molecules within biological structures. In the field of trauma and peripheral nerve or plexus injury, several derived parameters from DWI and DTI studies, such as apparent diffusion coefficient or fractional anisotropy among others, can be used as potential biomarkers of neural damage, providing information about fiber organization, axonal flow, or myelin integrity (Noguerol et al., 2017).

Electrodiagnostic Tests

Electrodiagnostic tests measure the electrical activity of muscles and nerves. By measuring the electrical activity, one can determine if there is nerve damage, the extent of the damage, and potentially the cause of the damage. Frequently, noninvasive neurological evaluations such as electromyography and nerve conduction velocity (NCV) testing are used. Quantitative sensory testing and autonomic testing are also commonly used.

Blood Tests

Blood tests are commonly employed to check for various factors that affect the nervous system directly or indirectly (vitamin deficiencies, toxic elements, evidence of an abnormal immune response). Depending on the individual situation, certain laboratory tests to identify potentially treatable causes for neuropathy by the following tests are employed: (1) Antibodies to nerve components (e.g., anti-MAG antibody); (2) antibodies to cytoskeletal components (NF; glial fibrillary acidic protein (GFAP); and tubulin, etc.); (3) vitamin B12 and folate levels; (4) thyroid, liver, and kidney functions; (5) vasculitis evaluation; (6) oral glucose tolerance test; (7)

antibodies related to celiac disease; (8) Lyme disease; (9) HIV/AIDS; and (10) hepatitis C and B.

Testing for Toxins

Toxins, poisons, and chemicals can cause peripheral neuropathy. This can happen through drug or chemical abuse or through exposure to industrial chemicals in the workplace or in the environment (after either limited or long-term exposure). Common causes include exposure to lead, mercury, arsenic, and thallium. Some organic insecticides and solvents can result in neuropathies. Sniffing glue or other toxic compounds can also cause peripheral neuropathy. Certain herbal medicines, especially those that are particularly rich in mercury and arsenic, can lead to peripheral neuropathy. Hence blood profiling for the presence of parent or metabolic products or metabolites of the drug pathways is commonly used to identify the basis of toxicity (Fig. 11.2).

Molecular Diagnostics

Molecular profiling techniques such as (1) sequencing, (2) quantitative real-time polymerase chain reaction (PCR), (3) amplification of refractory mutation system (allele-specific PCR), (4) fragment length analysis (to detect any deletions within the coding portion of the gene), (5) high-performance liquid chromatography (to distinguish between wild type and mutated
FIGURE 11.2   Innervation of organs by the autonomic nervous system. Preganglionic fibers are indicated by *solid lines* and postganglionic fibers are indicated by *dotted lines*.

DNA strands using heteroduplex formation), and (6) immunohistochemistry and fluorescence/chromogenic in situ hybridization are used to detect any defects at gene sequence level.

Molecular, Cellular, and Histological Techniques

Analysis of patient samples from various medical clinics and from animal model systems using various combinations of molecular, cellular, and histological techniques has become part of the routine laboratory protocols. Details of nucleic acid extractions (DNA and RNA), northern blotting, semiquantitative real-time PCR, and real-time PCR protocols have been described in detail in several publications (Damodaran, 2009; Damodaran et al., 2011). Similarly, methods of protein extraction and analysis using western blotting have also been described in several publications (Damodaran et al., 2009, 2011). Classical histopathological analysis and other nervous system—related structure-specific staining techniques were also described in detail in recent articles (Damodaran, 2009; Damodaran et al., 2011).

Toxicogenomics and Proteomics Approaches

RNA purity verification by Agilent analysis, microarray chip hybridization, data capturing, data analysis, Tree view analysis and clustering (Fig. 11.3), data mining for classifications, principal component analysis of gene expression (Fig. 11.4), and gene validation approaches are described in detail in many publications (Damodaran et al., 2006a,b). Functional analysis of the proteins expressed in a specific tissue and/or stage of toxic exposure is an essential step toward understanding biological processes. The proteins have been shown to undergo posttranslational modifications such as phosphorylation, glycosylation, protein processing, and other proteolytic cleavage. Both two-dimensional gels and automated mass spectrometry—based approaches for proteome and phosphorylation site analysis, as well as proteome data analysis, have been described in detail from several publications. Binding assays to unravel the mechanics of protein—protein and protein—enzyme interactions and the methodology for studying axonal transport have been described in detail in numerous articles.

Metabonomics

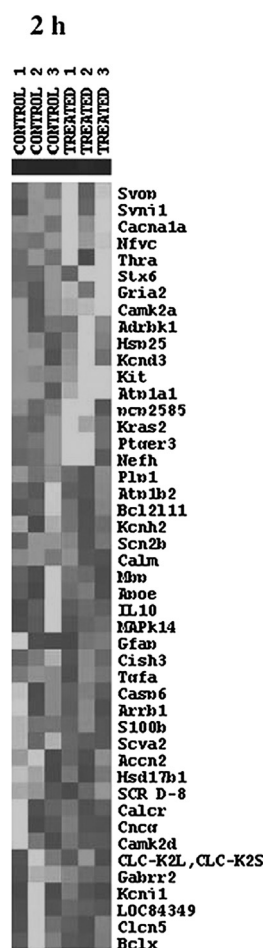
Neurotoxicity occurs after the neurotoxicants enter into the blood circulation, travel to sites of vulnerability, and gain access to tissues. Metabolic transformation is a key mechanism by which the toxicants become either


FIGURE 11.3 Tree view analysis of global gene expression at the 2 h time point is presented here. Hierarchical clustering was applied through the Cluster software program, and the results were visualized in Tree view (check http://www.microarrays.org/software for computational details). The expression level of each gene relative to the median expression level across all samples was represented by color: one representing log expression ratios of overexpressed genes and the other representing log expression ratios of underexpressed genes. The remarkable homogeneity of the coloring pattern validates the reproducibility of the replicate data from the control and treated groups (Damodaran et al., 2006b).

more toxic or less toxic. These processes predominantly produce more polar metabolites that facilitate the increased excretion (Abou-Donia and Nomeir, 1986). Thus, the process called toxicokinetics encompassing absorption, tissue distribution, storage, biotransformation, and elimination plays a major role in PNS neurotoxicity. Metabolic status during these stages can be assessed by measuring the quantity and type of metabolites. Detailed information about the toxicological outcome of toxicant exposure is required to make decisions about the long-term therapy protocols. Global profiling techniques are rapid in gathering data on the impact made on transcripts, proteins, and metabolites within the cell, tissue, organ, and organ systems of the

Clustering and Visual Representation of the Expression Data

FIGURE 11.4   Principal component analysis (PCA) of gene expression was prepared on a three-dimensional platform and is presented here as a graph providing a global view of the differences among the control (C1, C2, and C3) and treatment (T1, T2, and T3) groups (11.4 A). There is a clear separation among the controls and treatment groups (11.4 B), indicating differences in their total gene expression profiles (Damodaran et al., 2006b).

living organism. Metabonomics/metabolomics is one such approach that can provide a global profile of metabolites (Griffin et al., 2006). High-resolution nuclear magnetic resonance along with statistical pattern recognition analysis can provide valuable data, and detailed stepwise protocols are provided in several publications.

BIOMARKERS OF TRAUMATIC BRAIN INJURY AFFECTING PERIPHERAL NERVOUS SYSTEM

Traumatic brain injury (TBI) is a leading cause of death, disability, and resource consumption per year.

There are two kinds of brain injury in TBI such as primary and secondary injuries. Secondary injury occurs over a period of hours or days following the initial trauma and results from the activation of different pathways such as inflammation, coagulation, oxidation, and apoptosis that may involve PNS (Lorente, 2015). Primary injury refers to the initial physical forces applied to the brain at the moment of impact. The secondary PNS injuries have been shown to induce the levels of some circulating biomarkers such as SP, sCD40L, TIMP-1, MSA, and CK-18 fragmented, in patients with TBI (Lorente, 2015).

Biomarkers of Nerve Tissue Injury in the Peripheral Nervous System

Because of the higher abundance of Schwann cells in the PNS, regeneration after an injury is much faster and with a higher rate of nerve repair. The proximity of the cut ends of the nerve after an injury decides the higher likelihood of repairing of the injured nerve in the PNS. Clearing up irregular segments and other pieces of debris at the site of injury by macrophages facilitates the new sprout of synthesis of essential proteins and other cytoskeletal structures at the site of injury. Besides Schwann cells, satellite glial cells also undergo mitosis and other changes in the PNS. These cell types have been implicated in the genesis and maintenance of pain in the injured nerves of the PNS (Jasmin et al., 2010). Thus the coordinated functions of several important molecules in various cell types are required for this repair pathway. Table 11.1 provides a list of the biomarker genes/proteins identified by several studies on Schwann cells and myelination.

Biomarkers of Changes in Electrophysiology

Dai et al. (2012) showed that the compound action potential durations (CAPDs), compound muscle action potential amplitudes (CAPAs), and conduction velocities of sciatic-tibial nerve (NCVs) exhibited progressively abnormal changes over time in colistin-treated female mice. These changes were in correlation with ultrastructural changes. These results from electrophysiological methods provide valuable data about the status of the PNS nerves after acute or chronic neurotoxicity.

Ion Channels as Biomarkers

Peripheral sensory neurons are adapted to recognize danger to the organism by virtue of their sensitivity to intense mechanical, thermal, and irritant chemical stimuli. Although CNS-expressed sodium channels also occur in peripheral nerves, several additional channels occur mainly in dorsal root ganglion dorsal root ganglia (DRG) cells. Differential roles for Nav1.7, Nav1.8, and Nav1.9 in sensory transduction and nociception and transient receptor potential (TRP) ion channels conducting nonselective entry of cations on activation by various noxious stimuli were reported. TRPV1 is activated by high temperatures, low pH, and capsaicin, the vallinoid irritant component of chili peppers. TRPA1 mediates the detection of reactive chemicals including environmental irritants such as tear gas and industrial isothiocyanates, but more importantly, it is also activated during tissue injury by endogenous molecular signals including 4-hydroxynonenal and prostaglandins (Chiu et al., 2013). An extensive list of nervous system–related ion channel genes used for expression profiling (SABiosciences, 2013) is provided in Table 11.2. It is noteworthy to mention here that the highest number of altered gene expression and highest level of up- or downregulation were recorded for ion channel genes in global gene expression studies on sarin exposure at early time points (Damodaran et al., 2006a,b).

TABLE 11.1   Protein Markers of Schwann Cells

Myelin-forming Schwann cell: P0, P2, myelin basic protein, CNPase, proteolipid protein

Non–myelin-forming Schwann cell: common markers: NCAM, GFAP, NGF receptor, L1, A5E3, Ran-2, S100, vimentin, laminin, galactocerebroside, seminolipid

Myelin-associated glycoprotein, proteins/enzymes involved in myelination, demyelination, and other functions of myelin: Peripheral myelin protein 22, connexin 32 (Cx32/GJB1), periaxin, GDAP1 (ganglioside-induced differentiation-associated protein 1), NF-L (neurofilament light chain), dynamin-2 (DNM2), GARS (glycyl-tRNA synthetase), myelin-specific enzyme 2′,3′-cyclic nucleotide 3′-phosphohydrolase, transcriptional regulators of myelin, EGR2 (early growth response 2), Sox10 (sry-related high-mobility group box-containing gene 10), other PNS proteins, gamma-enolase, creatine kinase-B, beta-S100 protein

NGF, nerve growth factor; *PNS*, peripheral nervous system.

TABLE 11.2   Nervous System–Related Channels as Biomarkers

CALCIUM CHANNELS

Voltage-gated: CACNA1A, CACNA1B, CACNA1C, CACNA1D, CACNA1G, CACNA1I, CACNB1, CACNB2, CACNB3, CACNG2, CACNG4

Ligand-gated: RYR3

Transient receptor potential (TRP) channels: TRPA1, TRPC1, TRPC3, TRPC6, TRPM1, TRPM2, TRPM6, TRPM8, TRPV1, TRPV2, TRPV3, TRPV4

POTASSIUM CHANNELS

Delayed rectifier: KCNA1, KCNA2, KCNA5 (KV1.5), KCNA6, KCNB1, KCNB2, KCNH1, KCNH2, KCNQ1, KCNQ2, KCNQ3

Inward rectifier: KCNH2, KCNH6, KCNH7, KCNJ1, KCNJ11, KCNJ12, KCNJ13, KCNJ14, KCNJ15, KCNJ16, KCNJ2, KCNJ3, KCNJ4, KCNJ5, KCNJ6, KCNJ9, KCNK1

Calcium-activated: KCNMA1, KCNMB4, KCNN1, KCNN2, KCNN3

Other voltage-gated potassium channels: HCN1, HCN2, KCNC1, KCNC2, KCND2, KCND3, KCNH3

Modifier subunits: KCNAB1, KCNAB2, KCNAB3, KCNS1

SODIUM CHANNELS

Amiloride sensitive: ACCN1, ACCN2, ACCN3

Voltage-gated: SCN10A, SCN11A, SCN1A, SCN1B, SCN2A, SCN2B, SCN3A, SCN8A, SCN9A

Chloride channels: BEST1, CLCN2, CLCN3, CLCN7

Sodium/chloride transport: SLC12A5

SCN, suprachiasmatic nucleus.

Biomarkers of Axonal Injury

Axon degeneration is a hallmark consequence of chemical neurotoxicant exposure (e.g., acrylamide), mechanical trauma (e.g., nerve transection, spinal cord contusion), deficient perfusion (e.g., ischemia, hypoxia), and inherited neuropathies (e.g., infantile neuroaxonal dystrophy). Regardless of the initiating event, degeneration in the PNS and CNS progresses according to a characteristic sequence of morphological changes. These shared neuropathologic features suggest that subsequent degeneration, although induced by different injury modalities, might evolve via a common mechanism. Studies indicate that Ca^{2+} accumulation in injured axons has significant neuropathic implications and is a potentially unifying mechanistic event. It was proposed that diverse injury processes can lead to axon degeneration by an increase in intraaxonal Na^+ in conjunction with a loss of K^+ and axolemmal depolarization. A spontaneous mutation called WldS (slow Wallerian degeneration) showed us that Wallerian degeneration is not a passive disintegration of axon, when the axon is severed from the cell body, but an active process mediated by Nmnat protein (Mack et al., 2001). More recently, using a powerful forward genetics screen, a new pathway that involves Sarm protein has been found to prevent axonal degeneration after traumatic injury (Osterloh et al., 2012).

Biomarkers of Altered Axonal Transport

Axon transport mechanisms play a major role in transporting nutrients, organelles, and other molecules toward the presynaptic terminals by a process called anterograde transport, whereas the retrograde transport is a process by which damaged organelles and recycled plasma membrane (packed in endocytotic vesicles) are transported back to the neuron cell body. There are many major human neurodegenerative pathological disorders, such as Alzheimer's disease, Parkinson's disease (PD), and amyotrophic lateral sclerosis, which display axonal pathologies including abnormal accumulations of proteins and organelles, highlighting that disruption of axonal transport is an early and perhaps causative event. Disruption to axonal transport can occur via a number of routes such as damage to (1) molecular motors, (2) microtubules, (3) cargoes (such as inhibiting their attachment to motors), and (4) mitochondria, which supply energy for molecular motors (De Vos et al., 2008). Similarly, defective axonal transport has been shown to be involved in organophosphate-induced delayed neurotoxicity (OPIDN) (Damodaran et al., 2011). At cellular and tissue level axonal degeneration accompanied by synergistic neuronal and glial cell death pathways (e.g., apoptosis, necrosis, autophagy) have been implicated as major factors in neurotoxicity (Damodaran et al., 2011).

Biomarkers of Axonal Regeneration

Successful axonal regeneration is controlled by both intrinsic factors and extrinsic factors such as support or inhibition of regeneration by glial cells, scar formation, and vascular supply (Hoke et al., 2013). The role of mTOR and STAT3 pathways in modulating the intrinsic capacity of neurons to regenerate has been proposed (Hoke et al., 2013). Deletion of the PTEN gene in retinal ganglion neurons was shown to activate the mTOR pathway and enhanced regeneration after optic nerve crush (Park et al., 2008). Manipulation of both STAT3 and mTOR pathways leads to a synergistic increase in axonal regeneration in the optic nerve crush model (Sun et al., 2011). In the adult animal, regeneration has to occur over very long distances. As the rate of axonal elongation is determined by the rate of "slow" axonal transport, this is a very slow process leading to chronic denervation changes in the Schwann cells in the distal nerve and target tissues such as muscle (Hoke et al., 2013). A potential approach to overcome this challenge is to "speed up" the rate of regeneration by overexpressing a heat shock protein (hsp27) that plays a key role in axon outgrowth in injured neurons. There are several genes (Table 11.3) identified as playing significant roles in neurogenesis and neurotrophic signaling in the PNS (SABiosciences, 2013).

Potential Biomarkers of Pain

Neuropathic pain is defined as pain initiated or caused by a primary lesion or dysfunction of the nervous system. Pain is the outcome of noxious environmental stimuli, mechanical tissue damage, and infectious or other pathological disease processes. This can be the result of (1) spinal cord injury, (2) peripheral nerve damage resulting from diabetes or other autoimmune diseases, (3) treatment with anticancer drugs that affect axon integrity, or (4) postherpetic neuralgia (Goins et al., 2012). There are two types of pain: (1) neuropathic pain and (2) inflammatory pain. Neuropathic pain often results from damage to the PNS, CNS, and peripheral tissue damage, whereas inflammation generally initiates inflammatory pain. Neuropathic and inflammatory pain both cause activation of nociceptors (damage-sensing neurons) that innervate the skin, muscle, and viscera and terminate in the laminae of the spinal cord dorsal horn. Nociceptors conduct information to the CNS via neurotransmission (action potentials) generated by a variety of ion channels and receptors (purinergic, opioid, and cannabinoid) leading to secondary activation of neuronal pathways. This stage is followed by synaptic transmission (via glutamate, serotonin, and dopamine systems). Inflammatory mediators released by immune cells and damaged neurons can modulate the transduction nociception process.

TABLE 11.3 Candidate Biomarker Genes Involved in Neurotrophic Signaling, Neuropeptides Functions, and Neurogenesis in the PNS

Neurotrophins and receptors: ADCYAP1R1, ARTN, BDNF, CD40 (TNFRSF5), CNTF, CNTFR, CRHBP, CRHR1, CRHR2, FRS2, FRS3, FUS, GDNF, GFRA1, GFRA2, GFRA3, GMFB, GMFG, MAGED1, MT3, NF1, NGF, NGFR, NGFRAP1, NR1I2, NRG1, NRG2, NTF3, NTF4, NTRK1, NTRK2, PSPN, PTGER2, TFG, TRO, VGF

NEUROPEPTIDES AND RECEPTORS

Neuropeptide hormone: CRH, NPFF, NPY, PNOC, UCN

Bombesin receptors: GRPR

Cholecystokinin receptors: CCKAR

Galanin receptors: GALR1, GALR2

Neuropeptide Y receptors: NPY1R, NPY2R, PPYR1

Neurotensin receptors: NTSR1

Tachykinin and receptors: TACR1

Other neuropeptides and receptors: NPFFR2 (GPR74), HCRT, MC2R

NEUROGENESIS

Peripheral nervous system development: GFRA3

Negative regulation of neurogenesis: MT3

Other neurogenesis related genes: ARTN, BDNF, CBLN1, CNTF, CNTFR, FGF2, GDNF, MEF2C, NELL1, NGFR, NRG1, NTF3, NTRK1, NTRK2, STAT3, TFG

Transmission of nerve impulse: CBLN1, CNTF, CRH, GALR1, GALR2, HCRT, NPFF, NPY, NTSR1, PNOC

ADC, apparent diffusion coefficient; *PNS*, peripheral nervous system.

TABLE 11.4 Potential Biomarker Genes Related to Pain and Related Disorders

CONDUCTION OF PAIN

Ion channels: TRPA1, TRPV1, TRPV3

Sodium channels: SCN10A, SCN11A, SCN3A, SCN9A, SLC6A2

Potassium channels: KCNIP3, KCNJ6, KCNQ2, KCNQ3

Purinergic receptors: ADORA1, P2RX3, P2RX4, P2RX7, P2RY1

Opioid receptors: OPRD1, OPRK1, OPRM1

Cannabinoid receptors: CNR1, CNR2

SYNAPTIC TRANSMISSION

Glutamate receptors: GRIN1, GRIN2B, GRM1, GRM5

Serotonin receptors: HTR1A, HTR2A

Calcium channel: CACNA1B

MODULATION OF PAIN RESPONSES

Eicosanoid metabolism: PLA2G1B, PTGER1, PTGER3, PTGER4, PTGES, PTGES2, PTGES3, PTGS1, PTGS2

Inflammation: ACE, ALOX5, BDKRB1, CALCA, CCK, CCKBR, CCL2, CCR2, CD200, CD4, CHRNA4, CSF1, CX3CR1, DBH, EDN1, EDNRA,

Continued

TABLE 11.4 Potential Biomarker Genes Related to Pain and Related Disorders—cont'd

FAAH, GCH1, IL-10, IL-18, IL-1α, IL-1β, IL-2, IL-6, ITGAM, ITGB2, MAPK1, MAPK14, MAPK3, MAPK8, PENK, PNOC, PROK2, TAC1, TACR1, TLR2, TLR4, TNF

Neurotransmitters: ADRB2, COMT, DBH, MAOB, PDYN, PENK, PNOC

Neurotrophins: BDNF, GDNF, NGF, NTRK1

Parkin complex: HSPA4 (HSP70), PARK7, STUB1

Parkin substrate: ATXN2, ATXN3, GPR37, SYT11

Cell adhesion: APC, APP, CDH8, FN1, NFASC, NRXN3, PTEN, TPBG

Ubiquitination: CDC27, CUL2, FBXO9, LRRK2, PAN2, PARK2, PINK1, SKP1, STUB1, UBB, UBA1, UBE2I, UBE2K, UBE2L3, UCHL1, USP34

Inflammation: FN1, PRDX2, YWHAZ

APOPTOSIS

Proapoptosis: APC, APP, CASP1 (ICE), CASP3, CASP8 (FLICE), CASP9, CUL2, MAPK9 (JNK2), PSEN2, PTEN

Antiapoptosis: APC, BDNF, CASP3, CASP9, NEFL, NR4A2 (NUR77), OPA1, PPID, PRDX2, PSEN2, PTEN, SLC25A4, SNCA, TCF7L2, UBB, YWHAZ

Mitochondria: CASP3, CASP7, CASP8 (FLICE), HSPA4 (HSP70), LRRK2, NEFL, OPA1, PARK7, PINK1, PTEN, SLC25A4, SNCA, TH, UCHL1, VAMP1, VDAC3, YWHAZ

Synaptic vesicles: LRRK2, SEPT5, SV2B, SYNGR3, SYT1, SYT11, TH

SIGNAL TRANSDUCTION

Dopaminergic: D4S234E, DDC, DRD2, HTR2A, NR4A2 (NUR77), PARK2, PARK7, PINK1, SEPT5, SLC6A3, SNCA, TH

GABAergic: DRD2, GABBR2

MAP kinase: APC, FGF13, MAPK9 (JNK2), PRDX2, RGS4

Notch: APP, PSEN2, SPEN

Cytoskeletal organization: APC, CDC42, MAPT, NEFL, PARK2

Ion transport: ATP2B2, CADPS, CXXC1, DRD2, EGLN1, GBE1, GRIA3, HTR2A, KCNJ6, NSF, PSEN2, S100B, SRSF7, SLIT1, SNCA, VDAC3

Transporters: ATP2B2, GRIA3, SLC18A2, SLC6A3, SLC25A4, SV2B, SYT1, SYT11, VDAC3

Others: ALDH1A1, BASP1, CHGB, DLK1, NCOA1, NTRK2, RTN1

Consequently, the excitability of spinal neurons is modulated via activation of resident microglia that releases growth factors (such as brain-derived neurotrophicfactor), chemokines, and cytokines. Endogenous opioid peptides and arachidonic acid metabolites acting through G protein–coupled receptors also modulate neuronal excitability. Table 11.4 provides the list of genes, identified from above-mentioned pathways (SABiosciences, 2013).

Potential Biomarkers of Psychiatric Diseases, Neurodegenerative Diseases, and Insomnia

Dysregulation of GABAergic or glutamatergic synaptic transmission results in a wide variety of nervous system disorders, including chronic pain, psychiatric diseases, neurodegenerative diseases, and insomnia. The GABA neurotransmitter system includes the GABAA and GABAC classes of ligand-gated ion channels. The glutamate neurotransmitter system includes NMDA, AMPA, and kainate ligand-gated ion channels. Key enzymes synthesize GABA or glutamate as necessary, which are then transported into synaptic vesicles. Release of GABA or glutamate from vesicles activates postsynaptic GABA-responsive or glutamate-responsive ion channels, respectively, initiating downstream G protein signaling to propagate neurotransmission. There are a number of genes essential for the synthesis and transport of GABA and glutamate, as well as responsive ion channels and downstream signaling. Studying and monitoring these genes at all levels may yield insights into the interaction of these excitatory and inhibitory neuronal systems during essential cognitive functions, thereby facilitating the process of biomarker development (Table 11.5: SABiosciences, 2013).

Potential Biomarkers of Motor Function, Emotional Behavior, Temperature Regulation, Sensory Perception, Locomotion, and Psychosis

Two of the major neurotransmitter systems such as dopamine and serotonin play a major role in the previously mentioned aspects. Dopamine affects brain processes that control both motor and emotional behavior and plays a role in the brain's reward mechanism. Serotonin is critical in temperature regulation, sensory perception, locomotion, sleep, and psychosis. Pharmacological agents targeting dopaminergic/serotoninergic neurotransmission have been clinically used to manage several neurological and psychiatric disorders, including PD, schizophrenia, bipolar disorder, depression, attention deficit and hyperactivity disorder, and addiction. The dopaminergic/serotoninergic receptors act through diverse G protein–coupled and G protein–independent mechanisms that trigger downstream intracellular signal transduction events involving the cAMP/PKA, PI-3Kinase/AKT, phospholipase A2, and phospholipase C pathways. These pathways in turn regulate various functions including synthesis, transport, and degradation of dopamine and serotonin, as well as the transcriptional regulation key genes linked to multiple neuropathological conditions (Table 11.6: SABiosciences, 2013).

Potential Biomarkers of Sleeping Disorders (Apnea, Insomnia, and Desynchronosis)

Synchronization of the circadian clock occurs via light stimulus of the hypothalamic suprachiasmatic nucleus

TABLE 11.5 Potential Biomarker Genes Related to Glutamatergic and GABAergic Synapses

GLUTAMATERGIC SYNAPSE

Receptors: GRIA1, GRIA2, GRIA3, GRIA4, GRIK1, GRIK2, GRIK4, GRIK5, GRIN1, GRIN2A, GRIN2B, GRIN2C, GRM1, GRM2, GRM3, GRM4, GRM5, GRM6, GRM7, GRM8

Downstream signaling: ADCY7, APP, CACNA1A, CDK5R1, CLN3, DLG4 (PSD95), GNAI1, GNAQ, HOMER1, HOMER2, ITPR1, MAPK1 (ERK2), PLA2G6, PLCB1, SHANK2

Transport and secretion: ADORA1, ADORA2A, AVP, BDNF, IL1B, P2RX7, SLC17A6, SLC17A8, SLC1A1, SLC1A2, SLC1A3, SLC1A6, SLC17A6, SLC17A7, SLC17A8, SLC38A1, SLC7A11, SNCA

Metabolism: ALDH5A1, GAD1, GLS, GLUL, PRODH, SLC1A3, SRR

GABAERGIC SYNAPSE

Receptors: GABBR1, GABBR2, GABRA1, GABRA2, GABRA4, GABRA5, GABRA6, GABRB1, GABRB3, GABRD, GABRE, GABRG1, GABRG2, GABRG3, GABRQ, GABRR1, GABRR2

Downstream signaling: ADCY7, ADORA1, ADORA2A, CACNA1A, CACNA1B, GNAI1, GNAQ, GPHN, SNCA

Transport and secretion: CACNA1A, NSF, P2RX7, SLC1A3, SLC32A1, SLC38A1, SLC6A1, SLC6A11, SLC6A12, SLC6A13

Metabolism: ABAT, ALDH5A1, GAD1, GLS, GLUL, PHGDH, SLC1A3

TABLE 11.6 Potential Biomarker Genes Related to Dopamine and Serotonin

RECEPTORS

Dopamine: DRD1, DRD2, DRD3, DRD4, DRD5

Serotonin: HTR1A, HTR1B, HTR1D, HTR1E, HTR1F, HTR2A, HTR2B, HTR2C, HTR3A, HTR3B, HTR4, HTR5A, HTR6, HTR7

SYNTHESIS AND DEGRADATION

Dopamine: COMT, DBH, DDC, MAOA, TH

Serotonin: MAOA, MAOB, TDO2, TPH1, TPH2

Dopamine and serotonin transporters: SLC6A3 (DAT), SLC6A4 (SERT)

SIGNAL TRANSDUCTION PATHWAYS

cAMP/PKA pathway: ADCY1, ADCY2, ADCY3, ADCY5, CASP3, CDK5, CREB1, DUSP1, FOS, PRKACA, MAPK1, PPP1R1B (DARPP32)

PI3K/AKT pathway: PIK3CA, PIK3CG, AKT1, AKT2, AKT3, GSK3A, GSK3B

PLA2 pathway: ALOX12, CYP2D6, PDE4A, PDE4B, PDE4C, PDE4D, PDE10A, PLA2G5

PLC pathway: ITPR1, PLCB1, PLCB2, PLCB3

G protein–coupled receptor regulation: ADRB1, ADRB2, ADRBK1, ADRBK2, APP, ARRB1, ARRB2, GRK4, GRK5, GRK6, SNCA, SNCAIP

Dopamine and serotonin gene targets: BDNF, EPHB1, GDNF, GFAP, NR4A1 (NUR77), NR4A3 (NOR1), PDYN, PTGS2, SLC18A1, SLC18A2 (VMAT2), SYN2

PLC, phospholipase C.

TABLE 11.7 Potential Biomarker Genes of Sleep/Wake Cycle

Circadian clock: ARNTL (BMAL1), ARNTL2, BHLHE40 (DEC1), BHLHE41, CLOCK, CSNK1E, CRY1, CRY2, NR1D1, NR1D2 (REV-ERB), PER1, PER2, PER3, RORA, TIMELESS

Casein kinases: CSNK1A1, CSNK1D, CSNK1E, CSNK2A1, CSNK2A2

CREB signaling: AANAT, CAMK2A, CAMK2B, CAMK2D, CAMK2G, CHRNB2, CREB1, CREB3, KCNMA1, HTR7, MAPK1, MAPK14, MAPK3, MAT2A, PRKACB, PRKACG, PRKAR1A, PRKAR1B, PRKAR2A, PRKAR2B, PRKCA, PRKCB, PROKR2

LIGHT-SENSING PROTEINS

Melatonin receptors: MTNR1A, MTNR1B

Opsins: OPN3, OPN4

Others: CHRNB2, CRX

Circadian-regulated transcription factors: ALAS1, EGR1, EGR3, EPO, ESRRA, HLF, IRF1, MYOD1, NFIL3, NKX2-5, PAX4, POU2F1, RORB, RORC, SMAD4, SP1, SREBF1, STAT5A, TEF, TFAP2A, TGFB1, WEE1, DBP, PPARA

Other common circadian-regulated genes: CARTPT, CCRN4L, FBXL21, FBXL3, HEBP1, NCOA3, NMS, NPAS2, NR2F6, PPARGC1A, PRF1, PTGDS, SLC9A3

(SCN) in the brain and via hormone signaling from the SCN in peripheral tissues. Interacting positive and negative circadian gene feedback loops at the transcriptional and posttranslational level set up the circadian "oscillator" and ensure tight control over transcription factors regulating expression of the appropriate genes required during circadian days or nights. Genes regulated by circadian rhythms are involved in a diverse range of biological processes that affect physiology, metabolism, and behavior. Although the circadian rhythm target genes in its "output" pathways vary widely from tissue to tissue, the transcription factors encoded by central clock and clock-controlled genes are mostly shared across all cell types. Sleeping disorders (such as apnea, insomnia, and desynchronosis) disrupt the timing of the circadian clock, requiring re-entrainment and causing fatigue. The list of genes identified to be involved in these processes is given in Table 11.7 (SABiosciences, 2013).

Biomarkers of Peripheral Nervous System Infection

Interestingly, sensory neurons share many of the same pathogens and danger molecular recognition receptor pathways as innate immune cells, which enable them also to detect pathogens. Germline-encoded pattern recognition receptors (PRRs), which recognize broadly conserved exogenous pathogen-associated molecular patterns, include members of the Toll-like receptor (TLR) family. Following PRR activation, downstream signaling pathways are turned on that induce cytokine production and activation of adaptive immunity. In addition to TLRs, innate immune cells are activated during tissue injury by endogenous-derived danger signals, also known as damage-associated molecular patterns or alarmins. These danger signals include uric acid and heat shock proteins released by dying cells during necrosis, activating immune cells during noninfectious inflammatory responses. Furthermore, activation of sensory neurons by the TLR7 ligand imiquimod leads to activation of an itch-specific sensory pathway. A key means of communication between immune cells and nociceptor neurons is through cytokines. Interleukin (IL) 1 beta and tumor necrosis factor alpha (TNF-α) are two important cytokines released by innate immune cells during inflammation, which in turn induce activation of p38 map kinases leading to increased membrane excitability. Nerve growth factor (NGF) and prostaglandin E(2) are also major inflammatory mediators released from immune cells that act directly on peripheral sensory neurons to cause sensitization (Chiu et al., 2013).

MicroRNAs as Potential Biomarkers of Peripheral Nervous System Injury

The microRNAs (miRNAs) are a recently identified class of small regulatory RNA molecules found in most organisms. They are encoded by the genomes and processed into 22 nucleotide products, which play important roles in the posttranscriptional regulation of important cellular pathways in diverse biological processes, including cell proliferation, apoptosis, tissue morphogenesis, tumorigenesis, and heart disease (Dugas and Notterpek, 2011). Recently, changes in miRNA expression profiles have been detected in different injury models, and emerging evidence strongly indicates that these changes promote neurons to survive by shifting their physiology from maintaining structure and synaptic transmission (Wu and Murashov, 2013). The list of miRNAs that showed altered expression is presented in Table 11.8.

Yu et al. (2011) noted altered miRNA expression following sciatic nerve resection in dorsal root ganglia of rats. The expression pattern of miR-206 was different from that of miR-1 and miR-133a. Notably, two genes (Hnrpu and Npy) and one gene (Ptprd) were potentially regulated both in the denervated and reinnervated muscle by miR-1 and miR-133a, respectively. There were six potential target genes (Hnrpu, Lsamp, MGC108776, Mef2, Npy, and Ppfibp2) of the upregulated miR-206 in the reinnervated muscle. Among these, three (Hnrpu, Npy, and MGC108776) were potentially regulated by both miR-1 and miR-206. Because the Mef2 transcription factor was reported to promote the transformation of type II fast glycolytic fibers into type I slow oxidative fibers, the upregulation of miR-206 with decreased expression of the Mef2 transcript in the 4-month reinnervated muscle, which presented type II fiber

predominance 4 months after nerve microanastomosis, might indicate the role of miR-206 in determining the fiber type after peripheral nerve regeneration. Table 11.9 provides the details of target genes for these altered miRNAs and their functional role (Jeng et al., 2009).

Chemical-Induced Peripheral Neuropathy

Because of the need for complete eradication of cancer cells, a higher dose of drugs is used in cancer chemotherapy (Table 11.10), which very often results in chemical-induced peripheral neuropathy (CIPN), a dose-limiting neurotoxic effect of chemotherapy, which can lead to early cessation of cancer treatment (Wang et al., 2012). This can result in an increased risk of relapses and decreased survival rate. Biomarkers to assess the susceptibility or tolerance level of such treatment approaches can be very useful in making decisions about the choice, dose, and duration of the drugs that can help those cancer patients. Inflammatory cascade activation, proinflammatory cytokine, upregulation, and neuroimmune communication pathways play essential roles in the initiation and progression of CIPN. Most notably, TNF-α, IL-1β, IL-6, and CCL2 are involved in neuropathic pain. These cytokines could be used as biomarkers for predicting the onset of painful peripheral neuropathy and early axonal damage (Wang et al., 2012). Reactive oxygen species (ROS) have been shown to play a causal role in the development and maintenance of paclitaxel-induced pain (Fidanboylu et al., 2011), and hence the levels of ROS can be used as a biomarker for certain drugs.

Pharmacogenomic Biomarkers for Preventing Chemical-Induced Peripheral Neuropathy

Identifying genetic or molecular biomarkers for effective diagnostics of patients with high risk of developing neurotoxicity from a given chemotherapeutic agent could significantly impact the quality of life of cancer

survivors. There have been some candidate gene approaches to evaluate single-nucleotide polymorphisms (SNPs) in genes involved in the pharmacokinetic and pharmacodynamic properties of neurotoxic drugs, but no reliable biomarker has thus far been identified to detect patients at high risk of developing CIPN (Brewer et al., 2016). Variants in genes relevant to drug disposition, metabolism, and drug action can influence the patient's exposure and sensitivity to the drug. For paclitaxel, most studies focus on mutations in biologically relevant candidate genes such as CYP2C8, CYP3A4, CYP3A5, FANCD2, and ABCB1. Hertz et al. (2014) demonstrated an association between the CYP2C8*3 variant and a twofold increase in risk for paclitaxel-induced peripheral neuropathy across racial groups. Interindividual variability has also been found in the therapeutic target of paclitaxel, β-tubulin Iiα (TUBB2α) messenger RNA (mRNA) expression, and two genetic variants in the promoter region of the gene are involved in this variation. In addition, genome-wide association studies were performed to identify genetic markers predictive of peripheral neuropathy. SNPs in FGD4, FZD3, and EPHA5 were identified to be associated with a severity or dose at onset of paclitaxel-induced sensory peripheral neuropathy in patients with both European and African ancestry (Baldwin et al., 2012). In another study, a gene named RFX2 was identified to be associated with increased risk of paclitaxel-induced neurotoxicity (Wheelar et al., 2013). In a similar integration method using Asian cell lines and patient cohorts noted a decrease in AIPL1 level,

resulting in decreased sensitivity of neurons to paclitaxel. In addition, breakpoint cluster region protein was also identified as protecting the neurons from paclitaxel-induced toxicity (Komatsu et al., 2015). The set of genes that drive heritability of paclitaxel-induced neuropathy was found to be implicated in axonogenesis and, more specifically, the regulation of axon outgrowth (Chhibber et al., 2014). SNPs of CIPN neurotoxicity has been listed in Table 11.11.

Epigenetic Biomarkers of Axonal Regeneration

Gadd45 alpha, one of the key regulators of epigenetic modification of gene expression, is highly upregulated after axonal injury. In parallel, many genes involved in axonal elongation and synaptic activity are demethylated on axonal injury. Further studies are required to verify whether it is possible to use epigenetic manipulation to bring the adult neurons to a more "immature" state to promote better regeneration (Hoke et al., 2013). Peripheral myelination has been shown to be disrupted in various PNS disorders. Nuc-ErbB3 has been identified to be a master transcriptional repressor involved in epigenetic regulation H3K27me3 levels and methyltransferase activity during peripheral myelination, thus making it a good biomarker (Ness et al., 2016).

Biomarkers From Studies on Inherited Peripheral Neuropathies

A number of peripheral neuropathies are inherited, of which a number of them are associated with documented defects in axonal transport (De Vos et al., 2008). In Charcot-Marie-Tooth disease (CMT) type 2E, caused by mutations in the neurofilament light gene (NF-L), mutant protein aggregates perturb the cytoskeletal network and disrupt the normal localization of

mitochondria, leading to impaired axonal transport (Dequen et al., 2010). In CMT2A (mutations in mitofusin), axonal transport of mitochondria was compromised (Baloh, 2007) and in giant axonal neuropathy (mutations in gigaxonin) showed impaired retrograde axonal transport (Ding et al., 2006). X-linked demyelinating/type I CMT neuropathy, caused by mutations in connexin 32 (Vavlitou et al., 2010), showed reduced axonal transport and axonal pathology before demyelination occurs. Dynein dysfunction appears directly involved in at least a subset of these diseases. Dynein is regulated by a number of protein complexes, notably, by dynactin. Several studies have supported indirectly the involvement of dynein in neurodegeneration associated with Alzheimer's disease, PD, Huntington's disease, and motor neuron diseases (Eschbach and Dupuis, 2011). First, axonal transport disruption represents a common feature occurring in neurodegenerative diseases. Second, a number of dynein-dependent processes, including autophagy or clearance of aggregation-prone proteins, are found defective in most of these diseases. Third, a number of mutant genes in various neurodegenerative diseases are involved in the regulation of dynein transport. This includes, notably, mutations in the P150Glued subunit of dynactin, which are found in Perry syndrome and motor neuron diseases. Interestingly, gene products that are mutant in Huntington's disease, PD, motor neuron disease, or spinocerebellar ataxia are also involved in the regulation of dynein motor activity or of cargo binding (Eschbach and Dupuis, 2011).

The hereditary sensory and autonomic neuropathies encompass a number of inherited disorders that are associated with sensory dysfunction (depressed reflexes, altered pain, and temperature perception) and varying degrees of autonomic dysfunction (gastroesophageal reflux, postural hypotension, and excessive sweating).Types I—V have been shown to have mutations in the following genes: SPTLC1, HSN2, IKBKAP, NTRK1 (TRKA), and NTRK1. Neurodegenerative diseases characterized by brain, spinal cord, and PNS involvement often show widespread accumulations of tau aggregates. List of genes involved in hereditary PNS disorders is given in Table 11.12.

Multiple System Atrophy—Related Biomarkers

Multiple system atrophy (MSA) is a unique proteinopathy that differs from other α-synucleinopathies, as the pathological process resulting from accumulation of aberrant alpha synuclein (α-syn) involves the oligodendroglia rather than neurons, although both pathologies affect multiple parts of the brain, spinal cord, autonomic, and PNS (Jellinger and Wenning, 2016). Biomarkers include those based on neuroimaging (MRI,

DTI, MR spectroscopy, PET), peripheral biomarkers (by skin, peripheral nerve, and other biopsies), and fluid biomarkers (from serum, plasma, and CSF). Currently, the clinically most useful markers may comprise a combination of the light chain of neurofilaments, which is consistently elevated in MSA compared with controls and PD, metabolites of the catecholamine pathway (dopamine and norepinephrine), and proteins such as α-syn, DJ-1, and total tau (Jellinger and Wenning, 2016). In this multipronged approach, using several end point—specific biomarkers has been shown to be very effective.

Biomarkers of Demyelination Injuries

Axonal degeneration contributes to persistent neurological disability, affecting PNS and CNS. Demyelination has been shown to induce ATF3 (activating transcription factor 3) in dorsal root ganglia (DRG) neurons. ATF3 expression is modulated by retrograde axonal transport of c-Jun NH2-terminal kinase (JNK) (Lindwall and Kanje, 2005). Axonally derived signaling pathways can also be initiated by neurotrophins and the myelin proteins, NOGO, MAG, and oligodendrocyte myelin glycoprotein. Similar pathways and additional transcription factors may be modulated following demyelination in both PNS and CNS. Mitochondrial

function in Schwann cells has been shown to be important in maintenance of axons, and disruption of mitochondria in Schwann cells can also lead to axonal degeneration (Viader et al., 2011). Hence, gene products involved in the mitochondrial structure and function may qualify for biomarker status.

Biomarkers of Neuromuscular Junction Injuries

Neurotoxicants that target the neuromuscular junction are classified into two classes: (1) Those that alter the phenotypic synthesis, storage, or release of acetylcholine (ACh) and (2) those that disrupt the postsynaptic function of the effector cells, associated with the recognition of ACh by its target receptor, activation of conductances through the receptor-associated ion channel, or impaired hydrolysis of ACh. The neuromuscular junction has been the specific target for neurotoxins such as botulinum toxin or many of the cholinesterase inhibitors. Altered physiological splicing mechanisms of genes for agrin (AGRN), acetylcholinesterase (AChE), MuSK (MUSK), acetylcholine receptor (AChR) α1 subunit (CHRNA1), and collagen Q (COLQ) in humans and their roles in diseases involving neuromuscular junction have been shown. Molecular dissection of splicing mutations in patients with CMS (congenital myasthenic syndromes) reveals that exon P3A is alternatively skipped by hnRNP H, polypyrimidine tract-binding protein 1, and hnRNP L. Similarly, analysis of an exonic mutation in COLQ exon 16 in a CMS patient discloses that constitutive splicing of exon 16 requires binding of serine arginine-rich splicing factor 1. Intronic and exonic splicing mutations in CMS enable us to dissect molecular mechanisms underlying alternative and constitutive splicing of genes expressed at the neuromuscular junction (Ohno et al., 2017). These genes and their variants may be used as diagnostic and prognostic biomarkers.

Biomarkers From Surrogate Tissue Analysis for Peripheral Nervous System Disorders

Surrogate tissue analysis can be very useful for monitoring toxicant exposure and effect, disease development and progression, and drug efficacy testing (Tang et al., 2006). There are many accessible tissues (e.g., blood, urine, CSF, cord blood, buccal cells, or milk) that can be used as a surrogate tissue. Furthermore, recent studies from human disease conditions such as neurofibromatosis type 1, Tourette syndrome, and anticonvulsant drugs in pediatric epilepsy indicated the existence of quantifiable markers (Tang et al., 2006). Global gene expression studies using whole blood from patients with posttraumatic stress, stroke, and migraine yielded valuable data on candidate biomarkers (Segman

et al., 2005). Erythrocyte AChE for organophosphates, free erythrocyte protoporphyrin for lead, lymphocyte neurotoxicity target enzyme (NTE) for organophosphates, blood aminolevulinic acid dehydratase (ALA-D) for intermittent porphyria, and carboxyhemoglobin (CO-Hb) for carbon monoxide are few examples of good surrogate markers.

Biomarkers of Cholinergic System and Its Relevance to the Peripheral Nervous System

Acetylcholine (ACh) is widely distributed in the nervous system and has been implicated as playing a critical role in cerebral cortical development, cortical activity, controlling of cerebral blood flow, and the sleep−wake cycle, as well as in modulating cognitive performances and learning and memory processes (Schliebs and Arendt, 2011).

Peripheral Nervous System Biomarkers for Exposure to Organophosphates

Organophosphate insecticides share a common mechanism of toxicity through inhibitory effects on cholinesterase enzymes in the nervous system. Hydrolysis of the organophosphates yields a dialkyl phosphate and the leaving group, which do not inhibit cholinesterase enzymes and can be measured as biomarkers of exposure to organophosphates, as the metabolites are subsequently eliminated from the body in the urine. An individual with acute symptomatic overexposure to organophosphates will usually have an abnormally low level of activity of cholinesterase enzymes measured in the serum (as butyrylcholinesterase) or in red blood cells. Paraoxonase (or PON1) enzyme is responsible for the hydrolysis and deactivation of organophosphates. Polymorphisms in the PON1 gene exist in humans adding variability in OP exposure response. In a recent study on the associations between OP pesticide use and PNS function, it was shown that long-term exposure to OP pesticides is associated with signs of impaired PNS function among pesticide applicators (Starks et al., 2012).

Biomarkers of Organophosphorus-Ester Induced Delayed Neurotoxicity

organophosphorus compound-induced delayed neurotoxicity (OPIDN) is a neurodegenerative disorder characterized by ataxia progressing to paralysis with a concomitant central and peripheral distal axonopathy (Damodaran et al., 2011). Although the exact mechanism of OPIDN development is yet to be determined, cholinergic inhibition of AChE and differential alterations of several upstream and

downstream molecules and their associated biochemical machinery significantly contributes to the pathophysiology of OPIDN (Damodaran, 2009). AChE inhibitors (e.g., sarin, diisopropylfluorophosphate (DFP)) exposure may alter the regulation of the cholinergic system differentially, depending on the dose, duration, and mode of exposure as evidenced by numerous studies, thus affecting various functions such as muscle function, cognition, and sleep (Damodaran et al., 2006a,b; Damodaran, 2009). Alterations in the levels of mRNA of CaM kinase II alpha subunit, neural filament triplet proteins, GFAP, vimentin, alpha tubulin, beta tubulin subtypes, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) have been shown (Damodaran et al., 2009). Immediate early induction of c-fos and c-jun, PKA, CREB, and p-CREB in DFP-treated hen brain has been shown (Damodaran et al., 2009). The protein levels of protein kinase C, CaM kinase II, and several phosphatases (i.e., phosphatase 1 [PP1], and phosphatase 2A [PP2A], phosphatase 2B [PP2B]) were altered in the spinal cord of DFP-treated hens (Damodaran et al., 2011). Altered expressions of MAP2 mRNA (Damodaran et al., 2014), TAU mRNA (Damodaran et al., 2015), JUN-D mRNA (Damodaran and Abou-Donia, 2016), and GAP-43 mRNA (Damodaran et al., 2017) in OPIDN conditions warrant further studies to validate these genes as potential biomarkers for OP-induced OPIDN.

Sarin (molecular structural analogue of DFP) exposure initiated several validated and hitherto unreported pathways immediately (within 15 min of exposure) and a significant number of important genes (pathways) showed persistently modified levels at 2 h and 3 months posttreatment (Damodaran et al., 2006a,b). Furthermore, validation and candidate gene studies showed a similar overall pattern for both DFP (exposure to hens) and sarin (exposure to rats), in spite of the differences in species tested and structure of the analog used (Damodaran, 2009). Thus, there are common and evolutionarily conserved pathways (gene clusters) that are sensitive to AChE and NTE inhibition and probably other esterases' inhibition, irrespective of the test organism and differences in the structures of OPs tested. These organophosphorus esters-exposure related physiological genomic and nongenomic effects (such as hormonal, inflammatory, and other types) very often persist for a long time, if appropriate remedial measures are not taken (Damodaran, 2009).

AUTONOMIC NERVOUS SYSTEM

Autonomic nervous system (ANS) activity may be categorized into several measurable physiological systems or pathways, activated through sympathetic and parasympathetic mechanisms. These pathways provide a framework for a comprehensive review of stress reactivity measures. Measuring ANS activity include approximately 50 tools identified according to the ANS pathway, which are listed in the ANS Measures Table in Appendix A of the monograph published by Defense Centers of Excellence for Psychological Health and TBI (website: www.dcoe.health.mil) (Brierley-Bowers et al., 2011). Some of these tools, such as the electrocardiogram, are established and widely used. The utility of each tool is dependent on its purpose of use, target environment, and the sensitivity of measurement needed. The three ANS pathways most often used to measure the impact of mind-body skills, as seen in Table 11.2, are cardiac, vascular, and respiratory. These are the ANS pathways that physicians monitor via the vital signs (blood pressure, heart rate, temperature, and respiratory rate). Cardiac measurement, vascular measurement, respiratory measurement, galvanic skin response measurement, catecholamine measurement, cortisol measurement, pupillary response measurement, salivary amylase measurement, sweat analysis (Brierley-Bowers et al., 2011), and intracranial pressure analysis (Wostyn and De Deyn, 2017) are routinely employed.

Autoimmune Autonomic Disorders

Autoimmune autonomic disorders occur because of an immune response directed against sympathetic, parasympathetic, and enteric ganglia, autonomic nerves, or central autonomic pathways. In general, peripheral autoimmune disorders manifest with either generalized or restricted autonomic failure, e.g., isolated gastrointestinal dysmotility. Peripheral autoimmune autonomic disorders include autoimmune autonomic ganglionopathy, paraneoplastic autonomic neuropathy, and acute autonomic and sensory neuropathy (Mckeon and Benarroch, 2016). Some other disorders are characterized immunologically by paraneoplastic antibodies with a high positive predictive value for cancer, such as antineuronal nuclear antibody, type 1 (ANNA-1: anti-Hu) (Mckeon and Benarroch, 2016). Table 11.13 provides the list of biomarkers relevant to autoimmune disorders of PNS.

Autoantibodies as Biomarkers for Peripheral Nervous System Disorders

Recently, autoantibodies have been proposed as the new generation class of biomarkers because of their long-term presence in serum compared with their counterpart antigens (Raad et al., 2014). PNS axons and myelin have unique potential protein, proteolipid, and ganglioside antigenic determinants. Despite the existence of a blood–nerve barrier, both humoral and cellular immunity can be directed against peripheral axons and myelin. Among putative biomarkers, myelin-

TABLE 11.13 Biomarkers of Autoimmune Disorders Affecting Peripheral Nervous System (PNS)

Gene polymorphisms: FcγR, HLA, CD1, CD95, TNF-α, mannose-binding lectin, macrophage mediators, TCR, TLR4, killer immunoglobulin-like receptor, glucocorticoid receptor

Cytokines: IFN-γ, TNF-α, IL-17, IL-22, IL-18, IL-1β, IL-10, IL-6, IL-12, IL-16, IL-23, IL-37,TGF-β1

Complements: C3, C5b-9, C5a

Chemokines: CCL2, CCL3, CX3CL1, CXCL2, CXCL10, CCL7, CCL27, CXCL9, CXCL12

Others: Erythropoietin, heat shock protein, apolipoprotein E, C-reactive protein, neopterin, matrix metalloproteinases, reactive oxygen species, cell adhesion molecules, microRNA-155, osteopontin

BNB/B-CSF-B damage-associated biomarkers:

Brain-derived proteins: Prealbumin, transthyretin, S100B, cystatin C, prostaglandin D(2) synthase, hypocretin-1

Blood-derived proteins: Haptoglobin, fibrinogen, Apo A-IV, ApoH, vitamin D—binding protein, α-1-antitrypsin

PNS damage-associated biomarkers:

Myelin sheath—associated biomarkers: Autoantibodies to ganglioside, neurofascin, gliomedin, P0, PMP22, P214—25, connexin 32, α6β4, phospholipids

Neuron-component-associated biomarkers: Neurofilaments, tau proteins, 14-3-3 proteins, neuron-specific enolase

Other biomarkers for GBS: Creatine kinase heparin sulfate glycosaminoglycans, glial fibrillary acid protein, triglyceride, and hyponatremia

Adapted from Wang, Y., Sun, S., Zhu, J., et al., 2015. Biomarkers of Guillain-Barré syndrome: some recent progress, more still to be explored. Mediat. Inflamm. 2015, 564098.

TABLE 11.14 Autoantibodies to Gangliosides as Biomarkers

Clinical symptom	Antigen (potential targets)
Severe disability, mechanical ventilation	GD1a/GD1b, GD1b/GT1b
Pure motor GBS, conduction blocks at intermediate nerve	GM1/GalNac-GD1a Rb, GM1/PA, GM1/GD1a, GM1/GT1b
AMAN reversible conduction failure	LM1/GA1
Axonal sensory motor(AMSAN)	GM1, GD1a, GM1b, GalNAc-GD1a
Motor (AMAN)	GM1/GaINac-GD1a complex, GD3
Sensory/ataxic	GD1b, other disialosyl epitopes, sulfatide
Pharyngeal-cervical-brachial	GT1a, GQ1b
Miller Fisher	GQ1b (occasionally GT1a)
GBS/CMV infection	GM2
Multifocal motor neuropathy(MMN)	IgM GM1 (also asialo GM1, GM2, GD1a or NS6S)
Sensory/ataxic (CANOMAD)	IgM GD1b and other disialosyl epitopes
Gait ataxia with late-onset polyneuropathy (GALOP)	Sulfatide, Galopin (central nervous system [CNS] white matter antigen)
Distal acquired demyelinating symmetric (DADS)	IgM gammopathy, MAG, sulfatide
POEMS syndrome	IgG or IgA lambda gammopathy, ↑VEGF levels
Facial nerve involvement	GD1a
Reversible conduction failure, ataxia	GD1b
Ophthalmoparesis	GD3, O-Acetyl GT3
Ophthalmoplegia	GT1a
Ataxia	GT1b, O-Acetyl GT3
Dysfunction, distal weakness, low amplitudes for the compound muscle action potentials, facial palsy	9-O-Acetyl GD 1b

Adapted from Wang, Y., Sun, S., Zhu, J., et al., 2015. Biomarkers of Guillain-Barré syndrome: some recent progress, more still to be explored. Mediat. Inflamm. 2015, 564098.

associated glycoprotein and several antiganglioside autoantibodies have shown statistically significant associations with specific neuropathic syndromes (Fehmi et al., 2018). A detailed list of autoantibodies and corresponding clinical symptoms is given in Table 11.14.

Nonimmune Nodopathies

Peripheral nodopathies can also be induced by toxic, ischemic, nutritional, and genetic mechanisms (Fehmi et al., 2018). As many as 70% of patients who are critically ill develop neuropathies, reduced nodal voltage-gated sodium channels activity, and axonal depolarization (Dalaka et al., 2016). There is currently no recognized treatment for critical illness neuropathy, but a future ability to detect the early stages of this disease process could pave the way for disease modifying therapies aimed at preventing subsequent axonal degeneration. Acute and chronic ischemic neuropathies, often a result of systemic vasculitis presumably arising via an impact on the energy-dependent ion channel or pumps, leading to axonal degeneration (Williams et al., 2014).

Role of Peripheral Nervous System in Parkinson's Disease and Lewy Body Disease

ANS involvement occurs at early stages in both PD and incidental Lewy body disease, affecting the sympathetic, parasympathetic, and enteric nervous systems (ENSs) (Cersosimo and Benarroch, 2012). It has been proposed that α-syn pathology in PD has a distal to

proximal progression along autonomic pathways. The ENS is affected before the dorsal motor nucleus of the vagus, and distal axons of cardiac sympathetic nerves degenerate before there is loss of paravertebral sympathetic ganglion neurons. Consistent with neuropathological findings, some autonomic manifestations such as constipation or impaired cardiac uptake of norepinephrine precursors occur at early stages of the disease even before the onset of motor symptoms. Biopsy of peripheral tissues may constitute a promising approach to detect α-syn neuropathology in autonomic nerves and a useful early biomarker of PD. PD is among the most frequent neurodegenerative disorders associated with aging. Several nonmotor manifestations, such as autonomic, sleep, and olfactory dysfunction, may occur at early stages of disease and precede the onset of motor symptoms. Strong evidence indicates that autonomic involvement in PD starts in the periphery. Both its early involvement and the accessibility of peripheral tissues make the peripheral autonomic system an attractive target for detection of early biomarkers of the disease (Fanar et al., 2012).

Neural Stress System of Peripheral Nervous System

The two main arms of the stress system include the ANS and the hypothalamic—pituitary—adrenal axis. These two neural stress systems coordinate the response of many other physiological systems to a stressor, including the immune and cardiovascular systems, bringing the body back to homeostasis. The nervous and immune systems communicate with each other in a bidirectional manner. Collection of sweat and saliva and measurement of heart rate variability are noninvasive methods that can be applied to evaluate neuroimmune interactions. Levels of neuropeptides, such as NPY, VIP, SP, and CGRP, were shown to have tight correlation with levels in plasma in patients with a history of depression (Marques-Deak et al., 2006; Marques et al., 2010). The sympathetic and parasympathetic (vagus nerve, mediated by ACh) branches of the ANS play an important role in the regulation of the cardiovascular system and the immune system, where the parasympathetic nervous system has been shown to have an antiinflammatory influence on the immune system.

BIOMARKERS OF ENTERIC NERVOUS SYSTEM

Glutamate is the major excitatory neurotransmitter in the ENS. Prolonged stimulation of enteric ganglia by glutamate caused necrosis and apoptosis in enteric neurons. Glutamate immunoreactive neurons were found in cultured myenteric ganglia, and a subset of enteric neurons expressed NMDA (NR1, NR2A/B), AMPA (GluR1, GluR2/3), and kainate (GluR5/6/7) receptor subunits. Glutamate receptors were clustered on enteric neurites. Excitotoxicity in the ENS suggests that overactivation of enteric glutamate receptors may contribute to the intestinal damage produced by anoxia, ischemia, and excitotoxins present in food (Kirchgessner et al., 1997).

EMERGING AVENUES OF PERIPHERAL NERVOUS SYSTEM BIOMARKER DEVELOPMENTS: EXOSOMES

Most, if not all, types of mammalian cells release small membranous vesicles known as exosomes. In addition to their protein content, these vesicles have recently been shown to contain mRNA and miRNA species. Roles for these vesicles include cell—cell signaling, removal of unwanted proteins, and transfer of pathogens, such as prions, between cells. Exosomes can be isolated from circulating fluids such as serum, urine, and CSF, and they provide a potential source of biomarkers for neurological conditions. Exosomes have been proposed as being a means of intercellular communication in the normal physiology of the nervous system; several reports have demonstrated the release of exosomes by different cell types such as astrocytes or microglial neurons (Corrado et al., 2013). Recently, exosomes may also play a key role in neuronal communication during neurodegenerative diseases, such as Alzheimer's, PD, or prion diseases. For example, Alzheimer's disease and PD are also characterized by the accumulation of misfolded proteins; recent studies have shown that the misfolded protein incorporation into exosomes protects them from degradation and also facilitates their delivery over long distances. PD is characterized by intracellular aggregates of α-syn, the Lewy bodies, in dopaminergic neurons. Alvarez-Erviti et al. (2011) showed that α-syn released from cells overexpressing the protein is efficiently transferred to recipient normal cells through exosomes. Moreover, Surgucheva et al. (2012) showed that another member of the synuclein family, γ-synuclein, secreted from neuronal cells into exosomes, can be transmitted to glial cells, thus promoting the aggregation of intracellular proteins. In Alzheimer's disease, exosomal proteins were found to accumulate in the plaques of Alzheimer's disease (AD) patient brains, thus suggesting that exosome-associated amyloid peptides may be involved in plaque formation. Another characteristic of Alzheimer's disease is the intraneuronal

aggregation of abnormally modified microtubule-associated tau proteins. Saman et al. (2012) have recently shown that tau proteins are mainly secreted through exosomes in vitro and in vivo.

PERSONALIZED MEDICINE

The convergence of advancing research using the latest "Omics" technology in biomarker development and drug testing approaches has made it feasible to have an accurate, individual specific targeted therapy for PNS toxicity disorders.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

In this chapter, the latest evolving concepts about PNS toxicity—related biomarkers are provided. Extensive lists of proven biomarkers and candidate biomarkers identified so far have been updated. The following future directions may deserve immediate attention and action: (1) the role of posttranslational modifications such as phosphorylation and conformational alternates (resulting from pathological mechanisms), (2) research on exosomes is still in its infancy, so there is a need to identify relevant PNS mechanisms, (3) role of miRNA expression in PNS toxicity, (4) more studies on inherited disorders of PNS, (5) epigenetics of PNS toxicity, (6) more global approaches to gather useful data on PNS toxicity biomarkers, and (7) multiplex approaches for biomarker-based PNS toxicity assessment and management.

Cardiovascular Toxicity Biomarkers

Csaba K. Zoltani

Emeritus US Army Research Lab, Aberdeen Proving Ground, MD, United States

INTRODUCTION

Cardiac biomarkers reflect the current status of the heart. A marker may be a protein, an enzyme, or a hormone whose concentration deviates from the norm. A change in electrical activity, a structural change of the organ, an alteration in a physiologic measure of a functional process, such as blood pressure (BP), may indicate pathology. Biomarkers also serve as surrogate end points, useful for evaluation of benefit or harm of clinical interventions.

The deleterious response to an externally introduced substance mirrors the analogous effects of disease-producing toxins and ensuing pathological changes that alter cardiac function. Cardiac toxicity caused by xenobiotics can be from chemicals, drugs, pesticides, and heavy metals. Vascular toxicity is indicated by changes in wall structure and behavior, by a loosening of atherosclerotic deposits, or their injection into the bloodstream. Xenobiotics primarily interfere with metabolic processes or alter ionic processes causing necrosis and inflammation of the myocardium. As a consequence, when biomarkers are released, their presence gives an indication of the suspected cause and may indicate morbidity. Biomarkers thus serve both for risk stratification and also as prognosticators.

Because of poor specificity of the traditional biomarkers, such as aspartate aminotransferase (AST), lactate dehydrogenase (LDH), and creatine kinase (CK), several new markers have been developed, such as troponins, myosin light chain 3, and fatty acid binding proteins (FABP3). Because of their tissue specificity, validation, timeliness, and moderate cost of assay, microRNAs are replacing some of these conventional markers with a new palette of cardiac biomarkers.

The primary biomarkers measured in body fluids (blood, serum, and plasma) among others are troponin T and I, which rise within hours after myocardial injury, and usually indicate necrosis of the tissue. Natriuretic peptides (ANP and BNP), an intracellular fatty acid—binding protein (FABP3) and a marker for myocardial damage, are released into plasma after myocardial injury. Measurements of an increase in myoglobin, because of its lack of specificity and CK, have fallen out of favor (Kehl et al., 2012). Cardiotoxicity is also evidenced by changes in the ionic flow in the heart vasculature, measured, and expressed by the electrocardiogram (ECG), where deviation from the norm is usually the first indicator of cardiac injury. Noteworthy change in the QRS, the complex that reflects the depolarization of the ventricles, and an increase in the amplitude of the T-wave (repolarization of the ventricles), and ST-segment elevation (may indicate MI or left bundle branch block) and R-R (time between beat changes) are initial indicators of injury.

PubMed, when queried under "cardiac biomarkers" in October 2017, offered over 51,000 references. Their current utilization has also been summarized in several recently published books by Januzzi (2011), Maisel and Jaffe (2016), Patel and Preedy (2016), and Preedy and Patel (2017), as well as by Morrow (2006). Reviews by Jaffe et al. (2006), Braunwald (2008), Martin-Ventura et al. (2009), and Wettersten and Maisel (2016) give an overview of currently used markers. Excellent and comprehensive review was given by Upadhyay (2015), for all facets of cardiovascular disorders.

At present, we are witnessing the changing of the guard in cardiac biomarkers. The protein-based markers are being supplemented and replaced by miRNAs that are more sensitive, cell- and organ-specific, and faster in delineating the source and cause of cardiac injury.

Epigenetics offers new insights into environmental influence on cardiac functioning. Heart failure (HF) can be caused by subdued energy production because of mitochondrial DNA dysfunction. Biomarkers and epigenetic biomarkers of these processes are discussed in detail.

PHYSIOLOGY OF THE CARDIOVASCULAR SYSTEM

Basic Functions

The cardiovascular system delivers oxygen, nutrients, and hormones to tissues of the body and removes waste products, carbon dioxide, and metabolic end products with the aid of several organs, including the lungs, liver, and kidneys. It consists of a four-chambered pump and two circulating systems: the pulmonary and the systemic circulation. The pulmonary system transfers blood to the lungs to eliminate waste gases and then capture oxygen. The systemic circulation channels blood with the newly acquired oxygen through arteries, arterioles, and capillaries, which facilitate the exchange of gases and nutrients for waste products, and returns it to the heart by means of the venules and veins.

The myocardial tissue is similar to skeletal muscle but differs in several essential aspects. Cardiac myocytes are composed of contractile elements, thick and thin myofibrils. Protein myosins constitute the former, whereas thin elements are made of actins. Tropomyosin and troponin interdigitate with the thick filaments. Myocytes joined by intercalated disks facilitate the electrical propagation. Cardiac muscle fibers consist of cells serially connected and laying parallel to each other. The intercalated disks fuse the cells allowing easy ion movement and thus communication and progress of the action potential. In essence, the cardiac muscle is a syncytium of cardiac cells with an interconnection allowing rapid spread of the action potential.

The syncytia of the atria and the ventriculum are separated; thus the signal (potential) goes by special fibers, allowing the atria to contract ahead of the ventricles.

The excitation—contraction coupling of cardiac muscle differs from skeletal muscle in that additional calcium ions diffuse into the sarcoplasm from the T-tubules, which have diameters much larger than those of skeletal muscle, during the action potential. The contraction of the cardiac muscle depends on the calcium ion concentration in the extracellular fluid.

Cardiac Cycle

The events of a cardiac cycle, from the beginning of one heartbeat to the next, consist of a period during which the heart fills with blood, referred to as diastole. The cycle is initiated by generation of an action potential at the sinus node, which is located at the superior lateral wall of the right atrium near the superior vena cava. The action potential proceeds through the atria to the AV node and then into the ventricles. This moves the blood into the body's vascular system. From the right ventricle, the deoxygenated blood passes to the lungs where it is oxygenated, then back to the left atrium and the left ventricle, where it passes to the body.

Nervous System

The autonomic nervous system, consisting of the sympathetic and parasympathetic portions, innervates the heart. Sympathetic stimulation is very effective in substantially doubling the output, i.e., the pumping capacity of the heart, including the ejection pressure when required. The parasympathetic (vagus) nerves can decrease the output noticeably. Inhibition of the sympathetic nerves modulates the pumping, and depresses the heart rate (HR) and the strength of the muscle contraction. Strong stimulation of the vagal system decreases the heart muscle contraction. Vagal fibers are predominantly on the atria, and thus HR, and not the strength of the contraction of the ventricles, is affected.

Sympathetic efferent nerves are located at the atria and the ventricles along the outer wall of blood vessels and the sinoatrial (SA) and atrioventricular (AV) nodes. Release of the neurotransmitter norepinephrine occurs at varicosities. The vagus nerve, constituting the parasympathetic nervous system, regulates the heartbeat and mainly innervates the SA and AV nodes. The vagus nerve exerts an inhibitory action, whereas the sympathetic nervous system exerts excitatory actions, stimulating the sinus node and the atrioventricular conduction.

Immune System

Cardiac injury activates inherent immune mechanisms to alleviate the ensuing change in the affected area. This involves the initiation of inflammatory reactions, such as the toll-like receptors (TLRs) (Shintani et al., 2013), and reactive oxygen species (ROS) generation that in turn induces nuclear factor (NF)-κB activation responsible for cytokine production. In addition, transfer growth factor TGF-β (a multifunctional cytokine), mediator of inflammation and fibrosis (Frangogiannis, 2008), plays an important role. Thus, several cardiac biomarkers reflect the response of the immune system.

Neurohormonal System

The central nervous system's afferent nerve fibers carry information from the baro-, chemo-, and volume receptors that enable the regulation of the cardiac and vascular functions. Autonomic nerves and circulating hormones are the important conveyors in this process.

In HF, caused by disease or xenobiotics, neurohormonal modulation occurs (Francis, 2011). Vasoconstrictor hormones that are antinatriuretic and antidiuretic, as well as vasodilator hormones, are activated. As the disease progresses, the former hormones are overwhelmed by the latter, resulting in an elevation of plasma noradrenaline, a sign of left ventricular dysfunction culminating in ventricular arrhythmia. Subsidiary effects include the downregulation of calcium-regulating genes and apoptosis, and thus a loss of myocytes.

With an increase of the sympathetic nervous activity, atrial and brain natriuretic peptides (ANP and BNP) are synthesized and released by the atria in response to stretch partly caused by activation of the renin—angiotensin—aldosterone system, resulting in water retention. Initially ANP and BNP are instrumental in controlling HF, but as the severity increases, their effect is attenuated. The change in the ANP/BNP ratio, in effect a cardiac biomarker, gives a measure of the LV dysfunction. Other hormones, including endothelins and growth hormone, are elevated.

Right ventricular failure induces neurohormonal activation. Plasma norepinephrine rises with pulmonary artery pressure and atrial natriuretic peptide levels (Nootens et al., 1995).

Vascular System

The vascular system consists of blood vessels whose diameters are controlled by the vascular wall autonomic nerves and metabolic and biochemical signals from outside the blood vessels; it responds to and adapts to changing conditions. Vasoactive substances are released by the endothelial cells that control homeostasis and inflammatory responses.

Vascular toxicity is characterized by degenerative and inflammatory changes in blood vessels by alteration in membrane function and structure. Modulation of the contractile proteins in the vascular cells leads to the loss of homeostasis.

Xenobiotics

Xenobiotics, chemicals found in an organism but not normally present, affect body functions in a myriad of ways. This is expressed by organelles, genetic dysfunctions, mitochondrial or sarcolemmal injury, and interference with ion homeostasis. The immune system reacts and biomarkers are independently released from the myocardium into the circulation. There are indicators of impending changes, including necrosis and inflammation, as the immune system tries to counteract the presence of xenobiotics.

Oxidative stress is also caused by xenobiotics that promote cardiac toxicity (Costa et al., 2013). Sources include catecholamines, amphetamines, and excessive alcohol use.

EPIGENETIC MODIFICATIONS

Epigenetics refers to heritable transformations that are not solely caused by the genetic code per se but processes that activate or deactivate genes. The primary activities of chromatin modifications are DNA methylation and those controlled by miRNAs and noncoding RNAs. The effect is variable expression of genetic information reflecting environmental conditions.

The primary epigenetic modification involves DNA methylation that involves covalent binding of a methyl group to the 5′-position of a cytosine in the CpG (cystosine preceding guanosine) dinucleotides. CpG-islands harbor sites of transcription initiation and transcriptional repression (Lorenzen et al., 2012) by impeding the binding of transcription factors in the promoter regions of genes.

Modification of histones around which DNA is wound is catalyzed by enzymes regulating the accessibility of the DNA for transcription. Histone methylation impacts transcriptional activation and repression and thus cardiac function. MicroRNAs play an important role in impaired protein production, epigenetic silencing. Long noncoding RNAs also impact the development of disease. Thus specific miRNA expression profiles are biomarkers for treatment prognosis.

Epigenetic biomarkers thus are useful in predicting and following the progress of cardiovascular disease (Garcia-Gimenez, 2015) and genome-wide profiling technologies (Dirks et al., 2016). Genome-wide profiling technologies enable the identification of epigenetic biomarkers. Bisulfite-based DNA methylation profiling is preferred as it is not affected by freezing or chemical fixation and requires relatively small samples. Other techniques take advantage of mutated histone-modifying enzymes directly affecting posttranslational histone alterations. ChIP-Seq, under development, is another technique likely to be adopted. It analyzes protein interactions with the DNA to identify the binding sites of associated proteins.

Circulating posttranslational-modified histones expressed in acetylation, methylation, and phosphorylation are also considered biomarkers. The modifications can modify the structure of the chromatin thereby activating or silencing of genes.

Identification of epigenetic biomarkers in cardiovascular diseases (Backs and McKinsey, 2016) has markedly contributed to the unraveling of chromatin-based environment influenced mechanisms (Webster et al., 2013; Stefanska and MacEwan, 2015; Kaikkonen et al., 2011).

MITOCHONDRIAL DYSFUNCTION

The large number of mitochondria, structures within cells, produce energy by oxidative phosphorylation. Simple sugars and oxygen are used to create adenosine

triphosphate (ATP). Enzyme complexes carry out the oxidative phosphorylation.

Other cellular activities, including apoptosis and production of heme and cholesterol, are also performed by the mitochondria. Mitochondria also carry their own DNA that contains 37 genes. Thirteen of these genes take part in making enzymes involved in oxidation phosphorylation. Others produce RNAs that are instrumental in amino acids.

The primary task of the mitochondria, energy production, involves electron transport and phosphorylation apparatus as ATP is synthesized in the mitochondrion by addition of a third phosphate group to ADP by oxidative phosphorylation.

Mitochondrial dysfunction is at the root of a number of heart diseases. HF is associated with decreased mitochondrial biogenesis (Brown et al., 2017; Dorn et al., 2015). Sites of mitochondrial defects are within the electron transport and phosphorylation apparatus.

A number of biomarkers signal mitochondrial dysfunction. Changes in mitochondrial genome to nuclear genome (Mt/N) ratio in circulating cells signal dysfunction (Malik and Czajka, 2013). Increase in ROS with unpaired mitochondrial electron transport chain activity is also a sign (Frijhoff et al., 2015). In patients with mitochondrial disorders, FGF-21 is elevated and GDF15 is increased.

PROTEOMICS

Proteomics, the characterization of proteins within a biological system, has furnished insight into the behavior of cardiovascular entities and led to the discovery of biomarkers (Lam et al., 2016). Changes in proteome configurations describe the pathogenesis, protein alterations corresponding to the elicited pathological conditions.

Mass spectroscopy measurement of changes in plasma proteome due to cardiac dysfunction is available. The structure and abundance change of proteins are markers of disease. For example, in case of HF, a decrease in phosphorylation of protein kinase A located in the N-terminal extension of cardiac troponin I, as well as at other sites, is apparent. Proteomics data in cardiovascular medicine now offer new biomarkers and access to explanation of transformation processes (Anderson and Anderson, 2002).

CARDIAC TOXICITY

Toxic compounds, including drugs, can directly affect the heart. Typical effects are the formation of lesions and biochemical changes, including enzyme induction or inhibition with changes in metabolic pathways.

One of the characteristics of our environment is the acceptance of the introduction and distribution of man-made chemicals without the benefit of knowing possible side effects. Foods are part of this process and, in health care, substances that have not been a part of natural evolution are part of the treatment given to overcome undesirable genetically processed changes.

Many drugs, including the widely used antineoplastic adriamycin, are cardiotoxic. Adriamycin's toxicity is dosage-dependent and time-delayed. Although the precise mechanism of action is unknown, it is known that certain medications bind to cardiolipin on the membrane of myocytes. In addition, iron and redox reactions, resulting in the production of superoxide anions, may contribute to abnormal protein processing and hyperactivated innate immune responses, thereby causing inhibition of neuregulin-1 signaling (Shi et al., 2010).

Hydralazine, a drug used for hypertension, causes myocardial necrosis. The metabolism of allylamine, through amine oxidases, causes the formation of acrolein, a toxic compound. Likewise, heavy metals, including cobalt, cause cardiomyopathy by interfering with calcium ions in muscle tissue. There are countless other examples. These chemicals adversely affect the heart, and cardiac biomarkers give testimony to their effect.

BIOMARKER OF MYOCARDIAL IONIC DYSFUNCTION

Electrocardiogram

Among the cardiac biomarkers, the ECG, because of its ease of use and specificity in many instances, is one of the most widely used assays for detection of cardiac damage. Primarily, T-wave elevation (ventricular repolarization), ST elevation/depression (ventricle systolic depolarization) in leads I, II, III, or a limb lead of the 12-lead ECG is a hallmark of myocardial infarction (MI) and other cardiac conditions, and Q-wave evolution is an important feature that may indicate cardiac damage. The 12-lead ECG has a sensitivity of 45%−68% for MI (Menown et al., 2000) based on ST elevation. QT interval change can be considered a biomarker of sudden cardiac death, whereas the PR interval should be considered as a biomarker and indicator of atrial fibrillation. Drug-induced QT prolongation is caused by blockade of delayed rectifier potassium current, raising the possibility of arrhythmia. Overexpression of nitric oxide (NO) synthase 1 adaptor protein in cardiac myocytes leads to action potential shortening and is associated with QT interval and sudden cardiac death (Lilly, 2003).

Electrocardiographic biomarkers have been extensively used making long-term prognosis on

cardiovascular events in postmenopausal women without known cardiovascular disease (Gorodeski et al., 2011). Fourteen ECG biomarkers, associated with long-term prognosis, were selected. They reflected autonomic tone, (ventricular rate and variability), atrial conduction (P-wave characteristics) QT duration, and ventricular repolarization. Random survival forests, a nonparametric decision tree—based approach, was used to identify clinical and ECG predictors of mortality.

The widely used Minnesota Code (MC) and Novacode (NC) to identify Q-wave, ST-segment, and T-wave abnormalities are also strong predictors for CHD mortality.

METABOLOMICS

The metabolite footprints left by cellular processes are suitable biomarkers for the determination of therapeutics (Pintus et al., 2017; Ussher et al., 2016). Ischemia, CVD, and HF cause measurable cellular, functional changes; and certain components, because of changes in their occurrence, play important roles.

Cardiovascular diseases (CVD) are estimated to cause approximately one-third of the deaths in the developed world. PTX3, marker of inflammation and vascular damage, plays an important role in CVD (Fornai et al., 2016). Amyloid A is a recognized biomarker for acute coronary syndrome (Yayan, 2013). Low-density lipoprotein receptor-1 is significantly elevated in ACS and is considered a biomarker for coronary artery disease and marker for potential plaque rupture.

BIOMARKERS OF WALL STRETCH

Natriuretic Peptide

Peptide hormones regulate cardiovascular, endocrine, and renal homeostasis. Wall stretch and ischemia is the predominant mechanism for synthesis and release of natriuretic peptides from cardiac atria and the ventricles (Maisel et al., 2002). The biological effect is mediated by their binding to cell surface receptors of the cardiovascular system, and this acts as an antagonist to the major vasoconstrictor neurohormonal axis. Many factors, not only cardiac conditions, can affect the presence of NPB (B-type natriuretic peptide) and NT-proBNP (N-terminal fragment of its prohormone) (Balion et al., 2008).

In cardiac damage, biomarkers such as atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP) are cardiac-derived polypeptides encoded by a gene on chromosome 1 and produced both in the atria and the ventricles; the concentration of BNP is lower than that of ANP and C-type natriuretic peptide (CNP), a 22-amino acid polypeptide formed in the brain and in the vascular endothelium. These three polypeptides

result from cleavages of pre-prohormones and prohormones. ANP and BNP are secreted in plasma with half-lives of ∼1 h and 20 min. The circulating level of CNP is very low. Wall stretch is primarily responsible for the synthesis and release of BNP, and its release from cardiac myocytes is activated in HF. Norepinephrine and proinflammatory cytokines are simultaneously released. BNP's physiological actions include relaxation of vascular smooth muscle and venous and arterial dilatation. BNP affects left ventricular filling patterns by a lusitropic (myocardial relaxation) effect. BNP and NT-proBNP are markers of ventricular dysfunction and ventricular wall distension. CNPs are endogenous polypeptide mediators with natriuretic and vasodilator effects. CNP is derived from the brain and the vascular endothelium. Its circulating level in the bloodstream is low. Its effect is vasodilatory by activation of potassium channels. Contrary to ANP and BNP, CNP does not directly participate in natriuretic activity. Mainly, the cardiovascular effect of these peptides is vasodilatory, i.e., to decrease vascular reactivity (Table 12.1).

Circulating levels of ANP and BNP are elevated in congestive heart failure (CHF) (Tang et al., 2008). BNP levels above 100 pg/mL indicate the presence of HF.

TABLE 12.1 Biomarkers of Cardiac Toxicity

Biomarker	Source	Injury Type
Myoglobin	Muscle including the myocardium	Released on muscle damage
C-Reactive protein (CRP)	Necrosis causes the release of cytokines	Inflammation of arteries causes elevated level: precursor
	Triggering synthesis in the liver; binds to and clears	To heart attack
	Apoptotic cells	
Creatine kinase (CK-MB)	Myocardium enzyme; catalyzes conversion of ADP into ATP	Myocardial infarction elevated with muscle damage
Cardiac troponin	Cardiomyocytes, several types	Irreversible myocardial injury
B-type natriuretic peptide	Ventricular myocardium	Pressure overload, wall tension, heart failure
microRNA	Over 1000 types each reflecting the location and type of injury under validation	Significant volume change in plasma, serum, and blood
		On cardiac injury; the type depends on the injury
		Location and is very rapidly detectable in body fluids

The concentration reflects the severity of symptoms, such as the degree of LV (left ventricle) dysfunction.

Choline

A marker of ischemia, choline is released early into the circulation after cleaving of the phospholipids that are the constituents of cell membranes. In ACS (acute coronary syndrome) choline is increased. In conjunction with troponin, it is a marker of major adverse cardiac events. As biomarker it is used for prognostication of cardiac arrest and death (Zeisel, 2000; Danne et al., 2003). It is used to discriminate between high- and low-risk subgroups in troponin-positive patients.

Fatty Acid—Binding Protein

The cytoplasm of striated muscle cells contains fatty acid—binding proteins (FABPs) that transport long-chain unesterified fatty acids. The heart-type FABP (H-FABP) is rapidly released from the myocardium into circulation in response to myocardial injury (Azzazy et al., 2006). Because of the fact that it is also present in renal failure, its specificity for MI remains unresolved. However, it is 20 times more specific to cardiac muscle than myoglobin, and it is 10-fold lower in skeletal than cardiac muscle (Ghani et al., 2000). Levels of H-FABP exceeding 6.48 μg/L indicate a significantly higher probability of future adverse events than do low troponin levels or absent indicators of necrosis.

Mir-1, the muscle-specific microRNA, regulates FABP3, making its assessment in the plasma useful for determining cardiac pathological conditions (Catalucci et al., 2015). The inverse relationship between circulating level of FABP3 and miR-1 is a useful biomarker.

BIOMARKERS OF NECROSIS

Troponin

Troponins are regulatory proteins and part of the contractile mechanism of the cardiac muscle. Troponin is bound within the filament of the contractile apparatus. When cardiac myocytes are damaged, troponin is released into the circulation. At first the cytosolic pool is released, and then the structurally bound troponin enters the circulation. Elevated levels indicate myocardial damage. Cardiac troponin I levels of 1.0 μg/L or higher or cardiac troponin T levels of 0.1 μg/L or higher are considered elevated (Peacock et al., 2008).

Troponin is a complex of three regulatory proteins, troponin C (TnC), troponin T (TnT), and troponin I (TnI), which are integral to nonsmooth muscle contraction in cardiac muscle. They are located between actin filaments of muscle tissue. TnC binds to calcium ions and produces conformational change in TnI. TnT binds to tropomyosin and TnT binds to actin.

Troponin is difficult to detect in unaffected muscle, but troponin levels rise several hours after the onset of myocardial injury, such as MI. It is detectable up to 10 days after onset of injury. The degree of elevation of troponin also gives prognostic information on the subsequent outcome (Keller et al., 2009).

Troponin plays an important role during excitation—contraction coupling. During excitation, calcium ions bind to TnC; it interacts with tropomyosin to unblock active sites between the myosin filament and actin allowing cross-bridge cycling and thus contraction of the myofibrils that constitute the systole. Tension is reduced as the extracellular calcium entering the myocardial cells is reduced. Phosphorylation of TnI inhibits calcium binding of TnC whereby tropomyosin blocks the interaction of actin with myosin. During the subsequent diastole, one calcium ion is exchanged for three sodium ions. With FDA's recent approval of the next-generation assay, Roche's TnT Gen 5 Stat that delivers more sensitivity, the interpretation of the results is expected to lead to new standards.

Creatine Kinase

CK is an enzyme that catalyzes the conversion of phosphocreatine, the energy reservoir for regeneration of ATP, degrading ATP to ADP. CK consists of two subunits, a muscle-type M and a brain-type B. CK consists of three isoenzymes: CK-MM in skeletal muscle, CK-BB in brain, and CK-MB in heart. The myocardium has about 30% CK-MB, and thus lacks the specificity for cardiac damage. As noncardiac damage may also cause a rise, it is not used for MI diagnosis. CK-MB increases and disappears 12—36 h following the onset of symptoms. CK-MB usually returns within 2 days to baseline values. A relative index value, the ratio of CK-MB/CK, has a normal value 1. Values greater than 2.5—3.0 indicate heart damage. CK-MB has specificity not only for cardiac tissue but also rises for blunt chest trauma and cocaine abuse. It is no longer used as the main indicator of cardiac necrosis (Apple, 1999).

Myoglobin

Myoglobin is an iron- and oxygen-binding protein and it is related to hemoglobin. Myoglobin is only found in the bloodstream on injury of the muscles. It contains the heme prosthetic group that has iron-containing porphyrin in the center (Wittenberg and Wittenberg, 2003).

As one of the earliest biomarkers, it is a heme protein that is abundant in the cytoplasm of cardiac muscle cells. It appears in circulation within an hour of myocardial

necrosis. Its concentration increases before that of troponin. Myoglobin is ubiquitous in skeletal muscle and therefore it lacks specificity for myocardial injury. Its concentration is elevated also in renal insufficiency but displays excellent early sensitivity, increases more rapidly than troponin and CK, but also has a short plasma half-life. Thus, elevated myoglobin has low specificity for acute myocardial infarction. Its normal value is in the range of 17.4–105.7 ng/mL.

BIOMARKERS OF INFLAMMATION

C-Reactive Protein

Among the biomarkers of inflammation and swelling of the arteries, the highly sensitive C-reactive protein (hs-CRP) is also widely used as an indicator of atherothrombosis.

CRP stimulates monocyte release of cytokines, including IL-1, IL-6, and tumor necrosis factor (TNF)-alpha and expression of intercellular adhesion molecule and vascular adhesion molecule by endothelial cells (Pasceri et al., 2000). Because CRP detects inflammation anywhere in the body, it cannot give a specific location of the inflammation, but it is considered to play a role in the initiation of cardiovascular disease and is one of the strongest predictors of risk. At 3.0 mg/L, it confers high risk for CVD (Peters et al., 2013).

Galectin-3

A sign of HF is the increase of the plasma levels of Galectin-3. Primarily found in the cytoplasm and secreted into the extracellular space, it is involved in inflammatory and fibrotic processes and associated with remodeling HF (de Boer et al., 2009). With its expression in the heart lower than in several other organs, it has strong value in predicting HF.

There are a number of other markers under consideration with the potential of becoming cardiac biomarkers, such as copeptin for acute coronary syndrome (ACS) (Nickel et al., 2012), and soluble FMS-like tyrosine kinase-1 (sFlt-1) (Stratz et al., 2012), but more work needs to be done before their clinical utility is established.

Myeloperoxidase

Myeloperoxidase (MPO) is a hemoprotein expressed by polymorphonuclear neutrophils (PMNs) and it is secreted during leukocyte degranulation (Nicholls and Hazen, 2005). This enzyme is a marker of vascular inflammation and characteristic of acute coronary syndrome. High levels of MPO are associated with endothelial dysfunction as this reduces levels of NO and increases the risk of cardiovascular diseases. It is used in diagnosing HF. This inflammatory biomarker has been approved by the US Food and Drug Administration (FDA).

Tumor Necrosis Factor

TNF signals an inflammatory process and is a marker of HF. Excessive expression is associated with cardiac hypertrophy, fibrosis, and contractile dysfunction and indicates abnormal left atrial function and left systolic and diastolic dysfunction.

Proinflammatory cytokines, such as TNF, are produced by ischemia and act as an autocrine contributor to myocardial dysfunction. TNF depresses myocardial contractile function and reduces ejection function. The heart produces TNF receptors and IL-1 receptor antagonists that enter into the circulation.

TNF disrupts calcium handling, which affects excitation–contraction coupling. In addition, apoptosis ensues a characteristic of chronic HF and arrhythmogenic right ventricular dysplasia (Meldrum, 1998; Feldman et al., 2000). Recently, levels of circulating TNF receptors were correlated with infarct size and left ventricular dysfunction (Nilsson et al., 2013) and troponin levels. The increase in the circulating levels of TNF (sCD40L) is a marker of HF and vascular disorder.

REMODELING

ST2 and sST2

ST2 is a mediator of inflammation with marked soluble ST2 (sST2) concentration rise in autoimmune disease, fibrosis, and tissue injury. ST2 concentration changes are prevalent in cardiovascular diseases, including HF and MI (Weinberg et al., 2002). sST2 is a powerful tool for prognosis, exceeding even natriuretic peptide assays (Januzzi et al., 2007).

sST2 Soluble

A biomarker of cardiomyocyte stretch, ST2 is a member of the interleukin receptor family, which signals left ventricular dysfunction and fibrosis. Elevated levels of sST2 are characteristic of HF (Mueller et al., 2008; Shah and Januzzi, 2010). sT2 levels markedly increase after myocardial infarction and positively correlate with CK (Weinberg et al., 2002). Deletion of the ST2 gene enhances cardiac hypertrophy and fibrosis and ventricular dysfunction. ST2 elevation correlates with AMI and the infarct size.

Matrix Metalloproteinase-9

In instances of cardiac remodeling, matrix metalloproteinase is significantly increased and is associated

with inflammation, extracellular matrix degradation, and cardiac dysfunction. MMP-9 is a potential biomarker (Halade et al., 2013).

Growth Differentiation Factor 15

GDF15 is a cytokine that acts in regulating inflammatory and apoptotic pathways and is upregulated after cardiac injury (Ago and Sadoshima, 2006; Kempf et al., 2006, 2007). High levels of GDF15 correlate with recurrent MI.

NEUROHORMONAL ACTION

The overexpression of neurohormonal biologically active molecules, including norepinephrine that is an effector of myocardial diffraction and thrombogenesis in ACS (Blann, 1993; Spiel et al., 2008) and angiotensin II, which are synthesized in the myocardium, exerts toxic effects and contributes to HF. In vascular disease, elevated von Willebrand factor level is predictive. The TNF promotes left ventricular dysfunction (Bozkurt et al., 1998), whereas angiotensin II contributes to necrosis (Tan et al., 1991). In the failing human heart, the concentration of norepinephrine correlates with the degree of HF. Chronic catecholamine stimulation is cardiotoxic. Thus, increased activation of the sympathetic nervous system and a higher norepinephrine level go hand in hand with deteriorating HF. Antagonizing neurohormones obviate the progression of HF (Mann, 1999).

Fibrinogen

Fibrinogen is a marker for inflammation and it promotes atherothrombosis (coagulation) by altering the hemodynamic properties of blood. Elevated levels indicate an increased likelihood of coronary artery disease and vascular disease, but these remain under investigation (Danesh et al., 2005). Fibrinogen is a protein that helps blood to clot. The normal level is between 200 and 400 mg/L; higher levels enhance clot formation and increase artery wall injury.

Copeptin

A stable C-terminal fragment of arginine vasopressin (AVP), copeptin is a hormone important for cardiovascular function. The normal level of this glycosylated peptide is increased considerably in response to myocardial injury. Elevated values are associated with HF in AMI (Khan et al., 2007). This nonnecrotic biomarker is used to rule out myocardial infarction. A concentration of 0.7 pmol/L suggests a significant HF risk.

VASCULAR BIOMARKERS

Vascular damage usually is a result of endothelial cell dysfunction and increased permeability, resulting in swelling and necrosis. Multiple mediators are usually present and drugs may also play a prominent role in perturbing the endothelial cell matrix, triggering inflammatory signals, and enhancing cellular adhesion. Inflammatory cytokines are released and ROS are generated that enhance necrosis and cause vascular injury (Louden et al., 2006; Tardif et al., 2006; Zhang et al., 2010).

Endothelial cell activation results in the release of von Willebrand Factor (vWF), vascular endothelial growth factor, caveolin-1, and NO. The propeptide vWFpp in plasma is a marker of vascular injury because endothelial cells are the sole source of this protein so that even in moderate vascular injury it records significant elevation.

A potential diagnostic marker of vascular injury is the smooth muscle α actin (SMA). Vascular lesions also result from increased NO production and sustained NO synthase (NOS) activity. Excessive generation of NO leads to cell damage or cell death.

Vascular endothelial cells produce and release vWF in response to inflammatory cytokines and thrombin.

Homocysteine

Homocysteine is a protein that is created when the amino acid methionine is metabolized. Homocysteine damages arteries in high concentrations, beyond 10.8 μmol/L. It inhibits the structural components collagen, elastin, and proteoglycans of an artery (Wierzbicki, 2007). Hyperhomocysteinemia (Ganguly and Alam, 2015) changes the lipid profile, inflammation and fibrinolysis and damages endothelial cells increasing the risk of cardiovascular disease. Level of homocysteine has been suggested as a biomarker.

Lp-PLA$_2$

Lp-PLA$_2$, a vascular biomarker, also known as platelet-activating factor, correlates with other inflammatory risk factors. It is an enzyme that degrades oxidized phospholipids, resulting in proinflammatory and cytotoxic products (Uydu et al., 2013). Lp-PLA$_2$ levels signal the development of peripheral arterial disease.

Placental Growth Factor

The placental growth factor (PIGF) is a biomarker of vascular inflammation. The stimulated angiogenesis and the produced collagen-degrading enzymes with adhesion to vascular surfaces lead to plaque rupture

([Heeschen et al., 2003; Glaser et al., 2011](#)). PIGF is useful in risk stratification.

Pregnancy-Associated Plasma Protein-A

PAPP-A (pregnancy-associated plasma protein A) in dimeric form is significantly elevated in unstable coronary disease ([Body and Ferguson, 2006](#)). IGFBP-4, a substrate for dPAPP-A, is a marker for plaque rupture.

OTHER MARKERS

Heart Rate Variability

Neural injury may lead to arrhythmia. Variation in the R-R interval of the ECG, often referred to as HRV (HR variability), is a marker of sympathetic and parasympathetic influences on modulation of heart rate. Reduced HRV predicts increased risk of mortality. Reduced HRV reflects an increase in sympathetic activity that predisposes to myocardial ischemia and arrhythmia ([Tsuji et al., 1996](#)).

Rho Kinase

One of the symptoms of CHF, characterized by inflammation, is vasoconstriction where Rho kinases (ROCKs) are an effector. CHF causes ROCK activity to be considerably higher than normal, as well as protein levels of ROCK and activity of RhoA. Circulating ROCK activity in leucocytes is a biomarker for CHF risk ([Dong et al., 2012](#)). Combining ROCK activity with NT-proBNP has been used to predict long-term mortality.

ROCK has been confirmed to be involved in cardiovascular disease pathologies, including vascular muscle cell hypercontraction and endothelial dysfunction ([Shi and Wei, 2013](#)). Fasudil, a potent Rho-kinase vasodilator and inhibitor is being used for the treatment of ischemic diseases. Increased ROCK activity reflects CHF.

Plasma Ceramides

Ceramides are a family of lipid molecules originating from cell membranes, are linked to inflammatory processes they contribute to the regulation of cells, and are carried by LDL and become embedded in arterial wall containing atherosclerotic plaques where activation of platelets increases the likelihood of clot formation. There are several kinds of these lipids; ratios of different kinds are now used as markers.

Elevated levels of ceramides in the plasma are associated with the risk of myocardial infarction and mortality. High levels increase the likelihood of cardiovascular events 3–4 times. Ceramide measurement is important because ceramide ratios indicate likelihood of cardiovascular events in patients with stable coronary artery disease and stable acute coronary syndrome. However, causality was not demonstrated.

MARKERS OF DRUG-INDUCED TOXICITY

Considerable time delay for the appearance of cardiac toxicity is characteristic of a number of prescribed drugs. Adriamycin (doxorubicin), an anthracycline, used for the treatment of inflammatory breast cancer, is effective as long as the total dosage over time is limited. Only years later does doxorubicin-induced cardiac toxicity become apparent ([Geisberg and Sawyer, 2010](#)). Anthracyclines cause cardiomyocyte damage ([Zhang et al., 2012](#)) by the formation of free radicals that disrupt cellular function and cause apoptosis ([Sawyer, 2013](#)). Upregulated expression of miR-146a in doxorubicin causes cardiotoxicity by targeting the ErbB4 gene ([Horie et al., 2010](#)).

At the initiation of treatment with Adriamycin, there were no positive cardiac biomarkers measured for the patient whose ECG ([Fig. 12.1](#)) was taken after the lapse of a number of years following the first use of the drug. The drug invoked biomarkers that clearly showed an inverted T-wave in the V1–V3 leads, a right bundle block manifested by a QPR considerably extended over time. Simultaneously, measurement of troponin I gave a value of 0.2 ng/mL and natriuretic peptide array of 162 pg/mL, which were all in the normal range. Interestingly enough, in some cases N-terminal pro-B-type natriuretic peptide, marker of ventricular dysfunction, increased without clinical signs of cardiotoxicity ([Kilickap et al., 2005; Altena et al., 2009](#)). Over time, the cardiac toxicity of the drug-induced bradycardia and pacemaker-induced bradycardia and pacemaker syndrome, with asynchrony of the atria and ventricles prevented proper pumping of the blood.

Changes in the LVEF (left ventricular ejection fraction) were noted as a consequence of anthracycline chemotherapy ([Volkova and Russell, 2011](#)). Cardiotoxicity is usually noted within a year of the completion of treatment, although in some cases it may be delayed.

CARDIAC BIOMARKERS OF ILLEGAL DRUGS, CHEMICALS, AND TERROR AGENTS

Refer to Table 12.2 for cardiac biomarkers of several cardiotoxicity-inducing illegal drugs, pharmaceuticals, and environmental chemicals.
FIGURE 12.1   ECG of patient treated with Adriamycin.

Anthrax

Anthrax, caused by *Bacillus anthracis*, induces vascular insufficiency by curtailing neuronal NO synthase. Vascular function depends heavily on NOS (Casadei, 2006) and is involved in the response to injury of the myocardium. In experiments with anthrax lethal toxin–treated mice, ejection fraction and decreased ejection fraction, and contractile functions were noted (Moayeri et al., 2009). Consequently, markers of cardiac injury, myoglobin, troponin I, and heart fatty acid protein (H-FABP) levels were elevated. In addition, heart morphology changes are evident, and elevation in the permeability of blood vessel membranes is also caused by anthrax (Table 12.2).

Pharmaceuticals

Anthracyclines, extensively used for treatment of solid tumors and hematological malignances, cause cardio-myopathy and CHF, which is refractory to treatment. Their cardiotoxicity is attributed to abnormal protein processing, immune response, and inhibition of neuregulin-1 signaling. Anthracyclines block the functioning of topo-isomerase II (TOP2) (Sawyer, 2013) of tumor growth.

The side effect of TOP inhibition includes dysregula-tion of mitochondrial biogenesis. The innate immune system is dysregulated through miR-146 (Horie et al., 2010; Shi et al., 2010). The biomarker of drug-induced cardiac toxicity is primarily the ECG, which shows the breakdown of ionic conduction.

Cardiac glycosides elevate intracellular sodium and calcium transfer. An overload of calcium causes cardiotox-icity, arrhythmia, and premature ventricular contraction.

Slowed AV conduction results in bradycardia. An overdose may cause ventricular tachycardia and possibly ventricular fibrillation. Elements of the dysfunction of the ionic conduction system are shown by the classical bio-markers (Ma et al., 2001; Nagai et al., 2013).

Antidepressant serotonin reuptake inhibitors can cause cardiac effects, including prolonged QT_c, arrhythmia, and torsade de pointes (Leonard et al., 2011; Deshmukh et al., 2012). ECG monitoring is the best use of cardiac biomarkers. Several of the tricyclic antidepressants may cause cardiac sodium channel blockade, thereby increasing the cardiac action poten-tial and causing a delay in atrioventricular conduction (Thanacoody and Thomas, 2005).

Antihistamines selectively bind to histamine H1 receptors. These inhibit the repolarizing potassium currents, I_k (delayed rectifier), and the inward rectifier i_{k1}. Blockade of Ca^{2+}, Na^+ is also important. Blockade of the HERG channel increases the QT_c interval. Cardio-toxic effects of antihistamines include QT_c prolongation, K^+ channel blockade, and increased action potential duration (Zhang, 1997).

Illegal Drugs

Cardiac damage due to cocaine is myriad and no sin-gle biomarker can give a definite diagnosis. Cocaine causes irreversible structural damage in a number of or-gans, including the heart. It stimulates the sympathetic nervous system, inhibits the reuptake of catecholamines, and increases the sensitivity of adrenergic nerve endings to norepinephrine (Turillazzi et al., 2012). Myocardial infarction due to coronary artery vasoconstriction, thrombus formation, and arrhythmia is also observed.

ECG measurements are insufficient cardiomarkers. Troponin is also elevated, though the source may not be singular (Agewall et al., 2011). The activation of α

		Ventricular fibrillation	
Cyanide	Cardiovascular collapse	Cyanide in whole blood, rapidly	Muncy et al. (2012)
	Inhibits multiple enzyme systems,	Metabolized, short half-life	
	Cytochrome oxidase	ST elevation	
	Disrupts ATP production	QT segment shortening	
		PR prolongation	

and β adrenergic receptor sites, leading to increased catecholamine levels (Keller and Lemberg, 2003), is also significant. Calcium handling of the myocytes and changes in the conduction system leads to QRS and QT_c changes.

Cannabis (marijuana) through tetrahydrocannabinol (THC), its active psychoactive ingredient, triggers a number of cardiovascular system responses (Jarai and Kunos, 2002). Increased heart rate (HR) and lowered BP are present. THC binds to cannabinoid receptors of several organs, including the heart, and overstimulates the receptors. In addition, THC causes overproduction of a protein, ApoC-111, which is linked to triglycerides present in blood (Zuurman et al., 2009).

There have been reports of cannabis-caused arrhythmia and recently (Pratap and Korniyenko, 2012) a case of ST-segment elevation on the ECG. Several cardiac biomarkers can respond to the presence of cannabis.

Stimulation of the central nervous system produces the euphoria of amphetamine by the blockade of catecholamine reuptake and hyperstimulation of the postsynaptic neuron receptors. In addition, various noncatecholaminergic nervous pathways are stimulated.

Cardiovascular collapse, ventricular tachyarrhythmia, as well as MI, heart failure, prolongation of QT_c, and other ECG abnormalities are common (Watts and McCollester, 2006; Haning and Goebert, 2007).

Environmental Chemicals

In many parts of the world, arsenic enters the food chain through contaminated groundwater. Arsenic causes oxidative stress by reducing the activation of eNOS and it increases the phosphorylation of myosin light-chain kinase (Singh et al., 2011). Serious side effects of arsenic include the cardiovascular system, causing altered myocardial depolarization, prolonged QT_c interval, and ST-segment changes (Quatrehomme et al., 1992; Cullen et al., 1995). Long-term exposure to arsenic also damages the vascular system, causing "black foot disease," endemic in Taiwan. Raynaud's phenomenon, a peripheral vascular disease of spasm of the digital arteries and constriction of blood vessels, besides significant increase in systolic BP, is seen after long-term exposure to arsenic (States et al., 2009; Druwe et al., 2012).

The cardiac abnormalities caused by lead are primarily hypertension and heart rate variability (Navas-Acien et al., 2007). In addition to high blood lead content (Glenn et al., 2003; Kakkar and Jaffery, 2005), there is some evidence of possible autonomic dysfunction.

Weaponized Chemicals

Cyanide shuts down the aerobic pathway by inhibiting cytochrome oxidase activity, at the mitochondrial level. Cells cannot maintain themselves on anaerobic respiration. Lactic acid buildup deprives cells of the energy source needed for the sustenance of life. In addition, the CN molecule's affinity for hemoglobin reduces the available oxygen supply (Wexler et al., 1947; Muncy et al., 2012).

Organophosphates are used as pesticides and chemical warfare agents which cause serious cardiac dysfunction. Among these, QT_c interval prolongation, and changes in QRS and right bundle band block are especially important (Vijayakumar et al., 2011). Acetylcholinesterase inhibition and delayed neuropathy play prominent roles. The hyperstimulation of receptors and the intermediate syndrome characterized by proximal muscle weakness is also present. Considerable information is contained in the work of Bar-Meir et al. (2007), Gul et al. (2012), and Liu et al. (2012).

FUTURE TRENDS IN CARDIOVASCULAR BIOMARKERS

In view of the limitations of individually used cardiac biomarkers and the need to determine the source and location of the cardiac problem on presentation, the search for biomarkers with higher sensitivity and specificity

continues. Along these lines, multimarker approaches, whereby several markers are tested, have gained more promise (Sabatine et al., 2002; McCann et al., 2009). Gerszten et al. (2011) reported that troponin, C-reactive protein (CRP), and myeloperoxidase (MPO), as well as soluble CD40 ligands, were successful in predicting a cardiovascular event half a year in advance. It was noted that, individually, the markers did not yield the same prediction.

Current biomarkers reveal essentially similar pathways, thus proteomics offers an approach that may yield at present novel indicators of cardiac injury. Blood contains a number of high abundance proteins; for example, albumin contributes over 50% of the total protein mass, and 99% of the plasma protein mass is taken up by only 22 proteins, including albumin and immunoglobulin. An estimated one million different proteins exist in the blood but they range in concentration up to 11 orders of magnitude, from micro- to femtomoles per liter. Troponins are in the nanomolar range, whereas TNF is in the femtomolar range. Following myocardial injury, the leakage of proteins into the blood and subsequent posttranslational modifications open up a new avenue for biomarker identification.

A number of proteins associated with cardiovascular pathology appear to be viable biomarkers and are under close scrutiny for possible clinical use.

MicroRNAs as Cardiac Biomarkers

Currently used cardiac biomarkers in body fluids are derived from specific proteins. Their use incurs drawbacks of nonspecificity, lack of abundance, posttranslational modification, and lack of timely availability. Blood-based biomarkers are also based on antibodies, but these exhibit cross-reactivity with other proteins.

The recent realization that tissues can secrete miRNAs (microribonucleic acids), which exert an effect on other cells and tissues and play prominent roles in vascular and metabolic diseases, is now being explored for detection of cellular injury and in essence disease detection. Noncoding endogenously expressed microRNA is a short ribonucleic acid (RNA) molecule of eukaryotic cells. They posttranscriptionally regulate gene expression of their target mRNA (messenger RNA). The human genome encodes over a 1000 miRNAs, and miRNAs' expression is organ-specific, including the vasculature, with reaction to cardiac injury similar to that with cardiac enzymes. They have specific functions and regulatory roles in cellular processes (Tijsen et al., 2012). MiRNAs are endogenous, noncoding RNAs that regulate messenger RNA (mRNA) or protein levels validating their use as biomarkers (Fichtlscherer et al., 2011; Tijsen et al., 2012; van Rooij, 2012), miRNAs are endogenous, noncoding RNAs that regulate messenger RNA (mRNA) or protein levels by promoting mRNA degradation or by attenuating protein translation. Some miRNAs are located in body fluids, but most are found within cells. Distinct expression profiles are found among the different fluid types. In addition, because of the presence of ribonucleases that catalyze the degradation of RNA, miRNAs are enclosed in vesicles to protect them from RNA digestion; thus, their stability is assured. miRNAs are negative regulators of gene expression. The number of miRNA genes has been estimated to be over 1000 in the human genome, and each miRNA regulates a large number of target genes.

To protect them from degradation, miRNAs are included in lipoprotein complexes called microvesicles. Vesicles, also referred to as microparticles, are formed in successive steps that initiate ectosome formation during cell activation (Burnier et al., 2009). Particles also constitute a transcellular delivery system for biological information and intercellular communication (Hunter et al., 2008). By altering the expression of genes in the vicinity (Burnier et al., 2009; Mause and Weber, 2010) and at remote sites by transferring genetic information, this can result in the reprogramming of the phenotype of the target cell. These are actively secreted from cells in vesicles and exosomes, but the amount of RNA recovered from plasma is low.

Circulating miRNAs in body fluids are stable, their sequences are evolutionarily conserved and they are tissue-, cell-, and pathology-specific. Their presence in the fluid is detected by real-time PCR arrays but because of the low level of total RNA in the blood, it is difficult to measure their concentration. Next-generation sequencing (Creemers et al., 2012) has shown that there are over 100 different miRNAs in serum.

In addition to tissue specificity and sensitivity, presence of miRNA in cardiac injury correlates with troponin level. Change in miRNA, specific to a time, can be correlated with cardiac injury. miRNA leaks out of injured or apoptotic cells and those that lost their nucleic acid content. The serum level of miRNA increases up to a 1000-fold after MI and mirrors troponin I (Corsten et al., 2010).

For all practical purposes, and as their validation proceeds, miRNAs will be accepted as cardiac biomarkers with distinctive advantages over conventional ones. See Table 12.3, also (Sahu, 2014).

There are several microRNAs whose increase in plasma are specific and indicate different aspects of cardiac injury. MicroRNAs are named using the prefix miR and a number that reflects the order in which the gene was discovered. Sometimes the form used is hsa-mir-number, the first letters signifying the organism. Latter suffixes denote related sequences. For example, in an isoproterenol-induced myocardial injury, miR-208 increased significantly in rats (Ji et al., 2009). Because the miRNA signature is cell-specific, it greatly aids in the diagnosis. In the case of MI, six miRNAs, miR-1,

Drug Cardiotoxicity	miR-146a	miR-146				Reduces ErbB4 expression,	Horie et al. (2010)
						Modulates immune response	

miR-133a, miR-133b, and miR-499-5p, increased, though by uneven amounts (D'Alessandra et al., 2010). Also, even though miR-208 is undetectable in healthy individuals, it significantly increases after MI (Wang et al., 2010). The observation that miR-1 and miR-133 regulate cardiac electrical properties, with the former triggering cardiac arrhythmias and both targeting the pacemaker current, has significant implications (Terentyev et al., 2009). There are indications that miR-1 may alter the calcium signaling, inducing arrhythmia.

Cardiac injury is reflected in changes of functioning and the constitution of the organ which in turn reflects the engaged miR and its concentration change. The indicated gene may be up- or downregulated. Changes in genetic involvement are markers of cardiac injury.

Cardiomyocyte hypertrophy is indicated by changes in miR-1 and miR-195. In fact, inhibition of endogenous miR-18b and miR-21 enhances hypertrophy (Tatsuguchi et al., 2007). Hypertrophic mouse hearts show an upregulation, a fourfold increase in miR-21 (Cheng et al., 2007). Inhibition of miR-21 exhibits an antigrowth effect. miR-133 also controls cardiac hypertrophy; in fact, overexpression of miR-133 is a key regulator of cardiac hypertrophy (Care et al., 2007), whereas overexpression of miR-195 is a sign of pathological growth (van Rooij et al., 2006).

Ion channels, and thus the electrical activity of the heart, are targets of miR-1 and miR-133 (Yang et al., 2007; Ono et al., 2011) that can deregulate the expression of cardiac ion channels and promote arrhythmogenesis (Terentyev et al., 2009). Overexpression of miR-208a disturbs cardiac conduction (Callis et al., 2009).

Chemotherapeutic drugs express cardiotoxicity even at moderate doses. Doxorubicin, an anthracycline, upregulates miR-146a, and ErbB2 and ErbB4, expressed in cardiomyocytes, when inhibited, causes CHF (Horie et al., 2010).

In vascular scenarios, specific miRNAs regulate gene expression on the posttranscriptional level by inhibiting the translation of protein from mRNA or the degradation of mRNA. The integrity of the endothelial monolayer is signaled by the state of the mRNAs. These have distinctive expression profiles that play crucial roles in cardiogenesis and regulate endothelial cell function. miRNA-21 is aberrantly overexpressed in vascular injury (Ji et al., 2007). Proangiogenic miRNAs are miR-37b and miR-130a, whereas miR-221 and miR-222 oppose cell proliferation and angiogenesis. Overexpression reduces endothelial NO, the key regulator for endothelial cell growth and vascular remodeling. Impaired bioavailability is a marker of atherosclerosis and ischemic cardiomyopathy. Vascular inflammation and diseases are also signaled by miR-155, miR-21, and miR-126 (Urbich et al., 2008).

Dysregulation of multiple genes occurs in myocardial infarction (Salic and De Windt, 2012). In particular, miR-21 is dysregulated in infarcted areas, whereas upregulated elsewhere. Considerably elevated levels of miR-1 and miR-133 are present in the circulation and appear significantly sooner than troponin. The level of miR-1 correlates with QRS widening on the ECG. The most upregulated miRs in MI were miR-208b and miR-499, with both favorably correlating with troponin (TnT) levels (Corsten et al., 2010). Regulation of ischemic/reperfusion cardiac injury and dysfunction via antithetical regulation of Hsp20 (heat-shock protein) is associated with miR-320, and miR-1 and miR-133 produce opposing effects on apoptosis (Ren et al., 2009).

Cardiac fibrosis is facilitated by the connective tissue growth factor (CTGF) that is characterized by miR-133 and miR-30 (Duisters et al., 2009). Active fibrotic processes play a part in diastolic heart failure (DHF), and increased myocardial fibrosis is part of hypertensive heart disease (HHD). CTGF is a secreted protein that induces ECM (extracellular matrix) synthesis. A fibrotic ECM impairs cardiomyocyte function. It plays an important role in HHD. Next-generation sequencing technologies (Creemers et al., 2012), not biased by the currently used PCR and microarray platforms, reveal that mature miRNAs have an extensive degree of variation at the terminal nucleotides that may influence miRNA target specificity. These isomiRs may also be pathology-specific. If this turns out to be so, a new set of biomarkers would be available. Sequence variants (Humphreys et al., 2012) of miRNAs and their effect on cellular processes and subsequently on pathologies (Dorn, 2012) would be significant (see Table 12.4).

RISK PREDICTION OF CARDIOVASCULAR EVENTS

The utility of biomarkers for identifying sources and causes of cardiac dysfunction is well established. Risk prediction, affecting decisions on treatment, using the information derived from biomarkers, has also advanced. Multimarker risk scores (Wang et al., 2012) based on the Framingham Heart Study and the work of Arts et al. (2015) compared the predictive ability of four established cardiovascular risk models. The established multimarker score based on the chosen biomarkers uses the multivariable Cox regression model and the Kaplan—Meier method. The C statistic was used in the classification of risks. These, based on the receiver operating characteristic curve, moderate discriminations between patients with and without cardiovascular events diagnosed with early rheumatoid arthritis.

Biomarkers of endothelial activation correlate with chemokines but less frequently with inflammation. Combining circulating biomarkers from different pathways yields improved discrimination for end points.

TABLE 12.4 Potential Cardiac Biomarkers Up- or Downregulated Cardiac miRNAs

miR-1	Ionic channels affected, arrhythmia, hypertrophy, MI
miR-15	Hypertrophy
miR-21	Increased after vessel injury
miR-23	Hypertrophy
miR-24	Myocardial infarct size, activated in endothelial cells After MI
miR-29	Ischemia reperfusion injury
miR-126	Vascular integrity
miR-133	Affects ionic conduction, targets connective tissue growth factor
miR-145	Downregulated in carotid artery after mechanical injury
miR-155	Increased in heart failure
miR-195	Hypertrophy
mir-206	Markedly increased in MI
miR-208	Overexpression causes hypertrophy, arrhythmia
miR-214	Ischemic injury
miR-221	Blocks neointima formation after vessel injury, regulates angiogenesis
miR-320	Targets heat-shock protein ischemia
miR-499	Stress-induced dysfunction

Imaging biomarkers, especially coronary calcium scores, improve risk discrimination, although more data are needed before it can be included. Genetic biomarkers are also considered to be potentially of less importance.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Advancement of the field of cardiac biomarkers has been substantial. Development of high-sensitivity assays now allow diagnoses to be made earlier than before on samples containing lower concentration of the suspected marker. In addition to the standard markers, now over 20 items have been assessed.

The uses of miRNAs, endogenous noncoding RNA molecules that play a regulating role in gene expression, affecting an estimated one-third of the genome, have also gained prominence. Their involvement results in the impairment of protein synthesis from target RNAs that affect a number of important biological processes, including metabolism and proliferation. Measured up-/downregulation of circulating miRNAs can now be used as a biomarker of diagnosis, prognosis, and treatment.

Biomarkers assessment has gained from the recognition of the importance of the consideration of epigenetic modifications of the source of the sample. Also, using insights from metabolomics and proteomics effect on the sample is helpful. Mitochondrial dysfunction assessment has also yielded useable biomarkers. Dysfunction assessment thus is more specific and timely than it was before.

Cardiac biomarker's promises are exceeding expectations.

Respiratory Toxicity Biomarkers

Samantha J. Snow, Urmila P. Kodavanti

Environmental Public Health Division, National Health and Environmental Effects Research Laboratory, Office of Research and Development, United States Environmental Protection Agency, Durham, North Carolina, United States

INTRODUCTION

The respiration function of gas exchange is accomplished by lungs in land mammals. The respiratory system is composed of upper airways (nose and larynx), lower airways (bronchi and bronchioles), and the alveolar region (parenchyma). The structure of the respiratory system is complex and adapted to the atmospheric conditions that surround the organism. For example, because of the potential of lung exposure to large particles during burrowing in rodents, the upper airways form complex structures that enable removal and detoxification of the components inhaled, whereas, in man, the structure of the nasal airway is less complex. These habitat-related morphological adaptations are also reflected in the manner in which rats and humans breathe: rats are obligate nose breathers, whereas humans are oropharyngeal breathers. Relative to other organ systems in the body, the lung is unique in that airway and alveolar epithelial lining is directly in contact with the external atmosphere. The air—liquid interface within the alveolar region enables gas exchange to occur between the lung and vascular system for sustaining vitality. A thin layer of surfactant lining the alveolar epithelium reduces the surface tension of this air—liquid interface, thus protecting the lung from collapsing.

Because of the direct exposure of respiratory epithelium to the external air, any respirable toxic components that contaminate air can be inhaled and injure the respiratory tract. In most instances, the lung will be exposed to these materials as complex mixtures after these components are released in the air and photochemically aged. Lung injuries can also be inflicted by circulating factors, such as drugs, hormones, and other distally originating reactive substances within the body. Moreover, low atmospheric pressure, especially at high altitude, can cause lung edema acutely.

Depending on the physicochemical nature of these inhalants, the injury to the respiratory system can vary in location and lung cell type. Acute lung injury is often reversible but can also lead to longer and even permanent damage. In certain cases, some inhaled particles remain in the lung over the lifetime producing first acute inflammation, followed by a short-lived recovery, and later development of chronic lung disease, such as chronic obstructive pulmonary disease (COPD), fibrosis, or cancer. Lung injuries, thus, vary with the type and the degree of insult.

In context to the respiratory system, we can define biomarkers measured in biological samples obtained in a minimally or more invasive manner as the indicators that can reflect the nature of injury to the respiratory system. These may represent constituents released from damaged respiratory cells within the nasal passages or lung for which the degree of change will relate to the extent of injury. There is a unique opportunity available to diagnose nasal and lung injuries and diseases using a lavage technique. The ability to perform bronchoalveolar lavage (BAL) or nasal lavage (NAL) negates the need for more invasive techniques such as biopsies for disease diagnosis. This is in addition to determining biomarkers of lung toxicity in the exhaled breath, sputum, circulation, and urine samples. In this chapter, we will first provide a brief overview of the structure of the respiratory system and the types of pulmonary injuries (because the choice of biomarker selection is based on this) and then elaborate on biomarkers of lung injury. Descriptions of biomarkers determined in BAL fluid (BALF), exhaled breath, sputum, and NAL fluid (NALF); blood, serum, and plasma; and urine will be provided, with special emphasis on the use of emerging new technologies for biomarker identification. Although sputum specimens are routinely used for diagnosis in humans, they are not readily available when working

with laboratory animal models. Because the biomarkers measured in sputum are also measured in BALF and NALF, we will describe the biomarkers for all of these components together in the later discussion. Although BAL has generally been used as a terminal procedure in laboratory animals, it is often used in humans as a minimally invasive technique where a specific lung lobe is lavaged for biomarker assessment or disease diagnosis. We will include this approach for biomarker analysis because BAL can be performed repeatedly as a survival procedure on small laboratory rodents, as well as on large animals. The fluid recovered by BAL provides a unique opportunity to examine very specific biomarkers of lung toxicity. We will also briefly cover the sampling methodologies, especially for exhaled breath and BAL.

With the emergence of new biotechnologies in recent years, the field of biomarkers has seen revolutionary growth. Because high-throughput technologies enable global measures of hundreds to thousands of biomarkers in a single sample, the pattern of change in multiple functionally related biomarkers is given more emphasis than a single molecule–based assessment. This is also true for respiratory disease–specific biomarkers. We are on a steep slope of learning regarding biomarkers and their specificity. Because multiple disease processes share some common mechanisms, such as inflammation and increased oxidation, the biomarkers pertaining to these processes are similar for many illnesses or injuries, and thus, markers of these processes will not be specific to a given disease. We will also try to cover the newly emerging biomarkers with special emphasis to respiratory injuries and diseases.

THE RESPIRATORY SYSTEM

The respiratory system has evolved to absorb molecular oxygen from the air in exchange for carbon dioxide, providing energy for all cells within the organism. There are two major compartments of the respiratory system that will be important to consider with regard to biomarkers of toxicity: the airway passages used to transport air and the alveoli where gas exchange occurs.

The airway passages begin with the nose, followed by the trachea, which divides into two main bronchi, and then several small bronchioles within each lung. Different types of epithelial cells involved in various functions line the airway. The predominant cell type of the airway surface is the pseudostratified columnar ciliated cells, which function to remove particles encountered on the mucus layer from inhaled air and protect the lung from injury. Dome-shaped club cells found in small airways possess drug-metabolizing enzymes and also function as stem cells to replenish lost ciliated epithelial cells. Goblet cells produce and secrete mucus at the apical surface of airway epithelium. The mucus layer helps remove particulates and pathogens via mucociliary clearance, modulates innate immune response, and detoxifies reactive inhaled substances. The thickness of the mucus layer is anatomically related to the diameter of the airway and the number of goblet cells contributing to secretion (Voynow and Rubin, 2009; Widdicombe, 2002). The basement membrane supports airway epithelial cells, and the smooth muscle layer surrounds the interstitial space around the basement membrane. Dendritic cells project between airway epithelial cells and function as antigen-presenting cells that, on encountering antigen (particulate, microbial, or soluble), interact with T lymphocytes and direct antibody production by plasma cells to orchestrate humoral immune responses (Cook and Bottomly, 2007). The airway epithelium is innervated by sensory vagal C-fibers. When stimulated, C-fibers evoke classical reflex reaction leading to bronchoconstriction and cough that, in turn, stimulates parasympathetic tone causing bradycardia and hypotension (Pisi et al., 2009).

The bronchioles terminate into small alveolar sacs that are lined with type 1 and type 2 alveolar epithelial cells. In humans and primates, terminal bronchioles, in addition to alveolar sacs, perform the air exchange function. Type 1 epithelial cells cover most of the surface area of the alveoli. Type 2 cells function to synthesize and secrete surfactant material, in the form of lamellar bodies, as well as other proteins. Type 1 cells are in close proximity to the capillary walls, enabling diffusion of carbon dioxide from blood to air and oxygen from air to blood (Galambos and Demello, 2008; Herzog et al., 2008). Interstitial tissue supporting these structures comprises an extracellular matrix, including collagen, elastin, and myofibroblasts. The connective tissue network interlinks alveoli, and the entire unit is encapsulated by the pleural mesothelial layer, which provides anatomical structure to the lung. Injury to alveolar units can be detected using BAL and analysis of the recovered fluid for a number of biomarkers.

Alveolar type 2 epithelial cells function to secrete surfactant material that is made up of approximately 80% phospholipids, 20% neutral lipids, and proteins. The surfactant material is layered thinly over the entire alveolar surface, providing stability to the alveoli, preventing collapse, and preserving patency. It also functions as an important host-defense mechanism. Among the four surfactant proteins (SPs), SP-A and SP-D play roles in host defense, whereas hydrophobic SP-B and SP-C are involved in adsorption and spreading of the surfactant material along the alveolar lining (Enhorning, 2008; Griese, 1999). These proteins, when released in the circulation and detected in BALF, serve as important biomarkers of lung injury.

Free macrophages within the alveoli function to protect the lung from inhaled pathogens, bacteria, and particles. Macrophages also engulf excess surfactant material and neutrophils that are recruited to the lung after an injury. In addition, macrophages perform important innate immune function by expressing cytokines that are involved in mounting an inflammatory response and programming the resolution of inflammation.

CAUSES OF LUNG INJURY AND DISEASE

The respiratory system encounters a variety of toxic substances during inhalation. The soluble and gas components of air pollution can injure the epithelial lining layer, the cells underneath, and the entire respiratory tract. The inhaled substances include reactive gases, volatile organic substances, infectious agents, metals, pesticides, nanomaterials, biological substances, tobacco smoke, asbestos, and other respirable particulate matter (PM) of environmental origin. Many of these substances are removed readily by the mucociliary escalator and cleared by alveolar macrophages, but, in the process, lung injury is inflicted. In addition, some inhaled particles and fibers are unable to be cleared because of damage of the clearance system, leading to persistent lung injury. Occupational exposures involving metal fumes, silica, and asbestos have been shown to contribute to lung injury and chronic pulmonary disease burden (Clapp et al., 2008; Cohen et al., 2008). Lung injury can also be induced by decreased ambient pressure at high altitude. Sepsis-related lung injury is also common. Pulmonary exposures to circulating drugs have often been associated with lung toxicity. Examples include monocrotaline-induced pulmonary hypertension, bleomycin-induced pulmonary fibrosis, and pulmonary phospholipidosis induced by cationic amphiphilic drugs (Kodavanti and Mehendale, 1990). In addition, lung edema can occur following left heart failure (Gehlbach and Geppert, 2004). Clinical use of ventilators in infants is also associated with lung damage early in life, which affects normal lung growth and vulnerability to adult lung diseases.

Among environmental exposures, agricultural and industrial dusts, emissions from refineries, and vehicular emissions are the major causal factors of lung injury. These exposures generally occur as complex mixtures of organic and inorganic species, gases, and soluble and insoluble PM. Because each chemical and physical entity is likely to have unique lung site–specific impact, the causes of lung injury and subsequent diseases are complex and involve multiple pathologies. COPD caused by cigarette smoke is a prime example of such complexity. COPD is characterized by airway mucus hypersecretion, airway and alveolar inflammation, emphysema, and, often, overlapping asthma. Assessment of multiple biomarkers can provide more precise diagnosis in such complex diseases.

TYPES OF LUNG INJURIES AND PATHOLOGIES

Acute Lung Injuries

Acute lung injury can occur soon after exposure to noxious substances. Depending on the chemical nature and the concentration of inhalant, the injury can occur to the upper or lower respiratory tract or both. For example, exposure of rodents to high levels of sulfur dioxide produces airway inflammation and mucus hypersecretion but very little alveolar damage, as characterized by morphological analysis and determination of BALF markers (Kodavanti et al., 2006). In the case of upper airway injury, goblet cells within submucosal glands and epithelium are stimulated to produce more mucus to protect the epithelium and accelerate removal of noxious substances. The dynamic process of mucus secretion involves activation of epidermal growth factor receptor and IL-12 through FoxA2, TTF-1, SPDEF, and GABAAR signaling. These factors transcriptionally regulate MARCKS, SNAREs, and MUC proteins (Voynow and Rubin, 2009). The upper airway inflammation and mucus hypersecretion, if sustained, can lead to chronic bronchitis. In a chronic lung injury, these changes promote airway fibrosis, which leads to development of airway resistance and decreased ventilation.

Damage to the alveolar region is characterized by pulmonary edema, activation of alveolar macrophages, secretion of cytokines and immune mediators, and extravasation of inflammatory cells into the interstitial and alveolar lung compartments. The alveolar lining layer of surfactant is also altered after inhalation of respirable particles, gases, or other substances. The type of cell infiltration depends on the nature of initial damage and the animal species. For example, exposure of rats to ozone will lead to neutrophilic inflammation, whereas sensitizing substances, such as ovalbumin, will cause eosinophils to extravasate along with neutrophils (Bauer et al., 2010; Schneider et al., 2012). This inflammatory response is produced by cytokines and chemokines from epithelium and alveolar macrophages. Often, acute lung injury, depending on the degree of lung damage, type of insult, and duration, can lead to fibrosis and chronic inflammation.

During lung injury, mediators can be released basolaterally and into the circulation. SPs also have the potential to get released into the blood stream, serving as specific circulating biomarkers of alveolar damage. The mediators released apically from the damaged lung cells and infiltrating inflammatory cells can be

isolated by the BAL process. The resulting BALF can be analyzed for both the injury-causing substance and biomarkers of injury/inflammation. Furthermore, pulmonary injury can trigger a neurohumoral response, resulting in release of sympathetic modulators in the circulation (Kodavanti, 2016).

Acute respiratory distress syndrome (ARDS) in children is associated with a deficiency in surfactant during early lung growth (Turell, 2008). Along with injury to the lung cells, the surfactant can also be modified chemically when encountering mechanical stress, noxious endogenous or inhaled substances, or due to abnormalities in surfactant synthesis and secretion. Under disease conditions, the hydrolysis of phosphatidylcholine by phospholipases is thought to chemically modify the surfactant, reducing its ability to maintain airway patency (Ackerman et al., 2003). As SPs are involved in lung injuries and diseases, their ability to translocate into the circulation and be detected in serum serves as a biomarker specific to lung cell injuries.

Asthma

Asthma is characterized by chronic lung inflammation and airway hyperresponsiveness (Mauad and Dolhnikoff, 2008). Multiple environmental, host genetic, and physiological factors have been linked to different degrees of pathological features of this spectrum disorder (Bloemen et al., 2007). T helper (Th) lymphocytes are involved in inflammatory processes. Inhaled particulates, cellular components of Gram-negative bacteria, and proteoglycans can activate pattern-recognition receptors, stimulate dendritic cells, and increase Th2 polarization (Hamid and Tulic, 2009). Once sensitized, the airways react to subsequent exposure with exacerbated inflammation and bronchoconstriction in asthma. The differentiation of Th cells to a Th2 phenotype is critical in the development of allergenicity and airway hyperresponsiveness associated with asthma. Th2-mediated elaboration of cytokines IL-4, IL-5, IL-9, and IL-13 leads to recruitment and activation of mast cells, eosinophils, macrophages, endothelial cells, fibroblasts, and smooth muscle cells (Hamid and Tulic, 2009). Neutrophilic inflammation is also noted with involvement of $CD4^+$ T lymphocytes and regulatory T cells. Collectively, Th2 cytokines serve as specific biomarkers of asthma (Fahy, 2009).

Bronchitis, Emphysema, and Chronic Obstructive Pulmonary Disease

Bronchitis is characterized by increased mucus production and inflammation in airways. When a mucus-produced cough lasts for more than 2 months

per year, it is termed as chronic bronchitis. Emphysema is characterized by destruction of peripheral and central lung tissues, which generally occurs over a long period. Bronchitis and emphysema, when manifested together, are presented clinically by the obstruction of airways collectively known as COPD. Exposure to cigarette smoke and smoke from biomass burning in developing countries has been linked to the development of COPD (Prasad et al., 2012; Tuder and Petrache, 2012). Both airway and parenchymal injuries are inflicted by numerous toxic components found in cigarette and biomass smoke. The degree of damage to each lung compartment varies between individuals based on their genetic background. The disease is characterized by increased productive cough, resulting from chronic mucus hypersecretion, chronic inflammation (primarily neutrophilic), and destruction of alveolar walls, leading to decrement in lung function over time. A predominance of $CD8^+$ T lymphocytes and increased neutrophils, as well as macrophages, in COPD patients has been demonstrated (Barnes et al., 2006). $CD8^+$ T cells are thought to secrete interferon-γ and interferon-inducible protein 10, which are considered dominant features of the Th1 phenotype (Barnes et al., 2006). The macrophages in smokers are impaired functionally and exhibit greater elastolytic activity (Minematsu et al., 2011). Greater elastolytic activity of alveolar milieu, due to an imbalance between proteases/antiproteases and apoptosis, plays an important role in alveolar destruction. Because of the complex pathologies associated with COPD, therapeutic approaches have achieved limited success. Often, COPD patients express airway hyperresponsiveness associated with asthma. The involvement of both Th1 and Th2 phenotypes and the coexistence of these features are not well understood. Numerous biomarkers have been analyzed in BALF, sputum, and exhaled breath to determine disease characteristics.

Pulmonary Fibrosis and Granuloma

Pulmonary fibrosis is characterized by the presence of inflammation, increased fibroblast proliferation, and collagen synthesis. A number of occupational and environmental exposures to ambient PM, metals such as vanadium, reactive gases, asbestos, and silica, as well as drug treatments, can injure the lung and lead to fibrosis and/or granuloma (Khalil et al., 2007; Warheit et al., 2001). In susceptible individuals, granuloma formation occurs around the accumulated foreign materials that are not cleared by the mucociliary system and macrophages (Warheit et al., 2001). Occasionally, idiopathic lung fibrosis also occurs in susceptible individuals. Bleomycin, an antineoplastic drug, is known to induce

pulmonary fibrosis in rodents and is associated with abnormal or aberrant tissue repair resulting from increased expression of growth factors and collagens (Chaudhary et al., 2007). HIF-1α and VEGF activation via PI3 kinase have been shown to contribute to collagen- and fibroproliferative effects of bleomycin (Chaudhary et al., 2007). A number of cytokines and the associated inflammatory responses have been involved in the pathogenesis of lung fibrosis. The evaluation of mediators, cytokines, and growth factors in BALF and plasma, along with lung function outcomes, can help with disease diagnosis.

Pulmonary Hypertension

Pulmonary hypertension, a complex and multifaceted disease, is characterized by an increase in the vascular pressure within the lung causing shortness of breath, fainting, and, in more severe cases, heart failure. Pulmonary hypertension can originate from either artery or vein. Hypoxia or thromboembolism can also result in pulmonary hypertension. In some cases, no specific etiologies can be identified. Before 2003, pulmonary hypertension was classified into two broad categories, primary and secondary, but has since been reclassified into five categories based on an increased understanding of the pathobiologic mechanisms (Nef et al., 2010): (1) pulmonary arterial hypertension, which can be idiopathic, familial, or caused by other diseases; (2) pulmonary hypertension associated with left heart disease; (3) hypertension associated with lung diseases such as COPD, interstitial lung disease, reduced alveolar ventilation, high altitude, and, in some cases, developmental abnormalities; (4) pulmonary arterial thromboembolism; and (5) other miscellaneous causes. Despite the causes being very different, there are some pathobiologic commonalities in pulmonary hypertension, such as vasoconstriction resulting from endothelial dysfunction and increased cell proliferation with decreased apoptosis in pulmonary microvasculature (Wilkins, 2012).

Pulmonary Phospholipidosis

Pulmonary phospholipidosis is characterized by accumulation of surfactant phospholipids in alveolar space and in macrophages. Long-term treatment with cationic amphiphilic drugs, such as amiodarone and chlorphentermine, and classes of other antiarrhythmic and antipsychotic drugs have been associated with pulmonary phospholipidosis (Kodavanti and Mehendale, 1990). These drugs selectively accumulate in the lung where they inhibit phospholipases leading to accumulation of surfactant phospholipids (Kodavanti

and Mehendale, 1990). Exposure to silica has also been associated with pulmonary phospholipidosis (Kawada et al., 1989). Amiodarone, an antiarrhythmic drug, also induces pulmonary phospholipidosis while causing lung cell injury and fibrosis in patients (Bedrossian et al., 1997). A recent study shows that rats maintained on a fish oil–rich diet have increased accumulation of lipid-laden macrophages in the lung (Snow et al., 2018). BALF lipids and foamy macrophages could serve as biomarkers of pulmonary phospholipidosis.

SAMPLING METHODS FOR ANALYSIS OF BIOMARKERS OF LUNG TOXICITY

The sampling for lung toxicity biomarkers can involve noninvasive collection of exhaled breath, sputum, urine, and blood and invasive collection of BALF (Fig. 13.1). BAL is used extensively in humans for determination of toxicity and lung disease, as well as in clinical studies. In animal toxicology, BAL is generally performed as a terminal procedure; however, repeated BAL has also been used as a survival procedure (Novak et al., 2006). Because fluid recovered from BAL provides the most critical information of the lung injury, we will first discuss BAL and biomarker assessment in BALF.
FIGURE 13.1 Schematic of sampling sites for collecting biological materials for determination of lung injury biomarkers.

Bronchoalveolar Lavage

BAL is the unique technique that enables one to sample airway and alveolar lining fluid content to determine the state of lung health. This technique is invasive but provides highly accurate and specific diagnosis of the type of lung injury and causal factors, especially in cases where diagnosis is very difficult based on blood or urine analysis. In humans, segmental lavage is performed using bronchoscopy, whereas, in animals, one lung lobe or the entire lung is lavaged as a survival or nonsurvival technique (Fig. 13.2). The technique involves slow infusion of saline or calcium- and magnesium-free phosphate-buffered saline into the trachea of anesthetized animals or in a specific bronchus of humans. This fluid is then withdrawn slowly back into the syringe in a stepwise manner. Specific treatment and recovery protocols are followed for humans and rodents (Henderson, 2005; Hoffman, 2008; Reynolds, 2011). In some cases, this protocol might not be safe for susceptible humans and is not recommended. In rodents, this procedure can be repeated several times, but several days of recovery are needed prior to performing the technique again.

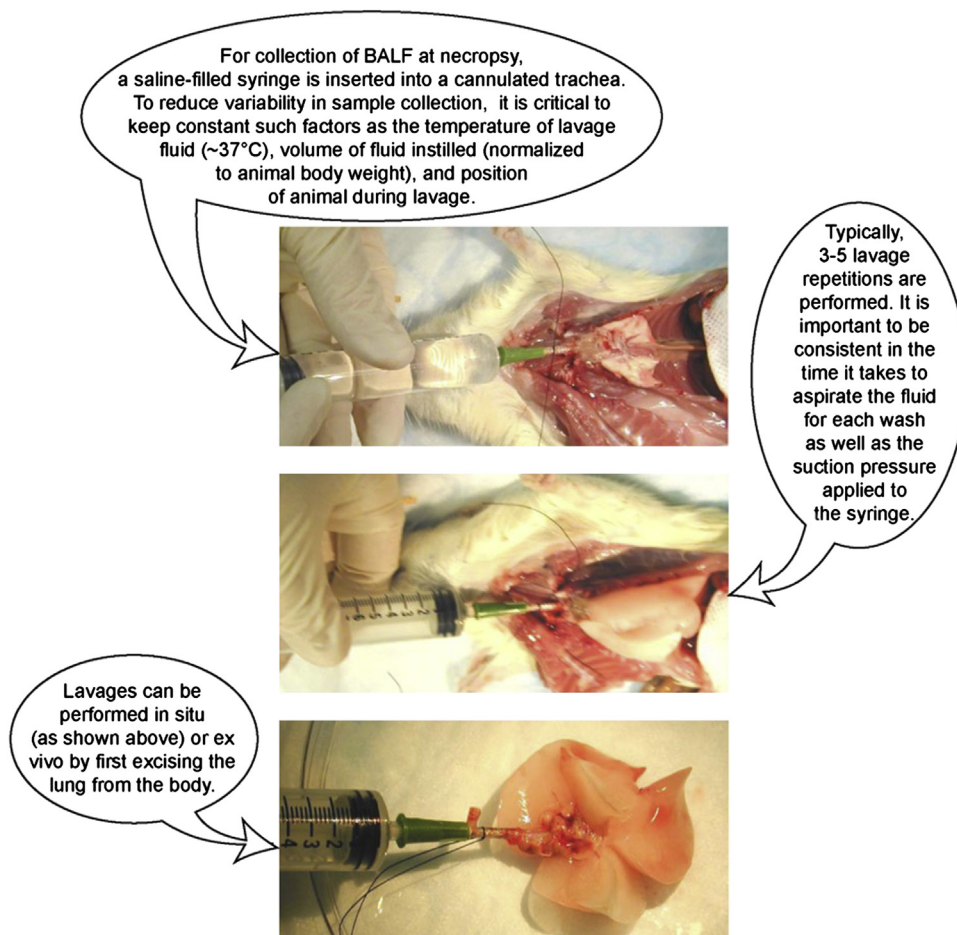
The volume of BALF collected in rodents and humans is fairly consistent. Underlying injury can, however, affect the fluid recovery. The fluid recovered from BAL can be processed for analysis of cell content and a variety of biomarkers. The recovered fluid can be centrifuged to separate cells. In healthy animals and humans, these cells generally should contain 80%—95%, or even more, alveolar macrophages, whereas the remaining cells comprise neutrophils, lymphocytes, and eosinophils. There is a wide variation in the number of these nonmacrophage-type immune cells in humans and animals, depending on the animal species and strains. For example, the BALF of guinea pigs contains more eosinophils than that of rats (Kodavanti et al., 1995, 2000). The cell-free BALF can be assessed for a variety of cytokines, epithelial and endothelial injury markers, and markers of exposure, which can inform the type of injury and potential therapeutic intervention.


FIGURE 13.2   Photographs of bronchoalveolar lavage fluid (BALF) collection in a rodent model performed during necropsy.

Sampling Sputum, Nasal Lavage, and Exhaled Breath

The protocol for inducing and collecting sputum is employed for humans to sample upper airways. The nebulized hypertonic saline is administered in the nostrils at increasing volume after inducing bronchodilation with inhaled albuterol (Vatrella et al., 2007). The patient is encouraged to expectorate sputum through voluntary coughing. The specimen is collected in a sterile beaker and processed. The sputum can also be generated spontaneously and thus collected; however, the consistency of biomarkers in this material is often a limiting factor. The thicker mucous material can be separated from saliva in the specimen and analyzed for cellular markers (Aitken et al., 2003). Generally, the volume of sputum will be sufficient from patients having COPD and chronic bronchitis, but it is often limited in healthy individuals. The analysis of antioxidants, cytokines, and inflammatory cells can often provide mechanistic insights into the underlying disease.

NAL can be performed in rodents to simulate the procedure of induced sputum in humans. Using a similar concept to BALF collection, this terminal procedure involves a slow infusion of saline via the nasopharyngeal passage through the nasal cavity to collect the NALF from the nostrils of the animal (Cho et al., 2012). Following collection, NALF is processed in an identical manner to BALF for analysis of cellular makeup and biomarkers of injury. This technique is typically used in cases where the pollutant is known to primarily affect the nasal passages and upper airways (Snow et al., 2017).

The collection of human exhaled breath is a simple noninvasive technique. However, the methodology for collection of exhaled breath and constituting condensate (EBC) remains inconsistent and is highly influenced by temperature change. The high degree of variability hampers its utility in identifying exposure- and pathology-related biomarkers (Rosias, 2012). Mainly, the issues with methodologies involve differences in the conditions of the subjects, condenser devices, and preservation/storage of the samples. Based on the interest in identifying biomarkers in exhaled breath, the American Thoracic Society and the European Respiratory Society organized a task force to develop guidelines on collection and analysis of biomarkers in exhaled breath (Ahmadzai et al., 2013; Grob et al., 2008). However, these methodologies still vary between laboratories (Carter et al., 2012; Popov, 2011; Rosias, 2012). Recently, more sophisticated devices and controlled exhalation techniques have provided fairly consistent sampling of exhaled breath for assessment of biomarkers (Pleil et al., 2017; Winters et al., 2017). Numerous biomarkers have been identified in EBC and linked to disease conditions.

Blood and Urine Sampling

Lung injury–specific biomarkers (i.e., inhaled substances and particles, SPs, and club cell secretory proteins) have been detected in the blood of humans and animals with pulmonary injury or diseases. In humans, blood and urine are collected routinely during their clinical visits. In animals, blood is generally drawn into the syringe directly from the abdominal aorta, vein, or by cardiac puncture at necropsy. Often, orbital, tail, or other surface bleeding techniques are employed for repeated sampling of blood for biomarker analysis in animals. For the collection of urine, special metabolic cages are used to collect samples in a noninvasive manner; however, urine also can be collected directly from the bladder during necropsy.

TYPES OF LUNG TOXICITY BIOMARKERS

One can classify biomarkers broadly into two categories: (1) biomarkers of exposure and (2) biomarkers of injury or disease. Exposure biomarkers are critical in epidemiology, clinical, and toxicological studies where the substance that is inhaled is subsequently detected in BALF, NALF, blood, EBC, sputum, or urine samples, thus providing conclusive evidence of causal factor (Fig. 13.1). On the other hand, toxicity biomarkers that involve disease-specific proteins, metabolites, or nucleic acids that are detected in the collection samples will need to be further assessed to gain knowledge about the dynamic nature of the injury or disease to develop therapeutic approaches. In this section, the biomarkers of inhalation exposure, lung toxicity, and diseases will be described.

Exposure Biomarkers

A variety of inhaled parent compounds or constituents, when detected in the blood, BALF, NALF, EBC, sputum, and urine, can provide evidence of the cause of lung injury. This is particularly important in regard to injuries and diseases caused by environmental and occupational exposures. Perhaps, the most commonly studied biomarkers of exposure are the plasma levels of cotinine (a metabolite of nicotine) and carboxyhemoglobin in smokers (Liu et al., 2011). Inhaled chemicals, metals, PM components (primarily nonessential metals such as arsenic, nickel, vanadium, and organic constituents of exhausts), benzo[a]pyrenes, and nanoparticles have all been detected in the circulation. These exposure biomarkers can provide evidence of the type and degree of exposure and, often, information about the temporality of lung changes. Exposure biomarkers can also yield information about the likely pathologies in the lung.

Translocation of nonessential metals, associated with inhalation exposure to industrial combustions, has been well studied in relation to air pollution. We have shown that nonessential metals, such as nickel and vanadium, are translocated rapidly from the lung after exposure of rats to a combustion source PM containing these metals (Wallenborn et al., 2007). Translocation of an essential metal, zinc, was confirmed by exposing rats to ^{70}Zn, a stable zinc isotope (Wallenborn et al., 2009). Metals have also been detected in EBC in individuals occupationally exposed to metal-containing dusts (Felix et al., 2013). There is evidence that some manufactured nanomaterials can be detected in the circulation on pulmonary exposure; however, often the concentration of nanomaterials has been very small (Choi et al., 2010), and, in case of exposure to carbon nanomaterials, the detection methodologies are still inadequate.

Translocation of reactive polycyclic aromatic hydrocarbons of diesel exhaust into the systemic circulation has been shown in a few studies. For example, a significant portion of diesel soot—associated benzo[a]pyrene adherent to carbon core, as would be expected for components of diesel exhaust, rapidly translocated systemically after pulmonary exposure in dogs (Gerde et al., 2001). However, the detection methods for organic constituents in biological tissue samples are often inadequate and lack sensitivity. Nevertheless, there are many opportunities for identification of exposure biomarkers, especially when exposures are expected to contain metals and nanomaterials.

Biochemical Biomarkers

Lung toxicity and disease biomarkers can be measured in the exhaled breath, sputum, BALF, NALF, serum, and urine (Fig. 13.1). Depending on the sample being analyzed, the type of biomarker examined could vary somewhat. However, many of the biomarkers in the sputum, BALF, NALF, and even blood samples are common. This section covers the description of biomarkers shown to be altered in lung toxicity and pathology (Table 13.1). It also provides evidence of their relation to lung injury and their pathophysiological roles. For example, in rats exposed to high levels of sulfur dioxide, the degree of BALF neutrophilic inflammation clearly reflected the severity of airway mucus secretion in a rat strain—dependent manner (Fig. 13.3) (Kodavanti et al., 2006). Thus, the biomarkers analyzed in BALF provide highly accurate information on the state of lung pathology.

This section does not include every known biomarker of lung toxicity and its biology, but rather the most commonly used biomarkers are described, with an emphasis on their functional correlation with lung toxicity and disease.

TABLE 13.1 Commonly Used Biomarkers for Determining Various Types of Lung Injuries

Possible Indication	Biomarker
Lung cell injury (biochemical)	Protein, albumin, lactate dehydrogenase, N-acetylglucosaminidase, γ-glutamyltransferase, lysozyme, alkaline phosphatase
Inflammation	Neutrophils, lymphocytes, eosinophils, macrophages, monocytes
	Cytokines, chemokines
	Lymphocyte cell surface markers (CD8$^+$, CD4$^+$)
Phagocytic activity (biochemical)	β-Glucuronidase, N-acetylglucosaminidase, α-mannosidase, arylsulfatase, acid hydrolase
Airway injury and mucus hypersecretion	KL-6, CC16, Muc5AC, Mucin1, CK-19, SLX
Alveolar epithelial and endothelial cell injury	RAGE, vWf-Ag, alkaline phosphatase
Oxidative stress	HO-1, TBA reactive substance, isoprostane, 4-hydroxynonenal, 8-hydroxy guanosine, H_2O_2
Oxidant/antioxidant imbalance	Ascorbate, glutathione, uric acid, albumin, ferritin, transferrin, lactoferrin, ECSOD, total antioxidant capacity
Coagulation and thrombosis	TF, PAI-1, protein C, thrombomodulin
Surfactant abnormality	Surfactant proteins
Alveolar destruction	Desmosine, elastin and collagen fragments, matrix metalloproteases, antiproteases

CC16, club cell protein 16; CK19, cytokeratin fragment 19; ECSOD, extracellular superoxide dismutase; HO-1, hemeoxygenase-1; KL-6, Krebs von den Lungen-6; Muc5AC, mucin5AC; PAI-1, plasminogen activator inhibitor-1; RAGE, receptor for advanced glycation endproduct; SLX, carbohydrate antigen Sialyl Lewis (x); TBA, thiobarbituric acid reactive substances; TF, tissue factor; vWf-Ag, Von Willebrand Factor antigen.

Biomarkers in Exhaled Breath Condensate

EBC is used widely to identify biomarkers of exposure, lung toxicity, and systemic diseases in humans. Different breathing maneuvers (i.e., cough, forced exhalation, slow exhalation) can be utilized during collection to increase the likelihood of obtaining samples from select airway regions (Larsson et al., 2017). This technique, however, is used less extensively in laboratory animals because of the difficulties with adequate sample collection and data interpretation. EBC contains nearly 3500 components that primarily are volatile organic components, nitrogen oxide, inflammatory molecules, oxidation by-products (hydrogen peroxide and isoprostanes, nitrates and nitrites, prostanoids, and leukotrienes), and cytokines (Popov, 2011). Cytokines, such as
FIGURE 13.3 Bronchoalveolar lavage fluid (BALF) neutrophils correlate with airway injury and mucus hypersecretion in Sprague Dawley (SD) and spontaneously hypertensive (SH) rats exposed to high levels of sulfur dioxide (SO_2). Rats were exposed to clean air or SO_2 for 5 h/day for four consecutive days, and the necropsies were performed either 1 or 4 days following the last exposure. The upper panel shows the number of neutrophils in the BALF. The lower panel shows representative histological staining of the lung sections for mucin and inflammation in SD and SH rats exposed to filtered air or SO_2. The extent of airway mucin secretion and inflammation was evaluated in rats at 4 days following the last SO_2 exposure. Serial lung tissue sections were stained with AB-PAS (mucin) and H&E, and representative airway changes are shown in the figure. (A–D) show AB-PAS–stained lung sections (A, SH-air; B, SH-SO_2; C, SD-air; and D, SD-SO_2) and (E–H) show H&E-stained serial lung section (E, SH-air; F, SH-SO_2; G, SD-air; and H, SD-SO_2) from air- or SO_2-exposed rats at 4 days following last exposure. *Asterisks* in (B) and (D) show purple mucus staining of airway epithelial cells. *Arrows* in (F) and (H) indicate inflammatory cells in airways. *Reproduced with permission from Kodavanti, U.P., Schladweiler, M.C., Ledbetter, A.D., et al., 2006. The spontaneously hypertensive rat: an experimental model of sulfur dioxide-induced airways disease. Toxicol. Sci. 94 (1), 193–205.*

TNF-α and IL-6, have been detected in breath condensate of rats after staphylococcal pneumonia (Heidemann et al., 2011). EBC biomarkers have been especially useful in occupational scenarios (Cherot-Kornobis et al., 2012).

The use of EBC for volatile organic biomarkers has provided insights into lung diseases (van de Kant et al., 2012). Exhaled nitrogen oxide measured using a handheld electrochemical detector in COPD patients

(Maniscalco et al., 2008) can also be used for other disease conditions to assess pulmonary inflammation. The levels of ferritin and superoxide dismutase, indicators of oxidative stress, are suggested as potential biomarkers of lung cancer (Carpagnano et al., 2012). Metabolomic approaches using NMR technologies have provided information on specific components of EBC in a number of pulmonary pathologies (de Laurentiis et al., 2008). Although significant advances have been made in the analysis of biomarkers in EBC, there still remain inconsistencies in sampling techniques (Ahmadzai et al., 2013; Grob et al., 2008). Recent recommendations for standardization of sampling, analysis, and reporting of data were created by a task force set up by the European Respiratory Society to address this issue (Horvath et al., 2017).

Biomarkers in Bronchoalveolar Lavage Fluid, Nasal Lavage Fluid, and Sputum

Many of the biomarkers assessed in BALF, NALF, and sputum are common, especially cytokines and inflammatory cells. However, the concentrations of other injury markers are likely to be different. Sputum and NALF content represent primarily the upper airway lining components, whereas BALF will contain both upper and deep lung components. Thus, the injury biomarkers in BALF give fairly accurate information about lower airway and deep lung injury. As discussed above, cells and the cell-free fluid recovered from BALF can provide information about exposure biomarkers because the lung lining fluid encounters all inhaled substances and pathogens. The BALF biomarkers described below can also be measured in sputum and NALF samples.

Total Protein and Albumin

In healthy individuals and animals, there is limited protein in the alveolar lining; however, injury to the airways and alveolar structures leads to leakage of vascular protein into the alveolar space. Increased synthesis of cellular protein can also leak proteins from epithelial cells into the apical side of the airways. BALF analysis of total protein provides the simplest and most accurate measure of acute lung injury and vascular leakage. Protein levels can be measured in BALF samples obtained from patients, human clinical studies, and research experiments with laboratory animals (Henderson, 2005; Hoffman, 2008). Because albumin is present at extremely low concentrations in the alveolar lining of healthy individuals and animals but can leak into the airspace on injury, the measure of albumin can provide evidence of the presence of blood proteins. Analyses of protein and albumin are made in numerous toxicological studies and in human clinical studies involving lung injuries and diseases. It should be noted that BALF albumin and proteins are the best indicators of acute lung injury, but, in some chronic lung diseases, their measurements might not reflect the degree and nature of lung pathology (Fig. 13.4). Standard colorimetric detection techniques are used to measure protein and albumin in cell-free BALF. A number of assays are available and widely used. In clinical situations, these assays are modified for automated analysis of multiple samples.

Activities of Lactate Dehydrogenase, γ-Glutamyltransferase, N-Acetylglucosaminidase, and Proteases/Antiproteinases

A number of enzymes can be released from injured airways and alveolar epithelial cells, which are readily detected in BALF, especially after acute lung injury. Their increases following chronic lung injuries or diseases will need to be examined with caution because not all chronic injuries are likely to be associated with active cell damage. When the activities of all these enzymes are measured, a more comprehensive assessment of lung cell injury can be made.

Lactate dehydrogenase (LDH) is a cytosolic enzyme released from cells on injury and is used widely for in vitro and in vivo toxicological studies to examine cytotoxicity (Schwartz, 1991). In many cases of lung injury, this enzyme is released into the airway lining and is detected in the BALF of animals and humans (Emad and Emad, 2008; Kodavanti et al., 2000). In occupational and acute injuries, this marker is useful; however, in chronic lung diseases, it might not be consistently increased in all types of pathologies. γ-Glutamyltransferase (GGT) is a membrane-bound enzyme involved in transfer of glutamyl moiety of glutathione (GSH) to other amino acids and dipeptides. Two isoforms of this enzyme are involved in various cellular functions. Lung epithelial cells, such as club cells and type II epithelial cells, express this enzyme that is released in the lining fluid on lung cell injury (Jean et al., 2003). Increased enzyme activity in BALF is associated with experimental lung injury and has proven to be highly sensitive in detecting a small degree of lung cell injury (Bass et al., 2015; Padilla-Carlin et al., 2011); however, its use as a biomarker of lung injury and pathology in humans is limited. Similar to GGT, N-acetylglucosaminidase activity assessment in the BALF of animals following experimental lung injury has proven to be useful in detecting lung cell damage (Snow et al., 2014). This lysosomal enzyme is involved in the degradation of polysaccharides and glycoconjugates containing N-acetyl glucosamine residues. It has been shown to be released from alveolar macrophages during phagocytosis of foreign particles (Wereszczynska-Siemiatkowska et al., 2000). The mechanism of its release in lung lining fluid is not well understood, and its increases in BALF following experimental injury are likely to be dependent on the type of insult
FIGURE 13.4 Temporal correlation between lung pathology and the levels of bronchoalveolar lavage fluid (BALF) injury and inflammation markers in Fischer 344 rats following exposure to asbestos. Rats were exposed once intratracheally to saline, Libby amphibole (LA2000, 5 mg/rat), or amosite (0.5 mg/rat) asbestos fibers suspended in saline. (A) Lung section stained with H&E and trichrome staining for collagen demonstrating fibrosis at 12 months after single instillation of LA2000. Measurements for (B) total protein, (C) γ-Glutamyltransferase (GGT) activity, and (D) neutrophils in BALF were measured at 1, 3, 7, and 14 days and 3, 12, and 24 months after the single instillation of asbestos fibers. Note that asbestos induces acute lung inflammation and injury (pathology not shown) that resulted in long-term fibrosis. The BALF biomarkers showed neutrophilic inflammation and increases in lung injury markers that were more pronounced shortly after exposure, which returned to baseline over time. However, lung fibrosis persisted for at least 12 months (A).

on alveolar macrophages. Alkaline phosphatase, which is present in type 2 alveolar epithelial cells, can be released in the alveolar lining and serve as a biomarker of type 2 cell damage (Aiso et al., 2010). The validity of these enzymes in BALF as biomarkers of lung cell damage will need to be verified in chronic disease conditions. The activities of these enzymes in BALF accurately reflect lung cell injury status, especially at early time points.

A variety of proteases involved in degradation of extracellular matrix proteins are shown to be increased in BALF after lung injury. In chronic diseases such as emphysema and COPD, matrix protein degradation is increased, resulting in impairment of structural integrity and contractile function of the lung. Especially in cases of cigarette smoke—induced lung disease, increases in proteases can cause protease/antiproteinase imbalance (Nyunoya et al., 2011). BALF levels of proteases are also augmented in patients with pulmonary infection (El-Solh et al., 2009) and ARDS (O'Kane et al., 2009). However, because a given protease might be involved in many different diseases and injuries, the diagnostic

values for these biomarkers are limited (Vuorinen et al., 2007). Protease inhibitors are often induced as a compensatory mechanism. These proteins can be detected in BALF by antibody-based techniques. Determination of their proteolytic activity by special gel-based assays can provide insight into the signaling pathways and the type of pathology.

Oxidation By-Products and Antioxidants

Because the lung is exposed continuously to high levels of molecular oxygen, the potential for oxidation of structural macromolecules exists, especially in a disease condition where appropriate antioxidant homeostasis cannot be maintained. The lung lining fluid is enriched with a variety of chemical antioxidants (i.e., ascorbate, urate, and GSH) and proteins, such as extracellular superoxide dismutase and iron-binding proteins (i.e., lactoferrin, transferrin, and ferritin). When the balance between oxidants and antioxidants is shifted to increased oxidation, lung injury ensues.

A high concentration of ascorbate is present in the alveolar lining fluid of humans and has been shown to

be the first line of defense in acute lung injury (Behndig et al., 2009). Humans, primates, and guinea pigs lack the mechanism to synthesize ascorbate in the body and, thus, require dietary supplementation, whereas laboratory rodents (rats and mice) can produce ascorbic acid. Specialized transporters exist on cells to transport ascorbate at the apical surface of the airway lining (Wilson, 2005). Determination of the level of ascorbate in BALF reflects the antioxidant capacity in experimental lung injury. The depletion of BALF ascorbate is associated with vascular leakage and inflammation following experimental lung injury (Kari et al., 1997). The levels of ascorbate in experimental cigarette smoke exposure are decreased because of increased oxidative burden (Ghio et al., 2008); however, in human COPD, asthma, or other diseases, the use of ascorbate as biomarker of oxidative stress is not well established. Urate, another enzyme with known antioxidant function, can also be measured in BALF (Vyas et al., 2001). Reduced ascorbate and urate can be measured colorimetrically or by high-performance liquid chromatography in acidified and deproteinized BALF (Molina-Diaz et al., 1998). However, accurate quantification of reduced ascorbate in biological samples poses a significant challenge because of its labile nature and the presence of chemical molecules that interact with ascorbate in BALF. Generally, biological samples can be stabilized by acidic deproteinization with perchloric and metaphosphoric acid (Roginsky et al., 1997).

GSH, a γ-glutamyl cysteinyl glycine tripeptide that is a major cellular antioxidant present in millimolar concentrations in cells, has also been shown to function as an antioxidant in alveolar lining fluid. However, the levels of GSH present in BALF are much lower, in the micromolar range, especially in animals. As a cellular antioxidant, GSH has a major role in thiol homeostasis and regulation of the activities of a variety of proteins whereas, in alveolar lining, it might function as a scavenger of reactive electrophilic species. GSH levels have been shown to be altered in a number of experimental lung injuries and in human diseases; however, depending on the pathologies, increases or decreases have been noted (Fitzpatrick et al., 2011; Kontakiotis et al., 2011). Often, the ratio of reduced and oxidized GSH has been used as a measure of cellular oxidative stress (Dalle-Donne et al., 2007). A number of colorimetric and chromatographic techniques can be used to measure GSH in BALF. Because GSH is also a labile molecule, sample preservation and storage become highly critical in accurate measurement. The use of GSH as a biomarker might be restricted to certain types of acute lung injuries where the changes in BALF GSH levels are expected.

Other airway lining antioxidants include extracellular superoxide dismutase, which is normally present within interstitial spaces and alveolar lining where it is a scavenger of superoxide radicals (Fattman et al., 2003). Following stress, the activity of extracellular superoxide dismutase has been shown to increase. This BALF protein can be detected using immunological techniques and can serve as a biomarker of oxidative stress.

Iron is the most abundant metal component of the body, is redox active, and is regulated precisely by tightly controlled transport mechanisms. Iron-binding proteins play a critical role in maintaining antioxidant homeostasis and removal of nonheme iron. High levels of ferritin, lactoferrin, and transferrin are detected in BALF, especially following lung cell injury (Ghio et al., 2008). Iron-binding proteins in BALF serve as biomarkers of acute lung injury and chronic diseases associated with increased iron overload (Ghio et al., 2008; Shannahan et al., 2010). Because these proteins are changed in a number of pathological conditions and after acute lung injury, the specificity of these proteins for a given lung disease cannot be ascertained. In addition to measuring BALF levels of iron-binding proteins, the measurement of iron-binding capacities using clinical assays can provide insight into the nature of lung pathology.

In many cases of lung injury, 4-hydroxynonenal (trans-4-hydroxy-2-nonenal; 4-HNE) is measured as a biomarker of oxidative stress. 4-HNE is produced from oxidation of polyunsaturated lipids under oxidative conditions associated with lung injury (Eder et al., 2008). Increased 4-HNE levels are observed in a number of diseases, such as ARDS and some types of cancers (Eder et al., 2008). At low concentrations, 4-HNE might induce proliferation, and high concentrations can lead to cellular apoptosis (Sunjic et al., 2005). Similarly, F(2)-isoprostanes, prostaglandin-like chemicals, have also been detected in BALF, and their increases have been associated with lung injuries (Janssen, 2008). F(2)-isoprostanes are formed in vivo by nonenzymatic oxidation of arachidonic acid, and their assessment in BALF can provide overall oxidative stress status of the lung. A number of studies have also shown increases in levels of malondialdehyde, which is produced by oxidative modification of lipids. Accurate measurement of its levels is challenging; however, increases have been shown in some lung injuries (Nemmar et al., 2012). Because oxidative stress and increased oxidation of macromolecules are associated with almost all lung pathologies and injuries, the changes in these markers will not provide specific insights into the type of disease or injury.

Cytokines, Chemokines, and Growth Factors

Cytokines and chemokines are secreted by lung epithelial, smooth muscle, interstitial, and endothelial cells and alveolar macrophages. Depending on the

host genetics, nature of lung cell damage, and type of disease, the dynamics of secretion of these molecules vary. The ability to analyze the pattern of change among many functionally related cytokines, as opposed to individual ones, allows for a more accurate prediction of the type of disease and its progression and severity. For example, increased secretion of Th2 cytokines will be indicative of an asthma phenotype (Hartl et al., 2009), whereas increased interferon gamma (IFN-γ) and associated cytokines might underlie infection or COPD (Chung, 2005). The increased secretion of these cytokines is noted during an immune response and can also occur in injuries not mediated by immune mechanisms. Some of these cytokines and chemokines serve to stimulate proinflammatory reaction, whereas others are involved in the maintenance of homeostasis. On activation of cellular receptors and subsequent signaling through MAP kinase and NF-κB pathways, the expression of cytokines is induced (Chung, 2005; Hartl et al., 2009). Therefore, proteins released into the airway lining fluid can serve as biomarkers of underlying lung inflammation, infection, or chronic disease. There are numerous studies that show increases in the cytokines and chemokines in BALF in experimental and clinical settings. The release of cytokines and chemokines from cells recovered during BAL can also provide insights into the mechanisms of lung injury or disease. A variety of immunoassays, including single-protein detection and multiplex platforms, are available to determine the levels of these cytokines and chemokines in the BALF of animals and humans.

Bronchoalveolar Lavage Fluid Cells as a Determinant of Lung Inflammation

Lung injury leads to recruitment of inflammatory cells from blood to the lung compartments through highly regulated immunological processes. Inflammatory cells that are recruited in the airways and alveolar lining are recovered in BALF. These cells can be mounted on a slide using cytospin centrifugation and stained for their microscopic examination and identification. Quantification of relative cell types is used for assessment of lung inflammation in many inhalation toxicological and human exposure studies. In lung diseases, these cells provide information on the nature of pathology, whereas the surface characterization of receptors can predict molecular mechanisms.

Lung injuries and pathologies associated with inhalation exposure to particulate and fibrous materials result in macrophage phagocytosis of these inhaled materials. The inhaled particles in the 0.2–10 μm diameter range can be identified within alveolar macrophages at the light microscopy level, which can provide insight into the type of exposure. Macrophages undergo phagocytosis and pinocytosis, leading to activation

(Zhang and Kaminski, 2012). Inflammatory cells are recruited into the alveolar space following lung injury through elaboration of cytokines and chemokines from activated macrophages and epithelial cells. This process brings neutrophils, eosinophils, lymphocytes, and monocytes into the lung and air spaces (Fig. 13.5). The type and the degree of cell infiltration depend on the physicochemical property of the inhalant and the degree of initial injury. The analysis of cellular content in BALF, thus, presents the most precise and accurate determination of the underlying disease process. The BALF of healthy individuals and animals primarily contains macrophages; therefore, the presence of other cell types, such as neutrophils, eosinophils, and lymphocytes, can clearly predict the nature of inflammation and the type of underlying disease (Barnes et al., 2006). The identification and quantification of inflammatory cells can provide insight into the type of pathology. For example, nonimmune lung injury involving innate response will be associated with increases in BALF neutrophils, whereas adaptive immune changes might be associated with eosinophilic and lymphocytic inflammatory response. Flow cytometry analysis for surface markers is often used to determine immunological mechanisms. In many cases, these cells recovered from healthy and diseased patients are cultured to study their potential to secrete cytokines on stimulation and their pathobiologic mechanisms.
FIGURE 13.5 Inflammatory cells in lavage fluid of rats. The cells isolated via bronchoalveolar lavage (BAL) were centrifuged to prepare cell differential slides using a cytospin centrifuge and stained with the DiffQuick staining kit (Fischer Scientific). Each cell type is marked. In healthy rats, most cells (85%–95%) are alveolar macrophages; however, after acute lung injury, more neutrophils, eosinophils, and lymphocytes are found in BAL fluid (BALF). Often, sloughed-off ciliated epithelial cells are present because of procedural injury.

Circulating Biomarkers of Lung Injury and Pathology

A variety of circulating components that are changed in response to lung injury, or as a result from crossing from the lung into the bloodstream, can serve as biomarkers. Because blood can be collected in a minimally invasive manner, as opposed to the invasive collection of BALF, identifying circulating biomarkers is more feasible. The blood sample collection is performed routinely in any clinical setting and in experimental studies. However, because only a fraction of the lung content can be translocated to the circulation (depending on the characteristics of the inhalant), the sensitivity of detection and the degree of change in levels are less robust than in the BALF. Many lung injury biomarkers commonly found in BALF are also present in the circulation. New approaches and discoveries have led to significant advances in global assessment of biomarkers in the blood. Here, we will discuss several lung toxicity biomarkers individually and as a group to enable a pattern of change to be examined.

Surfactant, Other Lung-Specific Proteins, and Immunological Biomarkers

SPs are made primarily in the lung and are released into the circulation following injury and under disease conditions. Therefore, their detection in the circulation can provide highly specific information concerning lung injury and pathology. Of the four types of SPs, SP-A and SP-D have been used frequently as biomarkers of lung disease and innate immune function (Takahashi et al., 2006). Depending on the nature of injury, the type of SP released in the circulation differs. In restrictive lung diseases, the expression of SP-A and SP-D is increased, and thus, they serve as specific biomarkers. SP-A is detected in COPD patients but not in patients with fibrosis (Ohlmeier et al., 2008). The levels of circulating SP-D have been shown to correlate with alveolitis (Hant et al., 2009). SP-D has also been shown to increase in the circulation of idiopathic pulmonary fibrosis patients (Hant et al., 2009). Temporal increases in SP-A and SP-B in plasma have been shown to result from progression in alveolar capillary permeability in patients with ARDS (Schmidt et al., 2007). Detection of SP-A and SP-D in circulation is predictive of interstitial lung diseases (Cheng et al., 2003; Greene et al., 2002). Because these proteins are secreted in limited quantities, their detection sensitivity is critical in determining the correlation between the severity of lung injury and the degree by which the protein level increases in the circulation. Plasma SPs can be analyzed using standard antibody-based immunological techniques.

Krebs von den Lungen-6 (KL-6), now classified as a human MUC-1 glycoprotein, has been shown to be elevated about 70%—100% in patients with various interstitial lung diseases (Ishikawa et al., 2011). Changes in KL-6 correlate with alveolitis and scleroderma (Hant et al., 2009). Club cell secretory protein 16 (CC-16) has been detected in the sera of ARDS patients (Doyle et al., 1998). CC-16 also increased after acute ozone exposure in humans (Blomberg et al., 2003) and has been proposed as a sensitive biomarker of acute lung injury. This protein is made in club cells within airway epithelium. Napsin A, which is a protease expressed in alveolar type II cells and also renal proximal tubules, has been shown to be a highly sensitive indicator of idiopathic pulmonary fibrosis, especially in the absence of renal disease (Samukawa et al., 2012). Increased levels in the blood are indicative of lung adenocarcinoma. CC-18, derived from alveolar macrophages, has been shown to increase in the circulation during lung fibrosis (Prasse and Muller-Quernheim, 2009). Many of these biomarkers are likely to be changed with multiple lung diseases, often limiting their specificity and predictive value for a given pulmonary disease.

A number of other circulating proteins have been implicated in lung injury. Smokers who have demonstrated reduced diffusion capacity at the capillary barrier have been shown to have increased blood lysozyme, a marker of inflammatory cells. This has been shown to correlate with the degree of impairment in lung diffusion capacity (Schmekel et al., 2013). Increases in soluble Fas (sCD95)/APO-1, involved in antagonizing cellular Fas receptors and apoptotic cell signaling, have been demonstrated to be increased in coal miners (Hoffmeyer et al., 2010). Increased levels of cytokeratin-18 immune complexes were present in patients with pulmonary fibrosis (Dobashi et al., 2000). Serum levels of antineutrophil cytoplasmic antibodies (ANCAs) have been shown to increase in response to a cell-mediated immune response to antigens in the respiratory tract, which generally is associated with granuloma formation in experimental and occupational asbestos and silica exposures (Rihova et al., 2005). ANCAs have been implicated in many immune disorders and are proposed to be specific to lung immune reaction in patients with granuloma. Pentraxin-3, a receptor involved in innate immune response, has been shown to increase after acute lung injury and in ARDS (Mauri et al., 2008). Ligand CCR5, involved in trafficking inflammatory cells, has been shown to be increased in the plasma of patients with Wegener's granulomatosis. Because ANCAs were positive for all patients with CCR5 increases, ANCAs might be involved in common pathways controlling inflammation (Zhou et al., 2003).

Some immunological mediators have the potential for being considered as biomarkers for infections. In individuals infected with influenza A, high levels of

circulating CD-4 T lymphocytes were noted (Zhao et al., 2012), suggesting that these lymphocytes could serve as potential biomarkers for this infection; however, their involvement in other types of inflammatory processes will need to be taken into consideration. A thymus- and activation-regulated chemokine (TARC)/CCL17, which is a functional ligand for CCR4, has been involved in a variety of pulmonary and other diseases and seems to track with eosinophilia (Miyazaki et al., 2007). This marker provides a highly sensitive indication of disease in patients with acute eosinophilic pneumonia, which closely resembles acute lung injury associated with ARDS (Miyazaki et al., 2007). These studies suggest that there are likely a number of immune response– related biomarkers that can be considered for further validation. The type of any immune biomarker change, however, can depend on the type of lung damage or infection.

Collagen and Elastin Fragments

Collagen and elastin are present at high levels in the lung and provide a unique structural framework. Injury to the structural components of the lung results in proteolytic degradation of extracellular matrix–associated collagen and elastin. The fragments of degradation by-products can then be detected in BALF, blood, and even in urine. Their presence in the plasma is indicative of lung structural impairment. Some of the fragments of collagen and elastin are highly reactive and have been shown to induce inflammatory responses within the lung (Overbeek et al., 2013). Desmosine and isodesmo- sine, degradation products of elastin, have been identi- fied in circulation and are considered fairly specific markers of emphysematous changes in the lung (Viglio et al., 2007). Other elastin degradation products have also been identified and are named elastokines based on their ability to cause inflammatory reactions (Cantor and Shteyngart, 2004). Endostatin, a proteolytic frag- ment of the basement membrane collagen XVIII, has been shown to inhibit angiogenesis via action on endo- thelial cells (Kanazawa, 2007), whereas procollagen type I and type III amino terminal propeptides have been associated with ARDS (Meduri et al., 1998). These fragments can serve as biomarkers of underlying lung disease (Ostroff et al., 2010). Because other organ injuries can also fragment collagen and elastin, the analysis of by-products in plasma should accompany additional measures of lung injury. The determination of these frag- ments is limited to the availability of specific antibodies.

Cytokines, Metalloproteases, and Acute-Phase Proteins

It has been shown that lung injury or infection can lead to increases in circulating cytokines, such as IL-6 and TNF-α; metalloproteases, such as MMP-9; and a number of acute-phase proteins (Calfee et al., 2011). Circulating cytokines as biomarkers have been impli- cated in a number of pulmonary diseases (Tzortzaki et al., 2007; Tzouvelekis et al., 2005). Increased levels of circulating cytokines have also been implicated in coal miners (Zou et al., 2011). Increased MMP-9 plasma levels have been shown to occur in patients with COPD (Bolton et al., 2009). We have shown that, in rats exposed to asbestos fibers, there is a marked in- crease in a number of acute-phase proteins and cyto- kines, such as lipocalin-2 and osteopontin, but no increases in IL-6 or TNF-α could be noted in F344 rats (Shannahan et al., 2012a). A number of experimental air pollution studies have shown changes in circulating cytokines; however, the increases have been inconsistent relative to the degree of lung injury. It is likely that ani- mal strain, temporality, and other host factors, in addi- tion to the types of lung injuries, play important roles. Thus, the use of circulating cytokines and other proteins in experimental lung toxicity or lung diseases as bio- markers should be considered in conjunction with other types of disease measures.

Adhesion molecules, such as P-selectin, E-selectin, ICAM-1, and VCAM-1, are involved in extravasation of inflammatory cells to the lung and are likely to be changed systemically. Many of these cell surface recep- tors have their soluble form present in the circulation and are involved in regulatory mechanisms. As an example, increases in plasma-soluble ICAM-1 and E- selectin were detected in pediatric acute lung injury (Ballabh et al., 2003). Relative to circulating cytokines, the changes in soluble receptors after local pulmonary injury as biomarkers of diseases are less explored. Iden- tification and validation of soluble receptors of adhesion molecules hold a great opportunity for discovery of novel biomarkers and as therapeutic targets.

Thrombosis Biomarkers

Lung injury can induce microvascular thrombosis by stimulation of the extrinsic coagulation pathway. Micro- vascular thrombosis plays an important role in pulmo- nary injuries and chronic diseases. During initiation of the coagulation cascade, the extrinsic pathway is trig- gered by activation of tissue factor (TF) and factor VII, but, subsequently, the intrinsic pathway is triggered, which involves factors VIII, X, and XI (Idell, 2003). It has been shown that acute lung injury induced by PM exposure can induce thrombosis in the vasculature away from the site of injury, suggesting that pulmonary-derived factors in the circulation are contrib- uting to this systemic response (Nemmar et al., 2006). TF, which initiates the thrombosis process after acute injury, has been shown to increase in the plasma of humans af- ter exposure to air pollutants (Emmerechts et al., 2012). It is also likely that platelet activation and secretion of

reactive coagulation mediators can trigger microvascular thrombosis. The neurohumoral factors released from activated mast cells might also contribute to systemic thrombogenic effect on lung injury (Nemmar et al., 2006). We have shown that the platelet aggregation and numbers were changed in rats after exposure to asbestos fibers (Shannahan et al., 2012b). Circulating thrombomodulin levels have been increased in cancer patients undergoing radiation therapy (Hauer-Jensen et al., 1999). Moreover, circulating von Willebrand factor and P-selectin levels are also increased following acute lung injury (Ochoa et al., 2010). The consideration of thrombosis biomarkers for diagnosis of lung injuries and diseases is attractive and will be critical for acute lung injuries and experimental studies. Examination of thrombogenic processes is performed routinely in clinics. Their use as biomarkers of chronic lung disease can be of value for selected lung diseases.

Circulating Progenitor Cells

An injury or inflammation response in the lung triggers bone marrow to release progenitor cells into the circulation to induce compensatory repair at the site of injury (Yang et al., 2016). Increases in circulating progenitor cells of various lineages have been noted in multiple studies and have been proposed to serve as biomarkers; however, more research is needed with greater emphasis on the correlation between the degree of increase with the level of lung damage, disease severity, and the time course of their release. Progenitor endothelial cells have been shown to increase in pulmonary fibrosis and bronchopulmonary dysplasia (Borghesi et al., 2009). It has been demonstrated that epithelial progenitor cells are recruited at the site of lung injury in a mouse model (Gomperts et al., 2006). A number of studies have shown the increases in mesenchymal progenitor cells in interstitial lung injuries, such as fibrosis (McNulty and Janes, 2012; Smadja et al., 2013). The origin and release of progenitor cells in response to injury provides novel mechanisms involved in tissue repair, and, if validated, these biomarkers can be predictive of the precise nature of underlying lung injury and pathology.

Microparticles

Microparticles are formed by shedding or blebbing of cell membrane. These particles include microvesicles, exosomes, and apoptotic bodies as well as cellular contents. These particles also contain deoxyribonucleic acid (DNA), ribonucleic acid (RNA), microRNA (miRNA), phospholipids, and molecules derived from the parent cell (Nieri et al., 2016). They are small and range from 0.05 to 3 μm in diameter. In normal circumstances, these particles are present at a low concentration in the circulation, but, under pathological conditions and following an injury, more of these particles are released into the circulation (Piccin et al., 2007). There is a growing interest in using these microparticles as biomarkers of specific organ and cell injuries. Moreover, the components associated with these particles can be released or fused with endothelial cells and can trigger a variety of systemic responses. Thus, their role as biomarkers and also in inducing pathobiologic processes away from their site of origin is of great importance. As far as predicting their role in lung injury, it has been shown that circulating microparticles from smokers can provide insight into the ongoing lung injury (Gordon et al., 2011). Microparticles have been shown to contain TF that, on its release, can induce thrombogenic effects on the vasculature (Mackman, 2006). Acute lung injury leads to increased microparticles into the circulation (McVey et al., 2012), whereas microparticles found in the sputum have been shown to have proinflammatory effects (Porro et al., 2013). More research is needed in using microparticles and associated cell content as biomarkers. A number of flow cytometry—based techniques are available to isolate microparticles from blood plasma and characterize their properties. Examination of their properties provides important mechanistic information about the underlying disease. Understanding of their formation, function, and relevance to the underlying disease may result in new therapeutic strategies for vascular diseases secondary to lung injury.

miRNA

miRNAs are small noncoding RNAs that function in transcription and translation processes. In mammalian cells, miRNAs function by pairing with complementary messenger RNA (mRNA) sequences, causing gene silencing during the translational process. Mammalian miRNAs exhibit only a partial complementarity to target mRNA, and, thus, one miRNA can target several mRNAs, and, likewise, one mRNA can be targeted by a number of miRNA molecules. miRNAs play important roles in many cellular processes such as apoptosis, differentiation, growth, and cell signaling. The presence of miRNA in the circulation has sparked a tremendous interest in their potential use as biomarkers and therapeutic targets as well as their role in gene regulation (Paul et al., 2018). Because of their encapsulation in microvesicles, exosomes, or apoptotic bodies or when complexed with proteins, miRNAs that escape degradation by endogenous ribonucleases are released into the circulation where they can serve as biomarkers (Harrill et al., 2016). A number of techniques are available to isolate miRNA from blood plasma, and high-throughput platforms are available to profile miRNA globally.

Although few reports are available for noncancer-related lung diseases, more research has been conducted

on miRNAs as biomarkers of lung cancer. It has been shown that miRNAs are expressed differentially in patients with lung cancer, tuberculosis, pneumoconiosis, and ARDS and in smokers (Abd-El-Fattah et al., 2013). Genome-wide analysis has been used to identify miRNA in coal workers with pneumoconiosis (Guo et al., 2013). Toxicology-based clinical studies have also been performed to examine miRNA expression levels in sputum and blood samples collected from individuals exposed to ozone (Fry et al., 2014), PM (Bollati et al., 2015), and diesel exhaust (Yamamoto et al., 2013). There is a great potential in using miRNAs as biomarkers of lung injuries and diseases and for therapeutic targeting; however, more studies are needed to understand their specific role in translational repression in an organ-specific manner.

Biomarker Identification Using Proteomic and Metabolomic Profiling

With the emergence of new biotechnologies, there is a growing interest in using global serum/plasma proteomic and metabolomic profiling for identifying novel biomarkers of various lung pathologies, including cancer (Cheung and Juan, 2017; Kumar et al., 2017). Proteomic profiling of blood can identify nonabundant proteins that are mediators of pathogenic and injury processes (Mehan et al., 2013). Proteomic analysis has also been applied to BALF samples to detect markers of early-stage lung cancer (Hmmier et al., 2017). Metabolomic analysis will identify small metabolites of all classes, including carbohydrates, amino acids, and lipids (Johnson et al., 2016). The characteristics of these metabolites or group of metabolites can reveal processes modified during injury to the lung. Generally, in identifying biomarkers, the patterns of change in multiple functional groups of biomarkers are better indicators of underlying disease or injury than that of an individual marker. For example, an experimental ventilator-induced rat lung injury model shows changes in serum metabolites and provides information about the pathological processes in the lung (Naz et al., 2013). Alterations in proteomic profiles provide distinct differences between cancer patients and those with asthma (Izbicka et al., 2012), suggesting that disease-specific biomarker profiles can be identified using proteomic and metabolomic approaches. COPD patients exhibit changes in amino acid metabolism based on plasma proteomic and metabolomic analyses (Ubhi et al., 2012). The metabolomic approach is also used in identifying cancer signatures (Wedge et al., 2011). Recently, metabolomic analysis has been used to investigate systemic changes following an acute ozone exposure in humans (Miller et al., 2016) and animals (Miller et al., 2015). A number of high-throughput platforms are available using combinational and mass spectrometric techniques that enable global profiling of plasma and serum samples. The use of proteomic and metabolomic techniques has provided novel insights into chronic diseases, the cross talks among pathological processes and cellular metabolism, and identification of novel biomarkers.

Biomarker Identification Using Genomic Profiling of Nucleated Blood Cells

Gene expression profiling of nucleated cells in the blood of patients with lung injury and in experimental studies can provide insights into the type of disease and injury. Circulating mononuclear cells respond to injury induced in the lung and are involved in inflammatory and immune processes. The specific mRNA expression differences between healthy and diseased individuals can lead to identification of new biomarkers and pathobiologic processes. The blood gene expression pattern of tuberculosis patients revealed humoral immunity changes (Cliff et al., 2013). Patients with ARDS show increased expression of pre-elafin, which can serve as a biomarker (Wang et al., 2008). Unique gene signatures have also been detected in blood of advanced non—small cell lung carcinoma patients (Chen et al., 2013). Use of combinational techniques including global single nucleotide polymorphism (SNP) analysis and genomic profiling has been employed for identifying new biomarkers in COPD patients (Kim et al., 2012). Transcriptional analysis of COPD patients' blood samples has revealed involvement of neutrophil proteases in the disease pathogenesis, whereas those with tuberculosis revealed inflammatory gene changes (Cliff et al., 2013) and also involvement of interferon-inducible signature (Berry et al., 2010). Thus, transcriptional profiling of blood cells during various stages in the disease process can provide mechanistic information about the disease progression and pathogenesis. Different gene expression platforms and whole genome, as well as RNA-sequencing arrays, are available for these applications; however, validation of these biomarker signatures remains a challenge.

Urine Biomarkers of Lung Injury and Disease

Unlike circulating, sputum, NALF, and BALF biomarkers, there are a limited number of injury-related molecules that can be filtered and collected in urine, and, thus, relatively few biomarkers have been identified that link to lung injury or diseases. Urine biomarkers include the components of lung structure and oxidation by-products that escape filtration across all passages. Desmosine, a structural component of elastin, and other fragments are released on lung injury. In various pathological conditions, these markers have been detected in the urine (Fill et al., 2006; Turino

et al., 2011). Oxidation by-products, such as 8-hydroxydeoxyguanosine, have also been detected in urine from patients with bronchopulmonary dysplasia (Joung et al., 2011). A bombisen-like peptide has been shown to be present in individuals with bronchopulmonary dysplasia (Cullen et al., 2002). Leukotriene by-products of arachidonic acid metabolism have been found in the urine of smokers (Duffield-Lillico et al., 2009). Increased urinary mesothelin was noted in patients with mesothelioma, suggesting that this could serve as a biomarker for lung cancer patients for diagnosis of mesothelioma (Creaney et al., 2010). The sensitivity of these urinary biomarkers and their predictive value for early diagnosis, however, are limited in lung injuries and disease. Newer metabolomic techniques might enable more thorough analysis for identification of biomarkers in urine samples.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The field of biomarkers has recently exploded as a result of numerous new discoveries in biological mechanisms and also the availability of high-throughput biotechnologies. This revolution in biology has shifted the focus of research from target organ biology to systemic biology. New interactive biological processes and pathways have been discovered that provide insights into the systems interactions. This is especially true for pulmonary diseases and toxicities, which recently have been linked to cardiovascular and neuronal impairments and metabolic syndrome. The great interest in understanding circulating factors that are changed as a result of lung injury and their ability to affect distant organs has rejuvenated our interest in identifying new biomarkers. A variety of approaches have been introduced recently—blood genomic, serum proteomic, and metabolomic approaches. In this exciting time, biomarker discoveries will influence therapeutic approaches for lung diseases. In toxicology, the emerging new biomarkers will provide the most critical knowledge of systems biology.

Hepatic Toxicity Biomarkers

Gurjot Kaur

Human and Environmental Toxicology, Department of Biology, University of Konstanz, Konstanz, Germany

INTRODUCTION

The liver is the largest internal organ in the human body and is the main organ for metabolism and detoxification of drugs and environmental chemicals. In addition, it regulates a myriad of functions such as glucose synthesis and storage, decomposition of red blood cells, plasma protein synthesis, hormone production, and bile formation. Anatomically, the liver lies slightly below the diaphragm and anterior to the stomach, a position that facilitates maintaining metabolic homeostasis of the body. Two distinct blood supplies, the portal vein (PV) and the hepatic artery (HA), feed the liver. The PV carries blood containing digested nutrients from the gastrointestinal tract, spleen, and pancreas, whereas the HA carries oxygenated blood from the lungs. The human liver consists of four lobes and each lobe is made up of many lobules at the microscopic level. The classical lobule is a hexagonal-shaped unit centered on a central vein (CV). In each functional unit, blood enters the lobules from the PV and HA, and then flows down past the cord of hepatocytes. The lobule is divided into three zones (Fig. 14.1): (1) periportal (Zone 1) is the closest to the entering blood supply and has the highest oxygen tension; (2) centrilobular (Zone 3) abuts the CV and has the poorest oxygenation; and (3) midzonal (Zone 2) is intermediate. Because of the blood flow from the stomach and intestine, the liver is the first organ to encounter a number of insults from ingested metals, drugs, and environmental toxicants (Klaassen et al., 2013).

Because of acute or chronic exposure to significantly high toxicant levels, liver functions can be adversely affected. For example, acetaminophen (APAP) is a widely used over-the-counter analgesic and antipyretic in the United States. When used at recommended therapeutic doses, APAP is rarely associated with liver injury. Unfortunately, APAP can cause fatal acute liver failure due to the production of a highly reactive hepatotoxic metabolite at doses exceeding therapeutic doses (Ciejka et al., 2016).

Because the liver is often exposed to the highest concentrations of oral drugs, it is not surprising that the liver is often the target organ with ensuing drug-induced liver injury (DILI). DILI is a major challenge for the pharmaceutical industry and public health because DILI is a common cause of drug development termination, drug restrictions, and postmarketing drug withdrawal. Currently, more than 1000 drugs have been reported to be associated with DILI (Shi et al., 2010). In addition, the increasing popularity of dietary supplements may contribute to the high incidence of DILI because some dietary supplements alter the toxicity of concomitantly administered drugs (Abebe, 2002; Salminen et al., 2012; Gwaltney-Brant, 2016; Gupta et al., 2018).

DILI has been classified into hepatocellular injury, cholestatic injury, and mixed hepatocellular/cholestatic injury. Hepatocellular injury involves cellular damage of the hepatocytes such as the centrilobular necrosis caused by APAP. This type of damage is often associated with elevated serum alanine aminotransferase (ALT) levels due to leakage from damaged hepatocytes. Cholestatic injury involves damage to some part of the bile processing or excretion apparatus, resulting in impaired processing and/or excretion. This type of injury is often associated with elevated serum bilirubin and alkaline phosphatase (ALP), indicating alterations in bile homeostasis and/or bile duct (BD) injury. Mixed injury presents with a mixture of both types of effects. Unfortunately, drugs rarely produce a single clear clinical picture, making the diagnosis of DILI difficult. For example, amoxicillin/clavulanic acid usually causes cholestatic injury but can also produce acute hepatocellular or a mixed type injury. The histopathological analysis of liver biopsies is the most definitive way to diagnose and differentiate between different DILIs. However, the biopsies are invasive and not routinely performed.
FIGURE 14.1 **Microscopic structure of the liver lobule.** Blood, supplied by portal vein (PV), or hepatic artery (HA), enters the liver lobule through the portal triad, which encompasses PV, HA, and bile duct (BD). Blood flows from Zone 1 (best oxygenation) to Zone 2 and out of the central vein (CV) in Zone 3 (poorest oxygenation).

Serum ALT activity has historically been used as a major biomarker for liver injury in humans and in preclinical studies. Damaged hepatocytes release ALT into the extracellular space with subsequent passage into the blood. However, ALT elevations can also reflect nonhepatic injury, particularly skeletal muscle injury. Additionally, the concentrations of ALT do not discriminate between different etiologies of liver injury, and ALT elevations can occur after a critical therapeutic window has passed. Another disadvantage is that ALT levels do not provide any insight into disease prognosis (Kaplowitz, 2005).

Adaptation during continued exposure to DILI drugs has been observed in preclinical and clinical studies. For example, 25% of Alzheimer's disease patients receiving tacrine experience transient, asymptomatic increases in serum ALT. The majority of these patients adapt to the drug as indicated by a return of serum ALT to baseline levels despite continued treatment. Most statins can also cause serum ALT elevations in a subset of treated patients, but often occur in the absence of histological evidence of injury. Therefore, elevated ALT levels do not necessarily indicate the severity of the liver injury and patient adaptability to the stressor or progression to total liver injury.

Another known liver toxicity biomarker is total bilirubin level (TBL), which is associated with altered bile homeostasis and/or hepatobiliary injury. The functional reserve of the liver for processing bilirubin is large; therefore, substantial hepatic injury often occurs before alterations in TBL are observed, making it an insensitive biomarker. By the time TBL is elevated, there may already be substantial loss of liver function, placing the patient in danger of liver failure. Therefore, unavailability of ideal clinical laboratory tests and inefficient

prognosis necessitate development of new biomarkers that are not only sensitive but are also specific and prognostic.

Hy Zimmerman first noted that "drug-induced hepatocellular jaundice is a serious lesion. The mortality rate ranges from 10% to 50%." He realized that when drugs cause substantial hepatocyte injury that affects overall liver function and, in particular, causes jaundice as the result of impaired bilirubin processing and transport, the hepatotoxicity is likely to lead to a life-threatening event (Senior, 2006). The combination of two biomarkers, ALT and bilirubin, defined as "Hy's Law," indicates more severe injury than serum enzyme elevations alone. The significance of Hy's Law is that the combination of ALT and bilirubin, neither of which by itself is sufficiently specific, seems to be highly specific for serious liver injury. Therefore, the FDA recommends a combination of tests, including serum ALT, aspartate aminotransferase (AST), ALP activities, and TBL concentration, to identify potential DILI.

In addition to the biomarkers described above, there are symptoms commonly associated with liver injury. Abdominal pain, enlargement of the liver and spleen, distended belly full of fluid, or enlarged breasts in men are common signs of liver injury (Chopra, 2001). In combination with biomarkers of liver injury, these nonspecific and specific symptoms can help a physician identify liver injury and its seriousness. Unfortunately, there are limited tools at the physician's disposal for determining the patient's prognosis.

OVERVIEW OF LIVER PHYSIOLOGY, TOXICITY, AND PATHOLOGY

Bioactivation and Detoxification

The liver is the main metabolic organ in the body and is considered a viable defense against environmental and metabolic toxins. In general, all foreign compounds (xenobiotics) are potentially toxic. To minimize potential injury, the liver is well equipped with metabolizing enzymes termed Phase I and Phase II enzymes and Phase III transporters (Xu et al., 2005). The coordinated metabolism and transport typically make the xenobiotic less toxic and more water soluble, thereby aiding in its elimination from the body. Classically, the initial metabolic step is referred to as Phase I or the oxidation phase. This step is most frequently catalyzed by cytochrome P450 (CYP450) enzymes, which derive their name from their maximal absorbance at 450 nm when bound to carbon monoxide. They are highly expressed in liver (specifically in hepatocytes) and to a lesser extent in the epithelium lining of the gastrointestinal tract. They are typically found associated with the lipid membrane of

the endoplasmic reticulum and the outer membrane of mitochondria. CYP1, CYP2, and CYP3 families are major enzymes mediating drug metabolism (Danielson, 2002). In general, Phase I CYP metabolism introduces a functional group, e.g., a hydroxyl group, to a xenobiotic. Phase I metabolism may not be a detoxifying function by itself because the metabolite may be more reactive and toxic than the parent compound, and thus it often works in conjunction with subsequent Phase II metabolism to produce a more water-soluble and less toxic compound. The functional group added by Phase I metabolism is often the target of Phase II conjugation. During this phase, the compound may undergo glucuronidation, sulfation, conjugation with glutathione, methylation, N-acetylation, or conjugation with amino acids. Typically these modifications make the compound significantly more hydrophilic, thereby enhancing excretion in the bile and urine (Klaassen et al., 2013).

Phase III is often referred to as a "metabolic" process; however, it essentially involves the transport of xenobiotics and their metabolites across biological membranes with no further metabolic alterations of the compound's structure. Phase III transporters are found in a wide array of organs/biological membranes, and they typically facilitate the removal of xenobiotics and their metabolites from the body. There are many different Phase III transporters with each one having specificity for different types of molecules. Human drug transporters can be classified under two major superfamilies: solute carrier (SLC) and ATP-binding cassette (ABC). Transporters of the SLC superfamily are the organic cation transporters (OCTs/SLC22A), the multidrug and toxin extrusion transporters (MATE transporters/SLC47A), the organic anion transporters (OATs/SLC22A), and the organic anion transporting polypeptides (OATPs/SLCO). Members of the ABC superfamily are important in drug toxicity, and these include P-glycoprotein (MDR1/ABCB1), multidrug resistance-associated protein (MRP/ABCC), and breast cancer resistance protein (BCRP/ABCG2) (DeGorter et al., 2012).

Many Phase I and Phase II enzymes show significant individual-specific variability resulting in dissimilar levels of exposure to reactive metabolites. Polymorphism and environmental exposure are the two primary causes of this variability. Polymorphisms in drug-metabolizing enzymes may cause dramatic differences in drug detoxification as demonstrated by various genome-wide association studies (GWAS) (Ahmed et al., 2016).

Protein Synthesis and Catabolism

The liver plays a vital role in protein metabolism such as deamination and transamination of amino acids,

plasma protein synthesis, and removal of ammonia as urea in the urine. Several enzymes required in the amino acid metabolism pathways (for example, ALT/AST) are commonly assayed in serum to assess liver damage because they are present at much higher concentrations in the liver than in other organs (Dejong et al., 2007). Almost all blood proteins, except gamma globulins, are synthesized in the liver. Albumin, the main protein in human blood, plays a major role in maintaining plasma osmotic pressure and transportation of lipids and hormones. Some liver injury can affect the concentrations of plasma albumin and result in hypoalbuminemia and hyperglobulinemia (compensatory rise to offset the fall in albumin level) (Farrugia, 2010). Fibrinogen and blood clotting factors (e.g., Factor XIII) are another group of plasma proteins synthesized by the liver. During blood clot formation, soluble fibrinogen is converted into insoluble fibrin strands through a catalytic activation cascade of blood clotting factors. When liver function is impaired, impaired synthesis of the blood clotting factors can lead to excess bleeding. Toxic ammonia, a metabolic product of amino acid deamination, is quickly converted by liver to less toxic urea. Inefficient removal of ammonia from the circulation in humans results in central nervous system disease called hyperammonemia-related coma (Klaassen et al., 2013).

Bilirubin Processing

A very important function of the liver is to process bilirubin. Unconjugated bilirubin is the yellowish heme degradation product, derived from the breakdown of erythrocytic hemoglobin. Bilirubin when unconjugated is very hydrophobic and binds albumin during blood circulation. One of the main reasons for elevated unconjugated bilirubin levels is displacement from albumin by competing hydrophobic drugs or fatty acids. Such an increase of bilirubin may lead to increase in total bilirubin levels causing jaundice, manifested as yellowing of the skin and eye sclera. Jaundice is commonly seen in infants because higher serum levels of unconjugated bilirubin exist due to low metabolic capacity of the neonatal liver (Cohen et al., 2010). Other health problems that display jaundice include hemolysis (rupturing of erythrocytes). Eventually, bilirubin is removed from the blood by conjugation with glucuronic acid in hepatocytes in the liver. Once conjugated, bilirubin derivatives are secreted into bile for further metabolism and elimination.

Covalent Binding

A large body of evidence has shown that reactive metabolites play an important role in the pathogenesis of

DILI. Biotransformation of drugs results principally in detoxification. However, in certain cases, highly toxic reactive intermediates are generated, typically during Phase I metabolism. Such metabolites are short lived; however, if not detoxified, they can form covalent modifications of biological macromolecules and thereby damage proteins and nucleic acids. Reactive metabolites have also been identified from liver injury–inducing drugs such as APAP, tamoxifen, diclofenac, and troglitazone (Park et al., 2005).

In the case of APAP, it is predominantly metabolized by the Phase II metabolic pathways of glucuronidation and sulfation. A small portion of APAP is metabolized by Phase I enzymes to the reactive metabolite N-acetyl-p-benzoquinone imine (NAPQI) and subsequently detoxified by conjugation with glutathione (GSH). Following a toxic dose of APAP, the glucuronidation and sulfation pathways are saturated and APAP is metabolized by the Phase I pathways to NAPQI. NAPQI is detoxified by GSH conjugation; however, once GSH stores are depleted, NAPQI covalently binds cellular macromolecules such as proteins. This covalent binding occurs mainly in hepatocytes resulting in disruption of cellular function and eventual necrosis (Hinson et al., 2010). Interestingly, protein adducts can be detected in the serum of APAP-overdosed patients, most likely because of their release from necrotic hepatocytes (Muldrew et al., 2002). Thus, quantification of the protein adducts is useful in the diagnosis of APAP-overdosed patients. Although covalent binding often occurs during hepatotoxic injury, it is not necessarily sufficient to cause hepatotoxicity. For instance, 3-hydroxyacetanilide (AMAP, regioisomer of APAP) and APAP show similar levels of covalent binding in vivo, but AMAP is not hepatotoxic, even at very high doses (Roberts et al., 1990). Similarly, troglitazone is converted to reactive metabolites that generate a high level of covalent binding, but a causal relationship with hepatoxicity has not been established (Yamazaki et al., 1999). Hence, the utility of protein adducts as DILI biomarkers has been limited because of localization of protein adducts exclusively in the liver and not in blood.

Furthermore, even if covalent binding equates poorly with hepatotoxicity in many cases, the cellular stress responses activated by reactive metabolites may play a decisive role in the toxicity. GSH is a critical cellular antioxidant, important in combating cellular oxidative stress that damages cellular macromolecules. In APAP overdose, NAPQI reacts with GSH leading to depletion of this cytoprotective molecule. NAPQI covalently binds to mitochondrial proteins, increases reactive oxygen species (ROS) production, impairs mitochondrial respiration, thereby causing ATP depletion and opening the mitochondrial permeability transition (MPT) pore and finally making the mitochondrial inner membrane permeable to solutes up to 1500 Da (Jaeschke and Bajt, 2005; James et al., 2003). These events lead to the onset of MPT, which is a common pathway leading to both necrotic and apoptotic cell death. Induction of MPT causes mitochondrial depolarization, uncoupling of oxidative phosphorylation, and organelle swelling, which all result in decreased ATP synthesis and cell death (Kim et al., 2003). Many in vitro assays have been developed to measure GSH, ATP, ROS, mitochondrial functions, and cell viability, which might be useful as in vitro DILI biomarkers in predicting hepatotoxicity.

Necrosis and Apoptosis

Liver cell death is a characteristic feature of many liver diseases, such as cholestasis, hepatitis, and ischemia/reperfusion (Malhi et al., 2006). There are two patterns of cell death: necrosis (death of a large group of cells) and apoptosis (ATP-dependent individual cell death). Cell death may be restricted to certain cell types such as hepatocytes, cholangiocytes (BD cells), endothelial cells, stellate cells, or Kupffer cells (Ramachandran and Kakar, 2009). DILI is commonly observed as acute hepatocellular necrosis (Luedde et al., 2014). Hepatotoxicity may manifest pathologically in either a zonal or a diffuse pattern. Often, hepatotoxicants that cause damage primarily through a reactive metabolite will produce hepatic necrosis in a zonal pattern because even though drug concentrations are highest in Zone 1, most CYPs necessary for bioactivation are concentrated in Zone 3. For a hepatotoxicant such as APAP, CYPs in Zone 1 are at negligible levels and cannot form reactive metabolite. In contrast, CYPs in Zone 3 are at much higher levels and form the reactive metabolite NAPQI, restricting covalent binding to this zone (Bessems and Vermeulen, 2001).

Inflammation (Immune) Hepatitis

Occasionally, reactive drug or bacterial metabolites can act as "haptens" by binding to proteins and resulting in immune responses. Emerging evidence supports the hypothesis that immune cells such as phagocytes, such as Kupffer and stellate cells, and newly recruited leukocytes play critical roles in liver injury. Although the main function of phagocytes is to remove dead cells and cell debris during liver regeneration, toxic mediators generated in this process can attack stressed hepatocytes (Adams et al., 2010). Hepatic inflammation is thus a common histopathological finding in a wide range of liver diseases. DILI is also frequently associated with lymphocytic infiltration where progression and severity of liver injury is determined by the extent of the inflammation. For example, halothane, an inhalation

anesthetic, is a classic example whose reactive metabolites cause immune-allergic hepatitis. Clinical hallmarks of immunological perturbation include time of presentation, general clinical features, and greatly enhanced reaction on reexposure to the drug (Martin et al., 1993).

Steatosis

Steatosis or "fatty liver" is caused by insulin resistance due to obesity (Saadeh, 2007). Histologically, it is characterized by multiple round, empty cytoplasmic vacuoles and excessive fat in the hepatocytes. Steatosis can be induced by acute exposure to many chemicals, e.g., carbon tetrachloride. Often, drug-induced steatosis is reversible and does not lead to cell death. However, it may make the liver more susceptible to other insults such as ethanol consumption (Sato et al., 1981) or it can develop into steatohepatitis (Saito et al., 2007) causing significant liver injury.

REVIEW OF EXISTING BIOMARKERS OF LIVER TOXICITY

The latest version of "FDA guidance for industry DILI: Premarketing clinical evaluation" recommends the use of a combination of four tests as DILI biomarkers (FDA, 2009). Table 14.1 lists these four biomarkers and other common serum biomarkers used in preclinical and clinical screening.

Alanine Aminotransferase

Clinical chemistry data are routinely used for noninvasive monitoring of liver disease in preclinical species and humans, and ALT is the most widely used clinical biomarker. ALT is responsible for the metabolism (transamination) of alanine and is found at much higher concentrations in the liver compared with other organs. When hepatocellular injury occurs, the liver-abundant enzyme ALT will leak into the extracellular space and enter the blood, with a slow clearance rate and a half-life of approximately 42 h (Ozer et al., 2008; Shi et al., 2010). The typical reference range is 7–35 IU/L in females and 10–40 IU/L for males (WebMD, 2017). An elevation of serum ALT activity is often reflective of liver cell damage. Unfortunately, extrahepatic injury, such as muscle injury, can also lead to elevations in ALT, making it not entirely hepatospecific. In addition, fenofibrate was found to increase ALT gene expression in the absence of apparent liver injury (false positive) (Edgar et al., 1998), whereas hepatotoxin microcystin-LR suppressed ALT gene expression (false negative) (Solter et al., 2000). Even though extrahepatic injury, such as muscle damage, can lead to an increase in ALT, serum

ALT is the most widely used and universally accepted biomarker for DILI. It is deemed as the clinical chemistry gold standard for DILI detection and has been used at the FDA to facilitate regulatory decision-making. Periodic monitoring of serum ALT is also a common recommendation given to clinical practices to reduce the risks of liver injury when patients are taking drugs with known DILI potential. Present studies have suggested that measuring the ALT isozymes, ALT1 and ALT2, may aid in differentiating the source of injury. ALT1 has been noted to be localized in human hepatocytes, renal tubular epithelial cells, and salivary gland epithelial cells. ALT2, on the other hand, is localized to the human adrenal gland cortex, neuronal cells bodies, cardiac myocytes, skeletal muscle fibers, and the pancreas. Compared to ALT1, ALT2 contributes less to the total serum ALT and is probably a reflection of mitochondrial damage. A novel immunoassay has been developed to discriminate human ALT1 and ALT2 activities, and it may improve the prognosis (Shi et al., 2015).

Aspartate Aminotransferase

Based on the same rationale as ALT, AST is a standard biomarker for DILI and is well accepted by clinicians. AST is responsible for the metabolism (transamination) of aspartate. Even though sensitivity of the AST assay is lower than ALT, presumably because of its expression in extrahepatic organs such as heart and muscle, it is still a widely used liver biomarker. Apparently, the ratio between serum ALT and AST is useful in differentiating DILI from extrahepatic organ injury and diagnosing acute alcoholic hepatitis and cirrhosis when AST/ALT ratio is 2:1.

At least two isoenzymes of AST have been found: a cytosolic AST and a mitochondrial AST (mAST). The relative contributions of cytosolic AST or mAST to serum AST elevation have not been critically assessed. It remains unestablished whether AST isoenzymes are susceptible to drug-driven induction or inhibition (Ozer et al., 2008; Shi et al., 2010).

Alkaline Phosphatase

ALP is located in the liver and its concentration in serum increases when the BDs are blocked. ALP is yet another diagnostic biomarker recommended in the FDA guidelines, and it is widely adopted by clinicians (FDA, 2009; Shi et al., 2010). The Council for International Organizations of Medical Sciences consensus criteria considers a more than twofold isolated elevation of serum ALP, or ALT/ALP ratio of no more than 2, as a key biomarker of cholestatic DILI (Devarbhavi, 2012). However, it should be noted that conditions other than DILI, such as bone disease and pregnancy, also elevate

TABLE 14.1   Summary of Current Clinical Biomarkers of Liver Toxicity

Biomarker	Tissue Localization	Injury	Specific Damage Marker	Comments
ALT	Primarily localized to liver	Elevated in blood because of liver necrosis and with heart and skeletal muscle injury (necrosis)	Hepatocellular necrosis	Commonly used to assess hepatocellular injury
AST	Localized in heart, brain, skeletal muscle, and liver	Elevated in blood because of liver or extra hepatic tissue injury	Hepatocellular Necrosis	Less specific than ALT
TBL	Taken up, conjugated in liver, and secreted into bile	Marker of hepatobiliary injury and liver function; also increased because of hemolysis	Cholestasis, biliary; Liver function	Conventional biliary injury; in conjunction with ALT, better indicator of disease severity in humans
ALP	Broad tissue localization	Marker of hepatobiliary injury	Cholestasis	Conventional biliary injury; associated with drug-induced cholestasis in humans
GGT	Activity localized more to kidney than liver, pancreas	Marker of hepatobiliary injury	Cholestasis, biliary	Conventional biliary injury; high sensitivity in humans, elevation can be caused by alcohol or heart disease
Albumin	Main constituent of serum total protein	Decreased in blood with chronic liver disease	Liver function	Liver fails to synthesize enough protein, especially albumin
Ammonia	Converted to less toxic urea in liver	Elevation in blood to liver injury	Liver function	Failure of the conversion in severe liver disease
Cholesterol/ triglycerides		Increased in blood because of the failure of bile elimination	Liver function	Liver fails to remove them to bile ducts
Clotting time		Increased with severe liver injury	Liver function	Liver fails to produce coagulation factors, increased clotting time; international normalized ratio equivalent to prothrombin time
Urobilinogen		Low level in urine because of biliary obstruction	Liver function	Colorless product of bilirubin reduction, similar role to bilirubin

ALP, alkaline phosphatase; *ALT,* alanine aminotransferase; *AST,* aspartate aminotransferase; *GGT,* gamma-glutamyltransferase; *TBL,* total bilirubin level.
Adapted from Ozer, J., Ratner, M., Shaw, M., et al., 2008. The current state of serum biomarkers of hepatotoxicity. Toxicology 245, 194–205.

ALP. Thus, it should not be regarded as a specific biomarker of cholestatic DILI but rather partially predictive of biliary obstruction during liver injury (Reust and Hall, 2001).

Total Bilirubin

Total bilirubin is a composite of unconjugated (extrahepatic) and conjugated (hepatic) bilirubin. Increased Total bilirubin level or TBL causes jaundice and can indicate metabolism problems in the liver such as reduced hepatocyte uptake, impaired bilirubin conjugation, or reduced bilirubin secretion (Greer, 2014). Therefore, serum bilirubin concentration is a real-time liver function biomarker, which measures the ability of the liver to clear bilirubin from the blood as it circulates through the liver. Although serum transaminase levels indicate the rate of enzyme release from injured cells, the TBL indicates rates of enzyme degradation (Senior, 2006).

Other Existing Hepatotoxicity Biomarkers

Although some liver function tests are not sufficiently sensitive to be used as diagnostic biomarkers of

hepatotoxicity, they are elevated in severe liver diseases and are indicative of liver injury. Therefore, these biomarkers are used primarily to confirm liver toxicity and indicate the extent of damage to liver function. Conventional biomarkers falling into this category are gamma-glutamyltransferase (GGT), serum total protein (albumin), ammonia, cholesterol/triglycerides, fibrinogen, prothrombin time, and urobilinogen (Greer, 2014).

Elevated serum GGT activity has a similar profile as ALP in detecting disease of the biliary system. Usually, ALP is the first test for biliary disease followed by GGT for providing a value to verify that the ALP elevations are due to biliary injury. Large quantities of alcohol intake can significantly increase the serum GGT level. Slightly elevated GGT is associated with myocardial infarction and heart failure (Betro and Edwards, 1973).

For both necrotic and obstructive liver diseases, serum total protein electrophoresis patterns are typically abnormal. In the acute stages of hepatitis, albumin is usually low and the γ-globulin fraction is elevated because of a huge increase in antibody production owing to the production of acute phase proteins. In addition, biliary cirrhosis may also cause β-globulin/antibody elevation. Similarly, blood ammonia, normally converted by the liver to less toxic urea, is elevated because of liver dysfunction. However, the liver has a high functional reserve for ammonia conversion, so it often takes a significant amount of injury to alter and detect changes in ammonia levels. Thus, blood ammonia elevations indicate end-stage liver disease and a high risk of hepatic coma.

During hepatic uptake of lipoprotein cholesterol, a portion is enzymatically converted to bile salt. Only hepatocytes have the rate-limiting enzyme, cholesterol 7α-hydroxylase, in the multistep conversion (Berkowitz et al., 1995). In acute hepatic necrosis, triglycerides may be elevated because of hepatic lipase deficiency. When the bile cannot be eliminated, cholesterol and triglycerides accumulate in the blood as low-density cholesterol. Additionally, as the liver is also responsible for production of blood coagulation factors, the clotting time increases because of impaired synthesis in the liver. However, it is not a sensitive biomarker because it only happens in the late stage of liver disease (Burtis et al., 2012).

Another insufficient biomarker is urobilinogen, a colorless product of bilirubin reduction in urine. Conversely, urobilinogen level can also indicate liver dysfunction. Low urine urobilinogen may result from biliary obstruction or complete obstructive jaundice. Because urobilinogen is formed in the intestine by bacteria, broad-spectrum antibiotic treatment can significantly decrease its level because of the damage of intestinal bacterial flora (Greer, 2014).

REVIEW OF EMERGING BIOMARKERS

There is a clear need to find additional biomarkers in serum and/or urine that can be measured in conjunction with ALT or outperform ALT with respect to specificity for liver injury. The omics methods (Table 14.2) are well suited to identify novel biomarkers of hepatotoxicity (Table 14.3) with desired specificity and sensitivity, with the potential to indicate injury earlier than the existing serum biomarkers.

Genetic Biomarkers of Hepatotoxicity

In the past 20 years, many GWAS have been conducted to test the association between genetic polymorphisms and DILI. Human leukocyte antigen (HLA) genotype has been established as a risk factor for DILI, including in drugs where immune-related toxicity was not suspected previously (Daly and Day, 2012). For example, in GWAS using DILI patients versus control subjects, HLA-B*5701 genotype was shown to be a major risk factor and ST6GAL1 as a possible cofactor of the individual vulnerability to flucloxacillin-induced DILI (Daly et al., 2009). As flucloxacillin-induced DILI occurs in 1 in 10,000 patients, it is estimated that screening for HLA-B*5701 would provide a positive predictive value of 0.12% (Alfirevic and Pirmohamed, 2012). At present, GWAS on DILI have focused either on drugs that are very widely prescribed or on those that are newly licensed; therefore, it is unclear if HLA genotype will be the strongest risk factor for DILI linked to a range of drugs. Another concern is that GWAS can reveal genetic determinants of DILI susceptibility, but they do not establish the mechanism of injury or identify individuals at imminent risk.

Genomics Biomarkers of Hepatotoxicity

Over the past decade, the use of a genomics approach to identify patterns of changes in mRNA transcripts, referred as toxicogenomics, has gained popularity for identification of novel DILI biomarkers (Yu et al., 2017). Most studies have employed microarray analysis of the rodent liver to identify unique gene expression profiles as biomarkers and elucidate the molecular mechanisms of DILI drugs. These genomics data sets, including multiple biomarkers, can be used to generate gene expression signatures associated with different drugs that cause liver injury. However, the use of liver tissue—based genomic biomarkers is not optimal because biomarkers requiring liver biopsy have limited value in a clinical setting, especially for monitoring DILI progress in patients. Thus, genomic biomarkers from a minimally invasive source, such as blood, have

TABLE 14.2 Common Platforms Used for Omics Biomarkers Discovery and Technical Challenges Associated With These Platforms

	Technological Platforms	Technical Challenges
Genetics	Genome Wide Association Study (GWAS)	• Weak associations of genetics biomarkers • Multiple polymorphic genes contribute to drug induced liver injury (DILI) • Pretreatment screening not cost-effective
Transcriptomics	Microarray	• Variability in sample storage and RNA isolation
	Quantitative real-time polymerase chain reaction (QRT-PCR)	• Lick of standard normalization method for circulating miRNAs
	Next-generation sequencing (NGS)	• Roles of miRNAs remain unclear
Proteomics	Matrix-assisted laser desorption/ionization tandem mass spectrometry (MALDI-MS/MS)	• Protein expression in constant flux • Large diversity and heterogeneity of proteome • Difficult to automate
	Sodium dodecyl sulfate polyacrylamide gel electrophoresis mass	• Wide dynamic range of cellular protein expression • Limited dynamic range and detection of MS platforms
	Spectrometry (Gels-MS)	• Relatively low throughput
Metabolomics	Nuclear magnetic resonance (NMR)	• Metabolites altered by diet and environment • Large diversity in chemical and physical properties
	Gas Chromatography/Mass Spectrometry (GC/MS)	• Wide range of chemical species requires multiple analytical platforms
	Liquid chromatography/mass spectrometry (LC/MS)	• Concentrations range over nine orders of magnitude
	Fourier transform infrared spectroscopy (FT-IR)	

Adapted from Yang et al. (2012).

been explored extensively in preclinical animals and humans. Interestingly, applying blood transcriptomic signatures generated from rodents to human blood data enabled differentiation of APAP overdose patients from healthy controls (Bushel et al., 2007). This study indicated that alterations in genes involved in an inflammatory response were the best discriminators between subtoxic/nontoxic and toxic exposure to APAP. In another study, a downregulation of mitochondrial genes involved in complex I of the oxidative phosphorylation pathway was seen in human blood samples after APAP exposure (Fannin et al., 2010). A comprehensive approach to demonstrate that transcriptomic signatures extracted from blood can predict liver injury caused by a wide variety of hepatotoxicants has been published (Huang et al., 2010).

Recently, next-generation sequencing (NGS) technologies have become available for fast, inexpensive sequencing of whole static genomes and dynamic transcriptomes (Goodwin et al., 2016). Although the microarray platform monitors the expression levels of most annotated genes within the cell, the powerful and rapidly evolving NGS technology allows for precise quantification of gene expression including transcripts that have not been sequenced previously. Initially, there was concern regarding the comparability of NGS to microarray platforms in terms of gene expression and biological variability in a real-life toxicological study design. The Microarray Quality Control group

evaluated the robustness of NGS for detecting differentially expressed genes and reported that both NGS and microarrays generate consistent biological interpretation (Su et al., 2011). However, the NGS data were fundamentally different from the microarray data, and translating these short sequences to genomic biomarkers must overcome several obstacles. One of the major challenges lies in the handling of immense volumes of NGS sequence data. Powerful bioinformatics tools are needed to assure sequence quality, conduct sequence alignment to the relevant genome and transcriptome, and provide biological interpretation from complex datasets. Over the past years, NGS has provided a more comprehensive understanding of complex transcriptomes, with turnaround time and cost comparable with those of microarrays (Goodwin et al., 2016). NGS technologies are anticipated to accelerate toxicogenomics research and play a pivotal role in identifying new DILI biomarkers.

Proteomic Biomarkers of Hepatotoxicity

Proteomics evaluates the differential protein expression between groups to determine novel protein biomarkers in toxicity and disease. Analyses involve a separation step, either gel based or gel free, followed by tandem mass spectrometry to identify proteins. To date, proteomics has successfully discovered several promising biomarkers of acute kidney injury (AKI), e.g., neutrophil gelatinase-associated lipocalin (NGAL),

TABLE 14.3 Summary of Emerging Biomarkers of Liver Toxicity

Biomarker Candidate	Biofluid Evaluated	Origin	Proposed Indication	Reference(s)
Cytokines	Plasma	Produced by all liver cells but primarily Kupffer cells	Cellular stress in the liver	Andrés et al. (2003), Ding et al. (2003a,b), Lacour et al. (2005), Steuerwald et al. (2013)
Interleukin-1	Plasma	Produced by a variety of cells	Cellular response to tissue damage	Akbay et al. (1999) Lacour et al. (2005)
Glutathione S-transferase P-form	Serum	Present in the hepatocytes	Hepatocellular injury	Fella et al. (2005), Glückmann et al. (2007)
Cytokeratin-18	Serum	Expressed by epithelial cells	Apoptosis or necrosis	Robles-Diaz et al. (2016)
High mobility group box protein I	Serum	Found in a wide range of tissues	Necrosis and inflammation	Robles-Diaz et al. (2016)
Glutamate dehydrogenase (GLDH)	Serum	Primarily found in the liver and to a lesser degree in the kidney and skeletal muscle	Hepatocellular necrosis	Robles-Diaz et al. (2016)
Malate dehydrogenase	Serum	Localized in mitochondria and extramitochondrial compartment; found primarily in liver but also in skeletal muscle, heart, and brain	Hepatocellular necrosis	Robles-Diaz et al. (2016)
Purine nucleoside phosphorylase	Serum	Primarily in the liver but also present in heart muscle and brain; mainly in cytoplasm of endothelial cells, Kupffer cells, and hepatocytes	Hepatocellular necrosis	Ozer et al. (2008), Robles-Diaz et al. (2016)
Paraoxanase 1	Serum	Produced primarily in the liver but also found in kidney, brain, and lung	Hepatocellular necrosis	Ozer et al. (2008), Robles-Diaz et al. (2016)
Glutathione S-transferase alpha	Serum	Liver specific	Hepatocellular necrosis	Ozer et al. (2008)
Apolipoprotein E	Serum	Produced in the liver but also found in brain and kidney	Hepatocellular necrosis	Robles-Diaz et al. (2016)
Bile acids	Urine, Serum	Synthesized primarily in the liver	Liver dysfunction including intrahepatic cholestasis	Xiong et al. (2014)
Ophthalmic acid	Serum	Analog of glutathione produced along a similar biosynthetic route as glutathione	Oxidative stress and glutathione depletion following hepatotoxic insult	Dello et al. (2013), Xiong et al. (2014)
5-Oxoproline	Urine, Serum	Intermediate in the synthesis of glutathione	Oxidative stress and glutathione status	Kumar et al. (2010), Xiong et al. (2014)
Steroids	Urine	Metabolites of cholesterol	Oxidative stress and liver damage	Kumar et al. (2012), Xiong et al. (2014)
Acylcarnitines	Urine, Serum	Located in heart, muscle, brain, liver, and kidney	Failure of fatty acid oxidation	Chen et al. (2009), Zhang et al. (2010)
Fatty acids	Serum	Nontissue specific	Disruption of fatty acid β-oxidation	Zhang et al. (2010)
miRNA-122	Plasma/serum	Liver-specific expression	Viral-, alcohol-, and chemical-induced liver injury; hepatocarcinoma	Ding et al. (2012), McGill and Jaeschke (2015), Robles-Diaz et al. (2016)
miRNA-192	Plasma/serum	Liver-specific expression	Chemical-induced liver injury	McGill and Jaeschke (2015)
miR-291a-5p	Urine	Unknown	Chemical-induced liver injury	McGill and Jaeschke (2015)

Adapted from Robles-Diaz, M., Medina-Caliz, I., Stephens, C., et al., 2016. Biomarkers in DILI: one more step forward. Front. Pharmacol. 7, 267 and Ozer, J., Ratner, M., Shaw, M., et al., 2008. The current state of serum biomarkers of hepatotoxicity. Toxicology 245, 194–205.

cystatin C (Cys C), kidney injury molecule-1 (KIM-1), liver-type fatty acids binding protein (L-FABP), and interleukin-18 (IL-18) (Gobe et al., 2015). These markers show promise as diagnostic markers and are being validated. The successful application of proteomics to determine more accurate biomarkers of AKI indicates the potential to also provide novel biomarkers of hepatotoxicity. There have been multiple literature reports of potential classes of protein biomarkers of hepatotoxicity.

One class of protein biomarkers includes the cytokines. The cytokines are generally associated with inflammation, immune reactivity, tissue injury or repair, and organ dysfunction and include interleukins, growth factors, interferons, tumor necrosis factors, and chemokines. All liver cells are capable of producing cytokines and the plasma levels may be indicative of cellular response (Laverty et al., 2010). Their production may be related to an initial toxic injury that activates Kupffer cells, a major source of cytokine production in the liver. The cytokine networks have been shown to mediate the hepatic response to diverse xenobiotics including APAP and PPAR ligands. However, the increase in cytokines is transient and declines rapidly, making it necessary to establish a time line over which they should be evaluated following dosing. IL-1 has been proposed to be a biomarker for liver toxicity (Lacour et al., 2005). IL-1 is a proinflammatory cytokine that can induce apoptosis, proliferation, and inflammatory processes. The activation of such proinflammatory cytokines can ultimately lead to activation of other processes, leading to generalized liver damage. The cellular stress response pathways are also activated in response to a toxic stimulus and either mount a homeostatic response or make cell fate decisions (Laverty et al., 2010; Simmons et al., 2009).

Amacher (2010) summarizes reported proteomic biomarkers associated with cellular stress response or toxicity pathways. Potential protein biomarkers of cellular stress response include proteins of the annexin family, anabolic and catabolic functions, and drug metabolism. The annexin family proteins act as calcium sensors and promote plasma membrane repair (Draeger et al., 2011). Additionally, carbonic anhydrase III, aflatoxin B1 aldehyde reductase, and GST-P, which play important roles in hepatocarcinogenicity, are reported in a study of chemically induced hepatocarcinogenesis (Fella et al., 2005).

Other potential protein markers of hepatocellular stress include the keratins and high mobility group box protein 1 (HMGB-1). Keratins are responsible for cell structure and integrity; the blood level of cytokeratin-18 (CK18) has been used to monitor apoptosis and necrosis (Cummings et al., 2008). HMGB-1 is proposed as a marker of inflammation as well as necrosis (Robles-Diaz et al., 2016). Similar to ALT and AST, these biomarkers are present in serum once hepatocytes have been damaged, thus resulting in leakage of the target protein into circulation (Ozer et al., 2008). However, all of these biomarkers are at early stages of development, and it remains to be determined whether they will be more selective than ALT and AST.

These emerging serum biomarkers include glutamate dehydrogenase (GLDH), purine nucleoside phosphorylase (PNP), malate dehydrogenase (MDH), paraoxonase 1 (PON1), sorbitol dehydrogenase, serum F protein, glutathione-S-transferase alpha (GSTα), and arginase I (Ozer et al., 2008). GLDH is a mitochondrial enzyme found primarily in the centrilobular region of the liver. GLDH plays a role in amino acid oxidation and serum activity increases with hepatocellular injury. GLDH activity is more liver specific than ALT and AST. In several recent studies, elevations of GLDH, similar to those observed with ALT, were reported in APAP-overdosed patients and patients receiving heparin. MDH catalyzes the reversible conversion of malate into oxaloacetate and is a constitutive enzyme in the citric acid cycle. MDH is a periportal enzyme whose release into the serum indicates tissue damage. Both GLDH and MDH levels are consistent in healthy populations, and they are strongly associated with elevated ALT in a broad range of liver injuries (Robles-Diaz et al., 2016).

PNP is an enzyme involved in purine metabolism and it is primarily located in the cytoplasm of endothelial cells, Kupffer cells, and hepatocytes. Several animal studies reported that PNP is released into hepatic sinusoids during liver damage in rodents. However, the value of PNP as a human liver injury biomarker has not been confirmed. PON1 is primarily produced in the liver and released into the circulation bound to high-density lipoproteins. Unlike other serum markers that indicate leakage, a decrease in PON1 is noted in serum after liver damage. Therefore, it is likely that liver damage reduces PON1 synthesis and secretion. PON1 is decreased after dosing with phenobarbital and APAP and in humans with chronic liver disease (Ozer et al., 2008). In a separate study evaluating the baseline level of emerging serum biomarkers, PON1 levels were found to be higher in African Americans compared with Caucasians (Robles-Diaz et al., 2016).

Although sorbitol dehydrogenase (SDH) is primarily located in the cytoplasm and mitochondria of liver, kidney, and seminal vesicles and is a marker of acute hepatocellular injury in rodents, serum F protein is a sensitive and specific marker of liver damage with a strong correlation to histopathology in humans. GSTα expression is restricted to liver and kidney and may serve as a region-specific marker of liver injury with a high concentration in centrilobular cells (Ozer et al., 2008).

An additional protein, serum arginase I, is highly liver specific and has been shown to have strong correlations to AST and ALT activities (Ozer et al., 2008). Finally,

apolipoprotein E (APOE) expression has been linked to hepatotoxicity in two separate studies. APOE is protein synthesized and secreted by hepatocytes with its major function being transport and distribution of lipids and cholesterol to cells. Therefore, it has a major role in determining the metabolic fate of lipids and proteins.

A hepatotoxicity protein biomarker panel based on a targeted proteomics approach has been developed for use in pharmaceutical toxicology assessment (Collins et al., 2012). The selected reaction monitoring (SRM) proteomics panel was developed in part based on the hepatotoxicity biomarkers reported within the review by Amacher (2010). In total, the panel contained 48 biomarker candidates from multiple pathways including, but not limited to, xenobiotic metabolism, PPARα/PXR activation, fatty acid metabolism, and oxidative stress. This proof of principle study demonstrated the ability to develop a robust, high-throughput, customizable SRM assay to evaluate putative protein markers of hepatotoxicity.

Metabolomics Biomarkers in Hepatotoxicity

Metabolomics involves the measurement of the metabolite pool that exists within a cell or tissue under a particular set of cellular conditions. The metabolic profile is greatly influenced by both genetic and environmental factors, thereby providing phenotype-specific data that can be evaluated in a longitudinal manner. Metabolomics analyses focus on the discovery of novel, clinically relevant biomarkers in easily obtained biofluids such as urine and serum. The major analytical platforms for metabolomics include nuclear magnetic resonance (NMR) spectroscopy and liquid chromatography (LC)−mass spectrometry (MS). As hepatotoxicity is the major cause for drug-related adverse events, metabolomics has been employed in multiple preclinical studies to identify more selective markers of DILI.

Metabolites from several major pathways, e.g., bile acids (BAs), are reported in multiple studies. Synthesis, secretion, and recycling of BAs are critical functions of the liver. The BAs are important signaling molecules in liver and intestine, and accumulation of BAs due to impaired secretion or biliary obstruction can cause hepatocyte damage. Multiple studies of hepatotoxicity have noted altered profiles of BAs. Because galactosamine is a known hepatotoxin, a targeted LC-MS method was employed to investigate the metabolic effects of galactosamine by rapidly profiling BAs. Galactosamine administration significantly increased taurine- and glycine-conjugated BAs in rat serum (Want et al., 2010).

Similarly, other hepatotoxicants also alter BA profiles and have shown distinct mechanism-based patterns of changes (Coen, 2010). APAP, carbon tetrachloride (CCl4), and α-naphthylisothiocyanate (ANIT) are classical hepatotoxicants that induce altered BA profiles after a toxic dose. APAP and CCl4 increased urinary cholic acid and lithocholic acid (Kumar et al., 2012). CCl4 and ANIT induced liver failure and elevated the serum levels of BAs compared to control (Yang et al., 2008). These compounds cause distinct types of liver injury and showed different patterns of altered BAs.

Isoniazid, which is used in the prevention and treatment of tuberculosis, is also hepatotoxic, and a study of serum metabolome in wildtype and Cyp2e1-null mice indicated that accumulation of BAs and free fatty acids may play a role in isoniazid-induced hepatotoxicity (Cheng et al., 2013). In a study of APAP-induced toxicity, increases in serum BAs concurrent with a decrease in the expression of BA synthesis-related genes (Cyp7a1 and Cyp8b1) and cholesterol transporter gene (Abcg8) and increases in the expression of BA transporter genes (Mrp3 and Mrp4) suggested a mild form of intrahepatic cholestasis (Sun et al., 2013). The aforementioned results indicate that BAs may be a sensitive marker of DILI. Additionally, the specific BAs may be able to differentiate specific types of liver injury.

Hepatotoxicants that form reactive metabolites generally induce an oxidative stress response ultimately resulting in cell death. GSH is a protective molecule that is consumed as it scavenges ROS to prevent cellular damage. GSH production proceeds through the folate-dependent transmethylation and transsulfuration pathways and thus, intermediaries in these pathways may serve as biomarkers of hepatotoxicants-induced oxidative stress. One such molecule is ophthalmic acid (OA), an analog of GSH in which the cysteine residue is replaced by 2-aminobutyrate. The synthesis of OA is catalyzed by the same enzymes that synthesize GSH, γ-glutamylcysteine synthetase (Gcl), and glutathione synthetase. The depletion of GSH may activate Gcl and correspondingly increase the synthesis of OA.

In a study of APAP hepatotoxicity in a mouse model, serum OA was linked to APAP-induced oxidative stress and GSH depletion. GSH depletion occurred with a concomitant increase in OA suggesting that the OA biosynthetic pathway had been upregulated (Dello et al., 2013). However, more studies are needed to fully understand the relationship between OA and the multiple stages of liver damage. Nevertheless, the multiple biosynthetic pathways involved in the biosynthesis of GSH and OA make it difficult to clearly understand the relationship between the two molecules and the oxidative stress response. 5-Oxoproline (5-OP; pyroglutamate) is an intermediate in the GSH biosynthesis pathway, and it may be more directly related to GSH content and cell status than OA. Hepatotoxicants such as APAP (Emmett, 2014), bromobenzene (Waters et al.,

2006), and ethionine (Skordi et al., 2007) induce elevations of 5-OP in biofluids and tissues in animal studies. These drugs are known to induce oxidative stress and deplete GSH. Increased 5-OP is seen in humans with inborn errors of metabolism that affect GSH synthesis, indicating its direct relation with GSH (Tokatli et al., 2007). Chronic use of APAP can also elevate 5-OP because of metabolic acidosis (Duewall et al., 2010). 5-OP is increased in human liver epithelial cells following exposure to APAP, whereas cellular GSH content is decreased (Dello et al., 2013). GSH consumption also occurs in hydrazine-induced hepatotoxicity, and 5-OP is increased in a dose-dependent manner in urine, plasma, and liver tissue (Bando et al., 2011). Based on available literature, 5-OP appears to be directly coupled to GSH depletion and, therefore, may be more reflective of GSH status than OA.

Kumar et al. (2012) employed a global profiling method for the initial discovery of potential urinary biomarkers of APAP, CCl4, and methotrexate-induced hepatotoxicity. BAs, steroids, and amino acids were selected as liver toxicity biomarkers. In the hydrazine-induced hepatotoxicity study, multiple amino acids were elevated in urine and plasma (Bando et al., 2011). These included the amino acid precursors of GSH, cysteine, glutamine, and glycine. The amino acid changes were associated with hydrazine-induced fatty acid degeneration and glycogen depletion in the liver. Amino acid metabolism was also altered in response to bromobenzene- and galactosamine-induced hepatic necrosis (Gonzalez et al., 2012). A metabolic profiling study of changes in rat urine related to dosing with the compound atorvastatin identified estrone, cortisone, proline, cystine, 3-ureidopropionic acid, and histidine as markers of liver toxicity (Kumar et al., 2012). Metabolic profiling identified 3-hydroxy-20-deoxyguanosine and octanoylcarnitine as urinary markers of valproic acid−induced hepatotoxicity in rats (Lee et al., 2009). APAP is known to inhibit fatty acid beta-oxidation; therefore, Chen et al. (2009) evaluated metabolites specifically related to this pathway in mouse serum. The results were consistent with a disruption of fatty acid β-oxidation with an accumulation of long-chain acylcarnitines and free fatty acids in serum. The pattern of accumulation of acylcarnitines in the above study indicated that they might be useful as complementary biomarkers for monitoring APAP-induced hepatotoxicity or other compounds that disrupt fatty acid β-oxidation. Other studies of APAP hepatotoxicity have also reported altered fatty acids and acylcarnitines (Bi et al., 2013; Xiong et al., 2014). Multiple biological matrices were evaluated by NMR after exposure of rats to aflatoxin-B1 (AFB1) (Zhang et al., 2010). Significant elevations in amino acids in plasma and liver tissue indicated that AFB1 altered protein biosynthesis. Hence, BAs, 5-OP, and OA, fatty acids, amino acids, and steroids are promising potential markers of hepatotoxicity that warrant further investigation.

A subset of metabolomics referred to as metabolomics flux analysis evaluates real-time synthesis and turnover rates in specific pathways through use of a ^{13}C-labeled precursor. Stable isotope ^{13}C-labeled glucose was used to investigate the toxic effects of valproic acid (VPA) on the plasma, urine, liver, brain, and kidney metabolites (Beger et al., 2009). Results indicated that VPA disrupted the flux of acetate and its disposal via plasma cholesterol, causing liver toxicity. Usnic acid, a dietary supplement promoted for weight loss, was shown to be cytotoxic to rat primary hepatocytes in a time- and concentration-dependent manner and isotopomer distributions from flux analysis indicated a reduction in oxidative phosphorylation and gluconeogenesis at the high dose. The results from flux analysis of ^{13}C-labeled glucose were consistent with cytotoxicity and ATP depletion in the cells. Lately, Fan et al. (2012) reviewed stable isotope-resolved metabolomics and potential clinical applications.

MicroRNAs as Biomarkers of Hepatotoxicity

MicroRNAs (miRNAs) are ∼22 nucleotides long, single-stranded, noncoding RNAs that have recently been recognized as novel agents exercising posttranscriptional control over most eukaryotic genomes. miRNAs are highly conserved among species, ranging from worms to humans, revealing their very ancient hierarchy. The human genome has been predicted to encode over 2000 miRNAs, which are usually produced in a cell- or tissue-specific manner and are predicted to regulate the activity of ∼60% of human genes (Friedman et al., 2009). Owing to their minimally invasive nature and unique stability in different body fluids, miRNAs in biofluids hold a unique position for use as a preclinical and clinical DILI biomarker (Weber et al., 2010). Using an APAP-induced mouse model of DILI, Wang et al. (2009) reported that the level of many plasma miRNAs inversely correlated with hepatic miRNAs, indicating that hepatic injury caused the release of miRNAs into the circulation. Specifically, miRNA-122 and miRNA-192, which are predominantly expressed in the liver, increased in the plasma with concurrent decrease in the liver. The increases in both miRNAs were detected earlier than the increase of ALT. The increase of serum miRNA-122 and miRNA-192 was confirmed later in patients with APAP poisoning (Starkey Lewis et al., 2011). The change in miRNA-122 was significantly smaller in serum from patients with liver injury due to hepatitis or hepatocarcinoma (Ding et al., 2012). Although the functions of the 10 common miRNAs remain unknown,

the possible target genes of these miRNAs are related to cell death, cell-to-cell signaling, and major metabolic pathways.

BIOMARKER QUALIFICATION AND VALIDATION

Applying omics-based technologies in rodents treated with a variety of hepatotoxic drugs, together with a better understanding of the hepatotoxicity mechanisms, may facilitate the identification of novel DILI biomarkers. However, it is worthwhile to point out that none of the new DILI biomarkers has been qualified for preclinical or clinical use from a regulatory perspective. Many of the potential biomarkers discussed in this chapter are not necessarily liver specific and could be a result of other tissue injury. True qualification of new biomarkers will ultimately require large numbers of samples from animals and patients treated with many different drugs.

A stringent qualification process is required to validate their specificity and sensitivity for DILI before they can supplement or replace existing biomarkers. Qualification has been described as "the process of linking a biomarker to a preclinical or clinical end point or to a biological process in a specific context" (Wagner, 2008). FDA and ICH have issued guidance on biomarker qualification and the content of data submissions. These guidance documents provide a foundation for qualifying a biomarker for a given context of use, such as preclinical versus clinical. Although specific testing and qualification plans are not provided in the guidance documents, they do highlight the need for robust data to develop a new biomarker (Food and Administration, 2011).

Nevertheless, a biomarker will require a clearly defined context of use as well as sufficient data to support a full review of its performance characteristics within that context. It is required that the biomarker be measured reliably on multiple analytical platforms. Finally, to successfully translate a biomarker from the preclinical to the clinical setting, the marker must be qualified for its intended use and should correlate with lesions observed by histopathology. As part of the qualification process, it will be necessary to quantify a marker and provide a range of normal values in a control state. Metabolomics biomarkers can be quantified by mass spectrometry based on a calibration curve or comparison of intensities after spiking a sample with an isotope-labeled standard. NMR metabolite data are quantified based on the concentration of an internal chemical shift standard. Protein biomarkers can also be quantified by mass spectrometry methods that include a labeling procedure and tandem MS analysis. A Bradford assay can be used for quantification of protein. Gene or miRNA biomarkers can be quantified using real-time polymerase chain reaction (PCR), microarray, and NGS platforms based on fluorescence signals.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

DILI is a major cause for limiting the use of a drug or its removal from the market. At present, the current DILI biomarkers sometimes fail to identify a toxic compound in the preclinical development stages and even in clinical trials. Among the existing biomarkers, ALT and AST are general indicators of hepatocellular injury; ALP is reflective of the cholestatic DILI and elevated TBL is associated with increased DILI severity. The omics technologies are well suited to identify novel biomarkers of DILI that can be measured in easily obtained biofluids. Genomics, proteomics, and metabolomics methodologies have produced many candidate DILI biomarkers for future investigations. In many cases, the same markers have been noted in multiple studies with overlapping cellular pathways such as GSH depletion as an initial response to a cellular stress. The measurement of circulating miRNAs has appeared to be promising in identifying new biomarkers of liver injury. Further studies are needed to evaluate the sensitivity and specificity of the emerging biomarkers as well as to validate the omics biomarkers to develop tests that are clinically useful and cost-effective.

Conventional and Emerging Renal Biomarkers

Sue M. Ford

Department of Pharmaceutical Sciences, College of Pharmacy & Health Sciences, St. John's University, Jamaica, NY, United States

INTRODUCTION

Determination of renal status and prognostication of the course of disease are important in clinical practice due to the human and economic costs of kidney diseases. Approximately 30 million adults (14.8%) have chronic kidney disease (CKD), many of whom are unaware that they have the condition (Centers for Disease Control and Prevention, 2017). Tremendous variability in etiology and severity of the underlying abnormalities can confound detection and diagnosis. The traditional clinical tools for assessing renal function are often inadequate for exposing early or mild impairment and lack specificity for evaluating injury, and the search for sensitive and specific clinical biomarkers of renal injury has increased dramatically in the past 20 years. Improved biomarkers are also needed for field screening and studies of populations at risk from exposure to environmental contaminants or toxins. Drug development is another area in which biomarker exploration has been extensive. Early recognition of nephrotoxic liability in preclinical studies allows pharmaceutical companies to eliminate less-promising drug candidates at the earliest stage possible. In addition, researchers studying the underlying mechanisms of nephrotoxic agents need reliable and expedient ways to assess kidney function in laboratory animals.

The complexity of the kidneys presents numerous challenges in assessing renal status. The kidneys are sensitive to events such as exposure to toxic chemicals, low perfusion, immune system activity, and prerenal pathological conditions such as diabetes, each of which may affect renal structure and function in distinct ways. Until recently, the term acute renal failure (ARF) was used to describe a myriad of conditions with inadequate standardization of clinical definitions, making it difficult to satisfactorily compare reports in the literature (Kellum and Hoste, 2008). However, two developments have provided structure to classification of renal impairment. First, standard criteria for stages of renal dysfunction were established. In 2003, guidelines for CKD were published (Eknoyan, 2012; Levey et al., 2003) defining it as kidney damage or glomerular filtration rate (GFR) less than 60 mL/min for more than 3 months. Classification guidelines for acute kidney injury were proposed in 2004. Termed the RIFLE classification, the stages are Risk—Injury—Failure—Loss—End-stage renal disease (Cruz et al., 2009). The criteria for assigning the stages are based on change in blood creatinine or GFR and urine flow rates during a specified interval (6, 12, or 24 h). In 2007 the acute kidney injury network proposed a classification based on modification of RIFLE; this system is referred to as the AKIN classification and is based on changes in serum creatinine and the urine output during the specified time. The Kidney Disease: Improving Global Outcomes (KDIGO) working group proposed a set of criteria that are a combination of RIFLE and AKIN (Kellum et al., 2012). The recognition that newer biomarkers need to be developed and incorporated into the AKI staging framework was formalized at the 10th Acute Dialysis Quality Initiative (ADQI) Consensus Conference (Murray et al., 2014). The other significant development was a change in terminology from *acute renal failure* to *acute kidney injury*. Acute kidney injury (AKI) now encompasses the spectrum of renal impairment, from subtle pathological and/or structural changes not detectable with current functional measurements to the extreme of severe dysfunction (Kellum and Hoste, 2008).

CHARACTERISTICS OF BIOMARKERS

Renal biomarkers have been categorized into "traditional" and "novel," although several of the "novel"

TABLE 15.1 Selection Characteristics for Biomarkers

Sensitivity	Responsiveness to changes in the quantity of the parameter
Specificity	Responsive only to the desired parameter
Interference by coexisting conditions	Disease, medications
Interference by physiological variables	Age, sex, body mass
Analytical considerations	Including cost, time, validation, analytical sensitivity and specificity

biomarkers have been used for at least a decade. Generally the traditional markers are indices of function, whereas newer biomarkers have been developed to detect injury, serving as signals for specific damage such as tubular necrosis or damage to the glomerulus. Renal biomarkers may be used to evaluate current status, to monitor function over time, or to predict the risk for decline in renal function (Table 15.1).

TRADITIONAL BIOMARKERS

Traditional assessments of kidney function have relied on blood and urinary parameters that reflect functional parameters such as GFR and/or renal blood flow (blood urea nitrogen, creatinine), glomerular patency (albuminuria), tubular function (β-microglobulinuria), or concentrating ability (polyuria). However, some of the most common are affected by extrarenal events and should be interpreted with consideration of the individual patient. Blood urea nitrogen (BUN) levels are related to diet, creatinine production is altered during increased muscle turnover, and urine output is affected by the state of hydration and possible endocrine diseases. The traditional biomarkers have several disadvantages for clinical assessment, most notably that they are able to reveal changes in function or structure only after significant damage has occurred. However, they still can be useful in monitoring the status of patients with CKD (Pena et al., 2017).

Glomerular Filtration Rate

The parameter most watched clinically is GFR, which can be determined by the renal clearance of model compounds. The model compounds should be freely filtered at the glomerulus and neither reabsorbed nor secreted in the tubule. The equation for renal clearance is $Cl = (Cu \times Q)/Cp$, where Cu is the concentration of the compound in urine, Q is the urine flow rate, and Cp is the concentration in plasma. There are several compounds that can be used for measured GFR (mGFR) include inulin, ^{125}I-iothalamate, or ^{51}Cr-EDTA. Obtaining a measured GFR is the preferred approach but impractical on a routine basis, so that endogenous molecules are used. For noncritical routine estimates, serum BUN is used as an indicator of renal function. The production of urea is sufficiently constant to provide a reasonable index of renal function, with serum BUN being inversely proportional to GFR. Urea is reabsorbed in the nephron back into the bloodstream, which compromises its value as a biomarker; nonetheless, it is easy to measure and well established.

Creatinine has been the mainstay for assessing renal function and GFR clinically. Creatinine has the advantages of being produced at a constant rate, freely filtered, and not being reabsorbed. There are several problems with creatinine including that its production and plasma concentration can be increased during excessive muscle breakdown or decreased following prolonged illness and loss of muscle mass. Nonetheless, serum creatinine (sCr) is routinely measured as a renal function test and can be a valuable index when renal dysfunction is anticipated, such as monitoring kidney function when nephrotoxic drugs are used (Caires et al., 2019). A more robust value is creatinine clearance (Clcr), which can be used to provide an estimated GFR (eGFR), requiring a serum creatinine value and a timed urine sample. Various equations that correct for secretion, age, and sex have been developed, so that Clcr and eGFR are the recommended parameters for clinical evaluation of glomerular filtration. Another endogenous molecule that is increasingly being used as an indicator of GFR is cystatin C (discussed later in the chapter).

The options for evaluating GFR in patients at risk have increased over the years, and it is important to understand the advantages and limitations of the various methods (Schaeffner, 2017). BUN and sCr are easy and inexpensive methods; however, the kidneys have significant reserve capacity and measuring renal dysfunction with eGFR may be insensitive, often showing abnormalities only after considerable renal function is lost. In addition, there is variability among criteria in the standard guidelines (RIFLE, AKIN, KDIGO), and some judgment in use may be advised. For example, increases in sCr that were smaller than recommended clinical guidelines were shown to be correlated with poor renal outcomes after surgery (Machado et al., 2014, Tolpin et al., 2012).

Proteinuria

The glomerular capillaries are the barrier to distribution of large plasma proteins into urine. Large proteins

such as albumin and IgM are impeded by the capillaries, whereas smaller proteins pass through the filtration barrier into the tubular fluid. In normal kidneys, only small amounts of large proteins such as albumin and IgM are filtered, most of which is degraded by the proximal tubule epithelium. Smaller proteins and peptides are filtered across the glomerular barrier depending on size, charge, and configuration and then degraded in the tubules. Consequently, there is generally little protein detectable in the urine of humans with healthy kidneys. Proteinuria may occur due to pathology of the glomerular filtration barrier, as in the case of the nephrotic syndrome, as well as damage to the proximal tubule. The type of protein in the urine can be diagnostic of the site of injury. Glomerular damage may result in large proteins appearing in the urine, which overwhelms the modest ability of the proximal tubule to remove them; in contrast, injury to the proximal tubule will impair the ability to remove smaller proteins such as β2-microglobulin or retinal binding protein from the tubular fluid. Thus, if glomerular filtration is reduced, β2-microglobulin will increase in the blood, whereas if the proximal tubule cells are damaged, β2-microglobulin will be found in the urine.

Urinary albumin is a more conventional marker of renal dysfunction, particularly CKD, which may still find utility in AKI as an adjunct to the primary classification systems (Bolisetty and Agarwal, 2011; Sugimoto et al., 2016). In fact, a recent analysis of preadmission data for patients with dialysis-requiring AKI indicated that the level of proteinuria (dipstick) was correlated with the risk of nonrecovery (Lee et al., 2018). Several specific proteins are currently being used as indices of renal dysfunction either individually (see following sections) or as part of biomarker panels (Chen et al., 2017a), and application of proteomics profiling with mass spectroscopy techniques may facilitate the identification of new biomarker candidates (Chen et al., 2017b).

Enzymuria

Enzymes released from damaged cells of the tubule have been used as markers of injury inasmuch as appearance of these enzymes in the urine is specific to kidney and they have been used in research with laboratory animals for several decades. The brush border enzymes alkaline phosphatase (AP), γ-glutamyltranspeptidase (GGT), the lysosomal enzyme N-acetyl-β-glucosaminidase (NAG), and isoforms of the cytoplasmic enzyme glutathione-S-transferase may be detected in the urine following tubular injury. Although their use for human studies has been minimal, in the future they may be valuable as part of a biomarker panel.

NEWER BIOMARKERS

Cystatin C

Cystatin C was first observed in 1961 as a "post-γ" protein detected in small amounts in the serum and urine of humans. Its presence in urine of the patients was clearly associated with renal tubular dysfunction (Butler and Flynn, 1961). The protein was sequenced and characterized in 1982 by A. Grubb, although the function was as yet unknown (Grubb and Löfberg, 1982). It was recognized as a cysteine protease inhibitor (Barrett et al., 1984; Turk and Bode, 1991), homologous with chicken cystatin (Filler et al., 2005) and renamed cystatin C (Barrett et al., 1984). Investigation of cystatin C as an indicator of GFR began as early as the mid-1980s. Cystatin C has characteristics that make it a good candidate as both an index of function (GFR) and tubular injury. It is produced by all nucleated cells at a constant rate and is cleared only by the kidneys. It is a low−molecular weight (13.3 kDa) basic protein and thereby freely filterable at the glomerulus. It is not secreted, and although it is reabsorbed by proximal tubule epithelia, it is completely catabolized within the cells and does not re-enter the plasma (Filler et al., 2005).

Because of these features, the plasma levels of cystatin C are inversely related to GFR, so that it has long been recognized that increased cystatin C plasma or serum levels reflect decreased GFR (Grubb, 1992). eGFR values calculated with serum cystatin C have been shown to correlate with 24-h creatinine clearance (Diego et al., 2016) and iohexol clearance (Schwartz et al., 2012). Whereas serum cystatin C is an index of GFR, urinary cystatin C has potential as a tubular injury marker because its presence in the urine in the absence of massive proteinuria would indicate tubular damage.

As with other biomarkers, there are some limitations that should be noted. Cystatin C has been shown to be influenced by large doses of glucocorticoids and thyroid dysfunction; such factors may influence the lack of specificity for AKI noted in a study of critically ill children (Safdar et al., 2016). Unlike creatinine, which can be measured in both serum and urine, cystatin C appears at very low levels in the urine of normal kidneys so that estimates of eGFR with cystatin use only the serum concentration. The production of cystatin C should be constant, but on a population basis, serum values have been correlated with physiological factors such as diabetes, body size, and inflammation (Grubb et al., 2011; Shlipak et al., 2006; Stevens et al., 2009; Zeng et al., 2017; Zhang et al., 2017). In addition, there are reports of large intraindividual variability compared to creatinine, which would limit its usefulness in monitoring individuals over time (Filler et al., 2005; Keevil et al., 1998). As with other clinical indices

of GFR, knowledge of such factors will aid interpretation of the results and selection of the appropriate equations (Lassus and Harjola, 2012).

Cystatin C was more closely related to GFR changes in diabetics than was serum creatinine (Shlipak et al., 2006). Herget-Rosenthal et al. (2004) selected 85 patients in intensive care who, though starting with normal measures of renal function, were at risk for AKI due to various causes such as ischemia, prerenal disease (e.g., diabetes), nephrotoxicity, or sepsis. Their status was categorized according to the RIFLE criteria. Serum cystatin C in this study was found to detect the development of AKI 1 to 2 days earlier than serum creatinine. In contrast, Royakkers et al. (2011) concluded that serum or urine cystatin C values were poor indicators for the development of AKI. In a study of patients who ingested toxic chemicals, serum cystatin C responded later and underestimated the extent of AKI (Wijerathna et al., 2017). Serum cystatin C was more closely associated with development and worsening of AKI than serum creatinine in ICU patients with sepsis (Leem et al., 2017) but was not superior to sCr in a different adult ICU population (Diego et al., 2016). The utility of cystatin C to evaluate the renal function of neonates shows promise (Askenazi et al., 2012), although there are few validation studies (Kandasamy et al., 2013).

Neutrophil Gelatinase—Associated Lipocalin

Neutrophil gelatinase—associated lipocalin (NGAL) is a 25-kDa polypeptide that is produced in numerous tissues and in laboratory animals. It was discovered as a protein secreted by neutrophils and bound to gelatinase (Kjeldsen et al., 1993). Lipocalin proteins bind and transport small molecules, and it is believed that one of the important functions of NGAL is the binding of bacterial siderophores and the transport of iron into cells (Singer et al., 2013). NGAL can be induced in both neutrophils and epithelia by various stimuli including inflammation, infections, and neoplasia. It has been shown to have protective functions against infection and ischemic kidney injury (Ma et al., 2011). It may play a role in repair of damaged proximal tubule epithelia, although the nature of the NGAL involvement—contributor to injury or repair effector—is unclear (Lippi and Cervellin, 2013; Mishra et al., 2003).

In healthy individuals NGAL is expressed at low levels in various tissues, filtered at the glomerulus, and then reabsorbed by the proximal tubule

(Chakraborty et al., 2012; Charlton et al., 2014; Singer et al., 2013). It is resistant to proteases (Kjeldsen et al., 1993; Mishra et al., 2003), which increases its stability before assay. NGAL is expressed by several tissues, including the nephron, in response to various pathological conditions (Singer et al., 2013). Using microarray technology, Mishra et al. (2003) identified NGAL as one of the genes upregulated in the mouse kidney within the first few hours after ischemic injury. Histochemical staining showed that NGAL protein was barely detectable in the kidneys of naïve mice but was upregulated in the proximal tubules within 3 h of ischemia. Following AKI, NGAL production is induced in the distal segments of the nephron, and it is released into the blood and lumen, resulting in elevation of both blood and urine levels (Tecson et al., 2017). In addition to increasing renal production of NGAL following injury, damage to the nephron may enhance NGAL presence in the urine by impairing proximal tubular reabsorption.

Serum NGAL has been shown to be associated with various causes of renal dysfunction including type 2 diabetes (Bacci et al., 2017), toxic injury (Luo et al., 2016), and high-salt diet in rodents (Washino et al., 2018). NGAL appeared in the urine of rats before other renal injury markers of ischemia, such as N-acetyl-β-D-glucosaminidase and β2-microglobulin (Mishra et al., 2003). They also demonstrated that NGAL was released into the media of cultured human proximal tubule cells depleted of ATP and could be detected in the urine of mice treated with the nephrotoxicant cisplatin.

NGAL can be detected in as little as 1 μL of urine. There are a number of validated clinical analytical platforms that allow results in 15—30 min (Hassanzadeh et al., 2015) Its concentration may increase 10,000-fold in response to injury, whereas in plasma the increase may be up to 100-fold (Lippi and Plebani, 2012). There are complicating factors that must be considered when interpreting NGAL data. For example, nonrenal sources such as neutrophils or urinary tract infections with leukocyturia may contribute to its concentration in some cases.

Kidney Injury Molecule-1

Kidney Injury Molecule-1 (KIM-1)[1] is a 104-kDa membrane protein resembling certain cell adhesion molecules (Ichimura et al., 1998). It is not detectable in normal kidneys but is expressed at high levels on the apical surface of proximal tubule cells following injury

---

[1] KIM-1 refers to the human form of the molecule, and Kim-1 refers to the rat form. Although there are amino acid sequence differences (654), this chapter will use KIM-1 for all species in discussing its use as a biomarker, except when studies cited specify Kim-1 or there is a notable species difference in human—animal performance. As a consequence of its independent discovery and naming by immunologists, KIM-1 is also referred to as TIM-1 (Rees and Kain, 2008).

or in certain types of renal carcinoma. Structurally, each molecule of KIM-1 has extracellular mucin and immunoglobulin domains (Ichimura et al., 1998), which comprise an ectodomain that is constitutively shed by metalloproteinase cleavage (Bailly et al., 2002; Lim et al., 2012). This process is increased by human serum albumin or TNF-α (Blasco et al., 2011). The dedifferentiation and proliferation of proximal tubules which are noted after injury, result in increased KIM-1 and its fragments in urine, leading to its use as an injury biomarker (Ichimura et al., 2004). A number of possible functions for KIM-1 in post—injury repair processes have been proposed, including regulation of adhesion of cells to the tubular basement membrane (Bailly et al., 2002), cell motility to facilitate covering denuded areas of the tubule (Ichimura et al., 1998), and inducing epithelial cells to take on phagocytic characteristics to remove dead cells (Ichimura et al., 2008; Rees and Kain, 2008). However, the question of whether KIM-1, such as NGAL, may actually contribute to the development of renal injury has been raised (Lim et al., 2013).

In rat kidneys subjected to reperfusion or toxicant injury, Kim-1 expression was found to be specific to proliferating cells in the S3 segment of the proximal tubule, with little response in the convoluted section (Ichimura et al., 1998, 2004). The magnitude of the increase was greater than and preceded any increase in serum creatinine, urinary NAG, or proteinuria (Sabbisetti et al., 2013). KIM-1 immunohistochemical staining of biopsy was more sensitive than histology for detecting tubular injury in transplanted kidneys (Zhang et al., 2008).

The possible beneficial role of KIM-1 in tissue repair is bolstered by the study of Zhang et al. (2008) revealing that KIM-1 staining from patients with biopsies showing acute tubular injury was correlated with recovery 18 months later. The group with higher KIM-1 staining scores had greater recovery, measured by BUN, serum creatinine, and estimated GFR. In contrast, Jin et al. (2013) observed that high serum levels of KIM-1 were correlated with lower survival rates, and a similar result was noted for urinary KIM-1 excretion (van Timmeren et al., 2007).

Urinary KIM-1 correlated well with blood lead levels in an occupational setting suggesting that it may be useful in early diagnosis of kidney injury in workers (Zhou et al., 2016a). A study of patients whose kidneys were subjected to ischemia during partial nephrectomy for renal cancer shows that urinary NGAL and KIM-1 were elevated within 1 h (Abassi et al., 2013). The levels remained high for 72 h for NGAL and 24 h for KIM-1 suggesting that NGAL can be a more reliable indicator of AKI in these patients. Similarly, whereas urinary NGAL correlated with CKD in a human population (Bhavsar et al., 2012) or tubular damage from a high-salt diet in WKY rats (Washino et al., 2018), KIM-1 did not in either case. The use of KIM-1 as an index or a predictor of renal status may depend on the conditions and calculations in which the value is used. For example, Helmersson-Karlqvist et al. (2016) studied day-to-day variability of urinary cystatin C and KIM-1 in healthy senior citizens (average age 75) and concluded that adjustment of uKIM-1 by uCr is advisable, particularly when spot urines are used. Koyner et al. (2015) observed that for cardiac surgery patients, the postoperative association between biomarkers such as KIM-1 with AKI is influenced by the preoperative eGFR.

Interleukin 18

Interleukin 18 (IL-18) is a widely distributed cytokine. It exists in a precursor form until cleaved by caspase-1 after which it has proinflammatory actions. In the normal human kidney it is found primarily in the distal segments of the nephron (Gauer et al., 2007) and is upregulated, including in the proximal tubule, following AKI and CKD (Liang et al., 2007). IL-18 appears to have a contributory role in the development of several types of renal injury, including lipopolysaccharide LPS-induced AKI (Nozaki et al., 2017) and ischemia (Melnikov et al., 2001). Numerous reports suggest that urinary IL-18 is significantly increased in various types of renal injury, including ischemia, posttransplantation acute tubular necrosis, liver cirrhosis, and cancer chemotherapy (Leslie and Meldrum, 2008; Puthumana et al., 2017; Zubowska et al., 2013). The specificity and sensitivity of IL-18 detection in these conditions suggest it has great potential as an early biomarker of injury. However, interpretation of IL-18 may be confounded by coexisting conditions such as sepsis (Li et al., 2013).

Liver-type Fatty Acid Binding Protein

Fatty acid binding proteins comprise a family of small proteins, which include the liver-type fatty acid binding protein (L-FABP; FABP-1). They are expressed in several tissues besides the liver, including the renal proximal tubules. L-FABP orchestrates the transport of fatty acids into mitochondria and peroxisomes for energy metabolism. In the kidneys it binds the breakdown products of lipid peroxidation facilitating their excretion into the urine, preventing damage by reactive oxygen species (Xu et al., 2015). L-FABP is released into the urine following different types of injury and has been extensively studied as biomarkers. The serum concentrations of these proteins increase in renal injury, which is convenient for cases where urine volume is drastically reduced. L-FABP concentrations have been shown to predict and correlate with renal status following cardiac surgery

(Moriyama et al., 2016), toxic exposure (Ferguson et al., 2010; Igarashi et al., 2013; Pelsers, 2008), or diabetic nephropathy (Colhoun and Marcovecchio, 2018).

Genomics, Proteomics, Metabolomics

The complexity of the kidney structure and function in health and disease makes it difficult to conceive of and develop a single biomarker that can give an adequate snapshot of renal status in an individual at a specific time, particularly when the need for information is critical. A panel of biomarkers is more likely to detect important changes and give a richer description of renal impairment. In fact, several companies are marketing immunology-based biomarker panels for assessment of renal function. The −omic analyses take this further in describing a pattern of gene, protein, or metabolite changes that can be analyzed and compared with fingerprints of various pathologies.

Genomic analysis has the ability to reveal increased expression of proteins and signaling molecules related to kidney injury, elucidating mechanistic information that can identify potential biomarkers and therapies (Devarajan et al., 2003; Minowa et al., 2012). Amin et al. (2004) used microarray to analyze kidney samples from rats treated with cisplatin, gentamicin, or puromycin at various doses and times ranging from 4 h to 7 days. They observed changes in gene expression in pathways related to creatinine biosynthesis, kinase signaling, cell cycle, renal transporters, renal injury, regenerative responses, drug metabolism, and resistance. The changes were related to severity of pathology, depending on time and dose. A larger-scale rodent study with 33 nephrotoxicants (Kondo et al., 2009) revealed changes in gene expression in similar pathways. An important issue with using genomic analysis for human studies is obtaining tissue samples (Ju et al., 2012). Even when biopsy material is available, frozen samples may not be available inasmuch as those taken for histological evaluation are formalin-fixed and embedded in paraffin, which fragments RNA during extraction. Some studies have obtained promising results with urine (Ju et al., 2012; Zhou et al., 2016b). The analysis of urine for nucleic acids, proteins, and transcription factors may be facilitated by their inclusion in exosomes (Gyurászová et al., 2018).

Characterization of protein expression has been productively exploited in studying renal biomarkers (Devarajan, 2007; 2008; Slocum et al., 2012; Zhang et al., 2014). Proteomic profiling has become feasible due to advances in mass spectrometry technology for proteins, specifically surface-enhanced laser desorption/ionization time-of-flight mass spectrometry (SELDI-TOF-MS), matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS),

and Multidimensional Protein Identification Technology (MUDPIT) (Devarajan, 2007; Raj et al., 2012; Smith, 2002). Proteomic analysis is amenable to biofluid analysis, particularly urine, serum, and cell culture media. The ability to detect multiple peptides and proteins in a sample will facilitate the discovery of new biomarkers and unraveling of mechanisms. However, for clinical use the MS methods are still expensive and need validation. Commercial renal protein array kits with antibodies to cytokines and renal injury biomarkers offer a useful alternative.

Metabolomics is the outgrowth of the concept of metabolic profiling or metabolic pattern analysis of metabolites in biofluids, initiated in the 1940s and further pursued in the 70s (Gates and Sweeley, 1978). The analytical technologies, GC/MS, LC/MS, and NMR, that are used to analyze samples for small-molecule analytes are available in more facilities and are augmented by the powerful data analysis systems that make the −omics practical. Metabolomics is only recently being applied to the nephrology for the study of diseases, toxicities, and discovery of biomarkers (Ezaki et al., 2017; Mussap et al., 2014; Slocum et al., 2012; Weiss and Kim, 2012; Zhang et al., 2012). Much work needs to be done to validate the procedures and to overcome problems when working with fluids such as urine, including bacterial contamination and the influence of diet on the metabolome (Weiss and Kim, 2012). The development of more powerful bioinformatics tools for the analysis of −omics data (Breit and Weinberger, 2016) will enhance the ability to construct and interpret profiles and fingerprints of various renal pathologies for prediction, diagnosis, and intervention.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

In view of the complexity of renal structure and function, and the wide variety of conditions that are of concern, it is unlikely that a single biomarker will be found that can serve all the purposes of an ideal biomarker that can detect, diagnose, and predict. The use of individual biomarkers and biomarker panels will need to be validated for factors such as age (Ferguson et al., 2010), sex (Tsuji et al., 2017), and appropriate time for evaluating (Susantitaphong et al., 2013;U.S. Food & Drug Administration). Currently the FDA has qualified several renal biomarkers for preclinical Good Laboratory Practice (GLP) studies (U.S. Food & Drug Administration) but not for clinical trials. The requirements for assessment and prediction, and the resources available, will be different for animal studies than clinical drug trials and still different for monitoring patients. It is likely that panels of serum and/or urine biomarkers can be

developed for (1) general assessment of patient renal function in routine clinical tests, (2) monitoring of renal function in patients at risk for particular renal pathology such as diabetic nephropathy, ischemia, transplant rejection, drug monitoring, (3) diagnosing the causes or injury site of renal disease, and (4) investigative preclinical and clinical uses. The biomarkers selected for the panels would be those for which sufficient studies have been completed to provide evidence for their individual or combined ability to answer the specific question being asked at the requisite level of sensitivity.

INTRODUCTION

The gastrointestinal (GI) tract serves as the normal entry and absorption route for dietary products, which makes it prone to direct exposure to toxicants. This organ presents a high degree of structural complexity with varied tissue types serving different functions, which essentially renders it sensitive to a multitude of natural, chemical, and radiation assaults at all times.

Traditionally, the occurrence of GI toxicity has been monitored using histopathological examination, presence of occult blood in feces, evaluation of GI content, and prediction of effects on GI absorption and contractility using in vitro/ex vivo systems.

However, there has been a constant search for clinically relevant minimally invasive/noninvasive biomarkers to better achieve prediction and prognosis of GI damage.

GI damage is most commonly encountered due to (1) nonsteroidal anti-inflammatory drugs (NSAID) overuse/sensitivity, (2) chemotherapy, (3) radiation, and (4) metabolic disorders. Key biomarkers have been known and assessed in different biological samples for monitoring of disease progression and prognosis (Fig. 16.1).

NSAID-INDUCED GASTROINTESTINAL TOXICITY

The primary mode of action of NSAIDs through the inhibition of the catalyzing enzyme cyclooxygenase (d) is also known to result in GI side effects, ranging from mild dyspepsia to GI hemorrhage and perforation. The most common adverse effects of NSAIDs include upper GI tract damage with manifestation as gastric and intestinal ulcers (Cryer, 2000; Carr et al., 2017).

Gastroduodenal mucosal injury due to NSAIDs includes not only a simple topical injury but also complex mechanisms with both local and systemic effects. The systemic effects principally result from the inhibition of endogenous prostaglandin synthesis (Schoen and Vender, 1989), which in turn leads to a decrease in epithelial mucus, secretion of bicarbonate, mucosal blood flow, epithelial proliferation, and mucosal resistance to injury (Whittle, 1977; Wolfe and Soll, 1988). The impairment in mucosal resistance permits further injury by endogenous factors, such as acid, pepsin, and bile salts, as well as by exogenous factors such as other NSAIDs and possibly alcohol and other toxicants.

CHEMOTHERAPY-INDUCED GASTROINTESTINAL TOXICITY

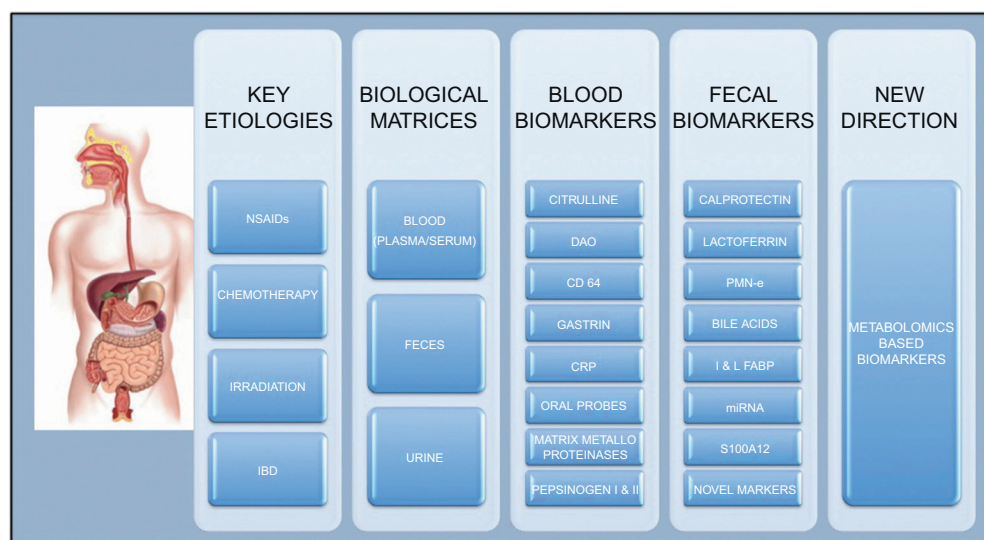
Chemotherapy is well associated with various side effects, with toxicity to the GI tract being a major clinical concern. Chemotherapy-induced GI toxicity is the key dose-limiting factor for any chemotherapeutic regimen which is not simply targeted to the upper gastroduodenal mucosa but also extends along the entire GI tract (Denham and Abbott, 1991) and hence chemotherapy-induced GI mucositis causes a major oncological challenge. The mucositis development pathway includes the activities of mitogen-activated protein kinase signaling, nuclear factor kappa B (NF-κB) signaling, Fos/Jun signaling, and Wnt signaling (Bowen et al., 2007). Cytokines, matrix metalloproteinases (MMPs), ceramide, and COX-2 are also activated as key downstream mediators of this mucosal disruption mechanism (Logan et al., 2008; Al-Dasooqi et al., 2010).


FIGURE 16.1 Summary of causes, analytical matrix, and key biomarkers currently in use for gastrointestinal toxicity monitoring across species.

RADIATION-INDUCED GASTROINTESTINAL TOXICITY

Complete manifestation of symptoms of the GI syndrome resulting as an outcome of acute radiation syndrome usually occurs with a dose greater than approximately 10 Gy (1000 rad) in humans. The pathophysiological mechanisms of gastric syndrome are complex and involve loss of clonogenic crypt cells with eventual depopulation of the intestinal villi, faulty regeneration of the intestinal stem cells postirradiation, and a systemic inflammatory response syndrome from a multitude of cytokines and growth factors released into the systemic circulation following radiation exposure and translocation of gut microbes (Potten, 1998; Marshman et al., 2002). Rapid turnover of intestinal epithelial cells causes the intestinal mucosa to be especially sensitive to high radiation exposure during radiation therapy or in any other nuclear exposure. Thus, maintenance of intestinal homeostasis is critical to combat radiation-induced GI injury (Saha et al., 2012). Organisms most commonly respond to irradiation by altering the expression and/or the posttranslational modifications of some proteins in cells, tissues, and/or organic fluids, such as serum or urine. Hence, it is perceived that protein expression profiling can be useful to evaluate a protein or a group of protein expression changes that can clearly differentiate between irradiated and nonirradiated biological systems, and between recoverable or irrecoverable radiation injuries. For further details on biomarkers of radiation-induced GI effects refer to Ray et al. (2014).

INFLAMMATORY BOWEL DISEASES

The two major forms of the chronic inflammatory bowel diseases (IBDs) are Crohn's disease (CD) and ulcerative colitis (UC). CD is characterized by discontinuous regions of intestinal inflammation normally involving the terminal ileum and colon, but can eventually affect any part of the GI tract. The inflammatory mechanism of UC is limited to the mucosa and submucosa of the colon, almost invariably affecting the rectum eventually. Biomarkers are currently used in conjunction with routine testing in the clinical care of patients with IBD (Iskandar and Ciorba, 2012).

BIOMARKERS FOR GASTROINTESTINAL DAMAGE

A number of GI toxicity biomarkers have been tested to investigate their usefulness in tracking adverse events. During this process, multiple analytical methodologies have been described for in vivo applications to track GI function in a number of species and in accessible biologic fluids such as blood and urine.

BLOOD BIOMARKERS

Citrulline

Citrulline is an intermediate metabolic amino acid produced mainly by enterocytes of the small intestine.

Levels of citrulline have been correlated with chemotherapeutically reduced enterocyte mass, independent of nutritional and inflammatory status. Plasma citrulline measurements have been used most recently in myeloablative treatment regimens as being indicative of mucosal mass (Butler, 2008; Crenn et al., 2008). Analysis of blood citrulline is challenging, and routine analysis has been limited to enzymatic assays, which are often less sensitive. However, Crenn et al. (2008) presented the utilization of high-performance liquid chromatography (HPLC) and mass spectrometry, to present citrulline as a promising GI biomarker. Alteration in diet and gut microflora is expected to alter biochemical and metabolic pathways that may lead to changes in metabolite measurements such as citrulline. However, these variables are likely to be normalized throughout the study design with the maintenance of uniform diet, age, and sex. The LC-MS/MS method is inherently highly specific for citrulline measurements and the presence of interfering metabolite components can be easily nullified.

Recently, Carr et al. (2017) reported that as a small intestinal toxicity, plasma citrulline appears to have some potential in nonclinical safety studies. However, further work is required to determine its applicability in humans as well as other preclinical species. The application of citrulline to in vitro models of intestinal disease/toxicity also requires further exploration.

Diamine Oxidase

Diamine oxidase (DAO) is an enzyme that catabolizes a variety of substrates including histamine and diamines. It is the degradative enzyme in the catabolic pathway of polyamines found in high activity in the mature upper villus cells of the rat intestinal mucosa (Luk et al., 1983; Wolvekamp and Debruin, 1994). Blood DAO activity has been well correlated with DAO activity in the villi of the small intestinal mucosa and also with the severity of small intestinal mucosal lesions induced by anticancer drugs (Luk et al., 1980; Tsujikawa et al., 1999).

However, the measurement of blood DAO has been an analytical challenge because of the extremely low measurable levels in the blood. Wolvekamp and de Bruin (1994) and Tsunooka et al. (2004) reported that DAO measurement is easily confounded by the fact that plasma levels rise markedly on heparin stimulation prior to blood draws (Wolvekamp and Debruin, 1994; Tsunooka et al., 2004). This causes blood DAO level use to be both impractical and inconvenient for routine GI toxicity screening in a preclinical setting. Thus, this biomarker measurement has not gained sufficient popularity in clinical or preclinical use.

CD64

Tillinger et al. (2009) suggested the flow cytometric measurement of neutrophilic CD64 as a useful biomarker for gastroenterologic injury in patients with inflammatory and functional diseases of the intestine. CD64, a high-affinity FcRI receptor for IgG, serves as a ligand for acute phase reactants, C-reactive protein (CRP) and amyloid P (Tillinger et al., 2009). CD64 was found to respond well to therapeutic interventions and was significantly higher in patients with IBD. Hence, it found an application as a biomarker to discriminate between gastroenterologic disorders. At this time, mouse antibodies are available for preclinical application and antibodies in other species are being researched to evaluate CD64 in other relevant preclinical in vivo toxicology studies in addition to clinical application.

Gastrins

Gastrins are a family of sequence-related carboxyamidated peptides produced by the endocrine G cells of the gastric antrum and duodenum in response to various GI stimuli. The mechanisms for gastrin release from G cells are not well understood, although antral distension, partially digested proteins, amino acids, and vagal stimulation appear to be involved in the process. Increased serum gastrin levels are generally associated with duodenal ulcers, bacterial infections, tumors, and other causative factors associated with GI damage. Serum gastrin levels were measured in rats treated with omeprazole and the effects of omeprazole on normal and ethanol-damaged gastric mucosa were observed (Fattaha and Abdel-Rahman, 2000). Serum gastrin levels were found to increase significantly in omeprazole-treated animals versus control or ethanol-treated rats. It has also been shown that chronic use of antisecretory drugs may induce hypergastrinemia by inflammatory mechanisms and the release of gastrin from antral G cells is closely regulated by neuroendocrine mechanisms possibly sensitive to local pH. The acidity of the gastric lumen has also been seen to decrease gastrin secretion through the release of somatostatin from D cells (Alvarez et al., 2007). Plasma gastrin levels were found to have increased in rats treated with acetic acid, which is known to induce gastric ulcers (Sun et al., 2002). Increased serum gastrin concentrations were also observed in dogs with chronic lymphocytic—plasmacytic enteritis compared to dogs without GI disease (Garcia-Sancho et al., 2005). Hence, a great deal of evidence exists to define gastrin as a good biomarker for GI modification, though a clear understanding of the mechanism is currently not available.

C-reactive Protein

CRP is a hepatic protein produced in response to a variety of acute and chronic inflammatory conditions and is often useful as an indirect biomarker of GI inflammation. Cytokines associated with active IBD [i.e., interleukin (IL)-6, tumor necrosis factor alpha (TNFα), and IL-1β] stimulate increased production of CRP by hepatocytes over baseline levels (Darlington et al., 1986). Such elevated CRP levels are not specific to IBD as levels are also increased in various viral and bacterial infections, other autoimmune disorders, malignancy, and other toxicities resulting in tissue necrosis (Pepys and Hirschfield, 2003). CRP serves as a robust biomarker as it is easily and reliably measured across diagnostic laboratories and has a short plasma half-life of ~19 h, which is determined by synthesis rather than degradation (Vigushin et al., 1993).

Orally Administered Probes

Fecal and urinary excretion of orally administered probes has been used to assess mucosal permeability as a marker of GI tract dysfunction and drug-induced intestinal barrier damage. Urine sucrose and ^{51}Cr-EDTA measured by radioimmunoassay correlated well with gross toxicological and pathological changes in a rat model of GI damage induced by various anticancer agents (Yanez et al., 2003). The use of ^{51}Cr-EDTA is confined to animal studies due to its radioactive nature and is most often not practical (Butler, 2008). D-xylose and 3-oxy-methyl-D-glucose (3-OMG) have been proposed as additional permeability biomarkers to reflect intestinal epithelial absorptive capacity and rhamnose/3-OMG ratio to assess intestinal transport function (Bjarnason et al., 1995). However, Butler (2008) argued that these tests measure small intestinal leakiness and additionally require HPLC for estimation and hence are also cumbersome. The ^{13}C sucrose breath test is also used to evaluate the absorptive capacity of the small intestine after ingestion of an isotope substrate and has been used in several animal models of chemotherapy-induced intestinal damage (Butler, 2008). The permeability of the small intestine can be used to indicate barrier function in a relatively noninvasive manner. In a healthy GI tract, disaccharides do not usually transfer across the mucosa. Using this concept, other methods utilizing differential absorption of monosaccharide and disaccharide in the small intestine, such as L-rhamnose and lactulose, were initiated to assess sugar permeability in celiac patients with villous atrophy (Menzies et al., 1979). The sugar permeability test measures urinary excretion of orally administered nonmetabolizable sugars and hence monitors the functioning of the small intestine (Keefe et al., 1997). The dual-permeability test using L-rhamnose and lactulose determines small bowel surface area and enterocyte tight junction concentration, respectively (Keefe et al., 1997). A correlation between high-dose chemotherapeutic effects (enteropathy and permeability of tight junctions) and altered monosaccharide and disaccharide urine concentrations has been established (Keefe et al., 1997; Daniele et al., 2001; Melichar et al., 2001).

Matrix Metalloproteinases

MMPs are a group of zinc-dependent endopeptidases that work toward extracellular matrix turnover (Al-Dasooqi et al., 2010). Recent research has identified these proteases as important mediators of chemotherapy-induced gut damage in rats (Page-McCaw et al., 2007). Hence, MMPs can be used as tissue-specific markers of chemotherapy-induced gut injury. However, the changes in MMPs have not yet been monitored sufficiently at this time for their systemic presence to be useful as toxicity biomarkers.

Pepsinogen I and II

Pepsinogen I and II, the precursors of pepsin, are produced by the gastric mucosa and released into the gastric lumen and peripheral circulation (Samloff and Liebman, 1973). Severe inflammation of gastric mucosa and its progression toward atrophic gastritis is correlated with a change in serum biomarkers pepsinogen I and II. The atrophy of the corpus mucosa leads to low synthesis of pepsinogen I and hence its low release into the serum. Advanced gastric atrophy and hypo- or achlorhydrias cause very low levels of pepsinogen I in contrast to pepsinogen II, which remains elevated in serum (Samloff, 1982; Samloff et al., 1982).

It has been previously reported that pepsinogen II is a good marker for the diagnosis of any type of gastritis as it can differentiate between subjects with gastritis from those with normal mucosa. The progression of gastritis to acute and pangastritis is associated with a continual increase in serum pepsinogen II levels, whereas the levels of pepsinogen I in the early stage of acute gastritis remain unchanged and in the normal range (Haj-Sheykholeslami et al., 2008).

FECAL BIOMARKERS

Calprotectin

Calprotectin is a calcium-binding protein found in abundance in neutrophils, where it accounts for 60% of the soluble proteins in the cytosol. Lower concentrations are found in monocytes and reactive macrophages.

Calprotectin is a sensitive, stable marker that is unaffected by medication, dietary supplements, or enzymatic degradation. This neutrophil-derived protein reflects the flux of leukocytes into the intestinal lumen. Studies indicate that increased levels of fecal calprotectin are found in IBD (Roseth et al., 1992; Bunn et al., 2001), colonic cancer (Roseth et al., 1993), and NSAID treatment (Meling et al., 1996; Tibble et al., 1999), suggesting it is a sensitive marker of GI inflammation. Accordingly, fecal calprotectin is now used for clinical assessment of GI inflammation in humans, using standard ELISA procedures.

Calprotectin, a 36.5 kDa nonglycosylated protein, plays a central role in neutrophil defense, and its fecal level correlates well with the numbers of neutrophils infiltrating the intestinal mucosa and the overall severity of GI inflammation. It is known to be stable in feces for several days after excretion (Roseth et al., 1999). However, the presence of calprotectin in feces appears to be directly related to neutrophil infiltration rather than GI damage. The release of calprotectin is most likely a consequence of cell disruption and death (Voganatsi et al., 2001), but it is also actively secreted and is hence useful as a fecal marker (Rammes et al., 1997).

Lactoferrin

Lactoferrin, an iron-binding glycoprotein, is secreted by most mucosal membranes and is a major component of the secondary granules of polymorphonuclear neutrophils, which constitute a primary component of the acute inflammatory response (Levay and Viljoen, 1995; Baveye et al., 1999). Other hematopoietic cells such as monocytes and lymphocytes do not contain lactoferrin (Naidu et al., 1997). During intestinal inflammation, leukocytes infiltrate the mucosa, resulting in an increase in the concentration of lactoferrin in the feces (Guerrant et al., 1992). Lactoferrin is resistant to proteolysis and unaffected by multiple freeze–thaws, providing a useful marker in feces as an indicator of intestinal inflammation.

Polymorphonuclear Neutrophil Elastase

Polymorphonuclear neutrophil elastase (PMN-e) is a neutral proteinase normally stored in the azurophil granules of polymorphonuclear neutrophils. It is released by activation of these cells as a mediator of inflammation (Poullis et al., 2002). Studies are ongoing to establish the utility of PMN-e as a useful GI fecal biomarker.

Bile Acids

Bile acids are minimally absorbed in the proximal small intestine, and the bile acid pool flows to the distal ileum, where the acids are reabsorbed by the enterohepatic transport system and then returned to the liver by the portal vein (Westergaard, 2007). Remaining bile acids are excreted in feces. The fecal bile acids are a complex mixture of metabolites of bile acids produced by intestinal microorganisms (Hirofuji, 1965). As a result, increases in fecal bile acids are indicative of malabsorption, which can cause diarrhea. However, the ability of fecal bile acids to accurately detect GI damage and/or decreased GI functionality is questionable based on assay reliability, though it is commonly used as a GI marker for clinical applications.

I-FABP and L-FABP

The small intestine is the initial site of dietary fatty acid uptake, and proximal intestinal enterocytes contain two fatty acid-binding proteins (FABPs), namely liver FABP (L-FABP) and intestinal FABP (I-FABP), at relatively high concentrations (Bass, 1985). I-FABP occurs in the enterocytes of the small intestine and constitutes 2% of enterocyte protein (Ockner and Manning, 1974; Sacchettini et al., 1990). Studies have described the use of I-FABP for the detection of rat intestinal injury after acute ischemic diseases (Gollin et al., 1993), rejection (Marks and Gollin, 1993; Morrissey et al., 1996), and necrotic enterocolitis (Gollin and Marks, 1993). Intestinal cells also express L-FABP, which occurs in liver and additionally in kidney (Ockner et al., 1982; Bass et al., 1989). I-FABP and L-FABP are very small proteins, which are released rapidly from GI enterocytes into the blood after cellular damage, making them good biomarker candidates.

MicroRNA

MicroRNAs (miRNAs) are small, endogenous noncoding RNAs that act as posttranscriptional regulators of gene expression. As emerging biomarkers of several organ toxicities, miRNAs are also being evaluated for their potential to track damage to the gastric and intestinal mucosa. On cell death, miRNAs are released into the surrounding environment and are stably present in the circulation (Gilad et al., 2008; Mitchell et al., 2008). Therefore, detection of tissues-specific or tissue-enriched miRNA in biological samples is expected to be a good biomarker of damage to that tissue. Serum miRNAs have been identified as biomarkers for liver toxicity (Wang et al., 2009) and myocardial injury (Adachi et al., 2010), as well as for lung, colorectal, ovarian, and prostate cancers (Mitchell et al., 2008). Urine miRNAs are being studied as indicators of renal tubular damage and a fecal miRNA assay is being developed as a screening tool for sporadic human colon cancer and active UC (Ahmed et al., 2009). The miRNA

named as miR-194 was chosen for initial experiments as it is highly expressed in the small intestine and colon, although it is not entirely specific (Godwin et al., 2010). Therefore, the presence of GI-specific or GI-enriched miRNA in feces or any other relevant biological sample could be indicative of GI toxicity.

Fecal S100A12

S100A12 is similar to calprotectin in its calcium-binding properties (Kaiser et al., 2007). This protein activates NF-κB signal transduction and enhances cytokine release (Mendoza and Abreu, 2009). S1000A12 is also detectable in serum, but the fecal assay is more sensitive and specific for IBD (Manolakis et al., 2010). Further work with this biomarker is ongoing.

Other Novel Approaches

Several other fecal biomarkers are being investigated for use in GI conditions and, though promise exists, these alternatives have shown lower correlation to disease activity (van der Sluys Veer et al., 1999). These include lysozyme, leukocyte esterase, elastase, myeloperoxidase, TNFα, IL-beta, IL-4, IL-10, alpha-1 antitrypsin, and alpha-2-macroglobulin (Desai et al., 2007; Mendoza and Abreu, 2009; Lewis, 2011). M2-pyruvate kinase is possibly the most promising of these new fecal biomarkers (Judd et al., 2011). Gene expression analysis has shown that the presumed adipocyte-specific protein, adipsin, had similarly elevated mRNA levels and is a potential marker for Notch/Hes-1 signaling disruption effects in the GI tract of rats. These protein levels were found to be upregulated in the intestinal contents and feces of FGSI-treated rats, which could be monitored noninvasively (Searfoss et al., 2003). Identification of such biomarkers that may predict these irradiation or subsequent treatment-associated adverse events is of great importance. In this context, peripheral blood biomarkers or noninvasive biomarkers would be preferred, as these are less invasive than a colonic biopsy. In another study, increases in expression of neutrophil activation markers, CD177 and CEACAM1, were found to be associated with the occurrence of GI immune-related adverse events (Shahabi et al., 2013), which is also being studied further for biomarker application.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Although GI toxicity is a significant dose-limiting safety concern noted in multiple therapeutic areas, there are no GI biomarkers that can accurately track, precede, or reliably correlate with predicted and histologic evidence of GI damage. While significant efforts have been made within the pharmaceutical industry, academia, and consortia to address the biomarker gaps in other target organs such as liver, kidney, and muscle (cardiac and skeletal), there have been no concerted efforts in the area of GI biomarkers. Moreover, the markers available are not suitable to be used across species to be appropriate for clinical as well as nonclinical research applications. Attempts are currently ongoing to qualify several biomarkers as discussed, to be applicable for diagnostic and research use in humans and as laboratory animals.

One of the key new directions of novel development in GI biomarker research is the understanding of metabolome-based biomarkers.

METABOLOME-BASED BIOMARKERS

The metabolomics approach is believed to have the potential to reveal novel biochemical outcomes of toxicant administration that can lead to mechanistic insights and identification of biomarkers of cause and/or effect (Robertson et al., 2011; Suzuki et al., 2014). Metabolomic fingerprinting can be conducted on minimally prepared peripheral biological fluids, and sample differentiation is an outcome of spectroscopic or chromatographic data. These "analytical fingerprints" comprise thousands of individual data points that relate to the composition of the sample, which may indicate their molecular origin. Such a data set is used as input into multivariate statistical tools such as principal component analysis. This approach avoids the time-consuming step of data annotation and therefore may be rapidly applied for establishing differentiation between individuals or groups, with applications during in vivo screening of similar drug candidates (Robosky et al., 2002; Dieterle et al., 2006; Robertson et al., 2011), prescreening animals before extensive toxicological evaluations, and creating toxicological classification models (Lindon et al., 2005). Evaluation of effects on gut flora has been a difficult task so far but metabolomic analyses should simplify that task such that gut flora as a potential target could be routinely studied in toxicity studies (Backshall et al., 2009). In one recent study, irradiation-induced metabolic changes in GI tissue of CD2F1 mice was estimated using ultra-performance liquid chromatography coupled with electrospray time-of-flight mass spectrometry. GI injury is a critical determinant of survival after exposure to irradiation and results from this metabolomics analysis showed a clear dose- and time-dependent response to GI tissue injury. GI tissue metabolomics profiles provided an information-rich matrix that led to the identification of metabolites such as lipids and organic acids, as well as amino acids, that may

impact overall GI metabolism and in part explain irradiation-induced GI toxicity (Ghosh et al., 2013).

In conclusion, it is safe to say that there still exists a lacuna in terms of a robust GI damage marker, and further focused research on identification and qualification of specific and rapid analytical methods for GI toxicity biomarkers for clinical and nonclinical application is the need of the hour.

Reproductive Toxicity Biomarkers

Emily Brehm, Saniya Rattan, Catheryne Chiang,
Genoa R. Warner, Jodi A. Flaws

Department of Comparative Biosciences, University of Illinois at Urbana-Champaign, Urbana, IL, United States

INTRODUCTION

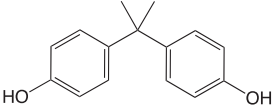
Biomarkers are measureable characteristics of various biological processes in the body and are often used to reflect how chemical exposures impact normal reproduction (Strimbu and Tavel, 2010). Chemicals such as polychlorinated biphenyls, pesticides, and plasticizers are considered endocrine disruptors (Schug et al., 2011), and these chemicals have been shown to affect biomarkers (Fig. 17.1). Biomarkers can be measured throughout development and reproduction in both males and females. In males, measurable biomarkers include examining different parameters of spermatogenesis, steroidogenesis in the testes, puberty, and reproductive aging (Figs. 17.2 and 17.3). In females, biomarkers include examining the process of folliculogenesis, steroidogenesis in the ovary, puberty, the uterus, the placenta, and reproductive aging (Figs. 17.2 and 17.3). This chapter discusses these biomarkers in both males and females and describes how chemicals such as endocrine disruptors can affect these endpoints throughout the reproductive life span.

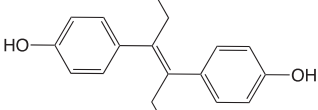
MALE REPRODUCTIVE BIOMARKERS

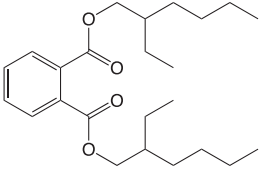
Spermatogenesis

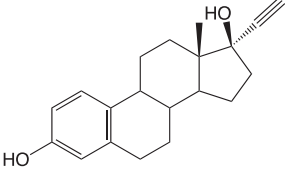
Testes are the male reproductive glands. The main functions of the testes are to produce sperm and androgens, mainly testosterone. Mammalian testes are made of seminiferous tubules and interstitial compartments. Within the epithelium of the seminiferous tubules are somatic Sertoli cells and the developing germ cells (Zirkin et al., 2011). During spermatogenesis, diploid spermatogonial stem cells divide mitotically to become spermatocytes. This process is followed by two meiotic divisions, which produce haploid round spermatids, and eventually the differentiation of the spermatids into elongated, mature sperm (Zirkin et al., 2011). Besides differentiation, some spermatogonial stem cells are able to self-renew, which maintains a pool of spermatogonia that is needed for the continuous production of gametes (Zirkin et al., 2011). Spermatogenesis has been morphologically defined in stages. Specifically, Hess and de Franca described in great detail the 12 separate stages in the mouse (Hess & de Franca, 2008).

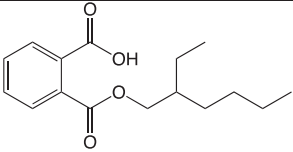
Many biomarkers have been used to evaluate the effects of endocrine disruptors and other toxicants on spermatogenesis. An important biomarker for examining spermatogenesis includes examining the morphology of the testes and epididymis. For example, Park et al. (2002) morphologically examined rat testes and found that di(2-ethylhexyl) phthalate (DEHP) caused apoptosis, necrosis, and loss of spermatogenic cells, resulting in testicular atrophy. Furthermore, adult exposure to bisphenol A (BPA) inhibited spermiation, characterized by an increase in stage VII sperm and a decrease in stage VIII sperm, in the seminiferous epithelium (Liu et al., 2013).

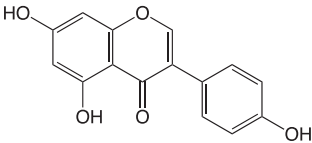
Other major biomarkers of spermatogenesis include examination of different semen parameters, including sperm number and concentration. When observing sperm number, the total number of sperm in an entire ejaculate is calculated by multiplying the sperm concentration by the semen volume (Cao et al., 2011). Sperm concentration refers to the number of sperm per unit volume of semen (Cao et al., 2011). Hemocytometer chambers and computer-aided sperm analysis (CASA) are used to evaluate sperm numbers and sperm concentrations (Mortimer, 2000; Mortimer et al., 2015). A hemocytometer is a thick glass slide with an indentation that defines two separate counting chambers. Sperm are


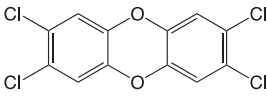


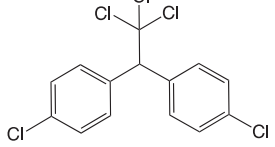


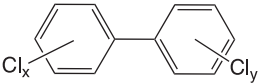












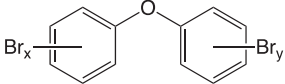


FIGURE 17.1 Select endocrine-disrupting chemicals (EDCs) discussed in this chapter.

loaded onto the slide, and a cover slip with a counting grid is placed on top. Sperm are then manually counted within a known area. Several studies have shown that endocrine-disrupting chemicals (EDCs) affect these biomarkers. For example, urinary BPA concentrations were associated with low sperm concentrations in men (Meeker et al., 2010). In another study, prenatal exposure to DEHP decreased sperm counts in the F1 generation of rats (Chen et al., 2015).

Another important biomarker of sperm quality is motility. Sperm motility is categorized as progressive motility, nonprogressive motility, or immotility (Cao et al., 2011). Besides evaluating sperm number and concentrations, CASA evaluates sperm motility and morphology (Mortimer, 2000; Mortimer et al., 2015). Studies have used CASA to show that polycyclic aromatic hydrocarbons (PAHs) and pesticides decreased sperm motility in humans (Tavares et al., 2016).

Sperm morphology is another biomarker of spermatogenesis. In humans, normal sperm morphology consists of a head, neck, midpiece, principal piece, and end piece (Cao et al., 2011). The head should be smooth and generally oval in shape with a well-defined acrosomal region (Cao et al., 2011). The midpiece should be slender and about the same length as the sperm head, and the principal piece should have a uniform diameter and be thinner than the midpiece (Cao et al., 2011). Abnormal sperm morphologies of the head include tapered, pyriform or pear-shape, round and small, amorphous, vacuolated, and/or having a small acrosomal area (Cao et al., 2011). Midpiece defects include a bent neck, asymmetry, and thick or thin insertion (Cao et al., 2011). The morphological abnormalities of the tail or principal piece include shortness, bent, coiled, and/or hooked structures (Cao et al., 2011). One technique to assess sperm morphology includes collecting
FIGURE 17.2   The diagram of biomarkers of development and reproduction measured in females and males.

wet sperm and mounting it on clean, grease-free slides that contain buffered formalin with eosin—nigrosin stain and morphologically examining 100 sperm per sample under an oil-immersion lens using a light microscope (Otubanjo and Mosuro, 2001). Agarwal et al. (1986) used this technique to determine that DEHP increased the percent of abnormal sperm in adult rats. Furthermore, in men, increases in urinary BPA concentration were associated with declines in sperm morphology (Meeker et al., 2010).

Other important biomarkers of spermatogenesis are pH and vitality of sperm. Semen pH is measured by mixing a semen sample and spreading a drop of it onto pH paper and then obtaining the pH level according to color (Cao et al., 2011). The pH of seminal fluid may play an important role in maintaining the viability and quality of sperm, but it can also ensure fertilization (Zhou et al., 2015b). Sperm vitality refers to the proportion of spermatozoa that are alive in a sample. It is measured by taking wet sperm and staining with eosin to observe whether the sperm are alive or dead (Talwar and Hayatnagarkar, 2015). If the sperm show any sign of the stain, the sperm are dead (Talwar and Hayatnagarkar, 2015). When studying viability of sperm, Tavares et al. (2013) treated human sperm with p,p′-dichlorodiphenyldichloroethylene (p,p′-DDE) and discovered that the chemical decreased the percentage of live sperm compared with control.

In vitro cultures can be used as biomarkers to examine direct effects of toxicants on sperm (Livera et al., 2000). Various in vitro techniques have been used to show that BPA increased sperm activity and accelerated capacitation-associated protein tyrosine phosphorylation in rats (Wan et al., 2016). Furthermore, mono(2-ethylhexyl) phthalate (MEHP), the principal metabolite of DEHP, has been shown to affect spermatogenic cells, leading to necrosis in rat testes *in vitro* (Andriana et al., 2004).
FIGURE 17.3 The diagram of biomarkers of development and reproduction measured in male and female rodents.

Synthesis of Steroids, Gonadotropins, and Peptide Hormones in Males

Reproduction is heavily controlled via hormonal interactions between the hypothalamus, pituitary, and the gonads (Yen et al., 2014). Together, these organs are known as the hypothalamic—pituitary—gonadal (HPG) axis. In males, the gonadal role in the HPG axis is filled by the testes. A variety of hormones play essential roles within the HPG axis and are required for normal male fertility and reproduction. Gonadotropin-releasing hormone (GnRH) is released in a pulsatile manner by specialized neurons in the arcuate nucleus of the mediobasal hypothalamus. GnRH travels through a series of blood vessels that facilitates rapid communication between the hypothalamus and the anterior pituitary known as the hypophyseal portal system. GnRH then stimulates gonadotropes within the anterior pituitary to secrete the gonadotropin hormones, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). LH and FSH travel to the testes where they stimulate steroidogenic activity. Leydig cells and Sertoli cells are responsible for the production of the sex steroid hormone, testosterone, and the peptide hormone, inhibin B, respectively. Leydig cells, Sertoli cells, germ cells,

and spermatozoa collectively produce estradiol within the testes (Hess, 2003). Testosterone, inhibin B, and estradiol all play negative feedback roles to help control the secretion of gonadotropins (Yen et al., 2014).

Chemicals can affect hormone levels through a variety of mechanisms, including interfering with feedback systems, interfering with communication between organs, altering enzymatic expression, altering enzymatic activity, directly activating or inhibiting the production of hormones, and inducing changes in hormone metabolism. Hormone levels can be used as biomarkers for normal reproductive health, or lack thereof, in males. Hormone levels are commonly measured via an enzyme-linked immunosorbent assay (ELISA). ELISAs work by utilizing conjugated antibodies that bind specifically to a particular antigen (i.e., the hormone being measured). These antibodies are conjugated to an enzyme that produces a color change when given a specific colorless substrate. The color intensity produced by the enzyme conjugated to the antibody can be used to determine the concentration of the hormone in question. A variety of ELISAs exist, and depending on the type, the color intensity may be directly or inversely correlated with the concentration of the hormone being measured (Crowther, 2008). Another type of assay that is commonly used for measuring levels of hormones is the radioimmunoassay (RIA). RIAs use radiolabeled antigens in a known concentration to compete with the unlabeled antigens present in the sample being tested. After the radiolabeled and unlabeled antigens compete for binding to the antibodies during an incubation period, any unbound antigens are washed away. Only the antibodies bound to radiolabeled or unlabeled antigens remain. Radioactivity produced by the remaining radiolabeled antigen can be measured and used to assess the concentration of the unlabeled antigen (Yalow, 1987).

Using the aforementioned assays, several studies have investigated the effects of various chemicals on the HPG axis in males. Carou et al. (2008) found that exposure to low doses of the UV filter 4-methylbenzylidene camphor (4-MBC) decreased LH, FSH, and GnRH levels in adult male rats. In addition, 4-MBC administered to pregnant rats has been shown to alter LH, FSH, and GnRH levels in male offspring (Ponzo and Silvia, 2013). Axelstad et al. (2011) found that octyl methoxycinnamate (OMC), another UV filter, reduced testosterone levels in male rats that were exposed from gestation through lactation. Faber and Hughes found that the phytoestrogen, genistein, decreased pituitary responsiveness to GnRH in postnatally exposed rats (Faber and Hughes, 1991). DEHP has been shown to reduce testosterone levels and alter LH and FSH levels in males (Ponzo and Silvia, 2013). *In vitro* procedures can also be used to assess the effects of chemicals on steroid production.

Chauvigne et al. (2011) found that treatment with MEHP significantly decreased testosterone production in cultured fetal rat testes.

Male Puberty

Puberty is the period of maturation of the HPG axis, leading to the development of the genital organs and physical changes that result in the ability to sexually reproduce (Delemarre-van de Waal, 2002). Puberty is an important process because it marks the beginning of sexual development and growth. In both humans and rodents, the onset of puberty is governed by a complex neural network in the hypothalamus that regulates the secretion of gonadotropin hormones and gonadal growth and function. Puberty consists of whole-body changes from sex organs to skeletal growth. However, early onset of puberty in males is associated with increased risk of heart attack, hypertension, and type 2 diabetes (Zhu and Chan, 2017).

A critical biomarker for puberty in males is the formation of adult Leydig cells. To measure the presence and number of adult Leydig cells, studies often use immunohistochemistry (IHC) and histological evaluation of the testes. Fetal Leydig cells are round and present as clusters, whereas adult Leydig cells are spindle-shaped and contain smooth endoplasmic reticulum and few lipid droplets. Adult Leydig cells are more heavily stained by 3β-hydroxysteroid dehydrogenase (3β-HSD) antibody than fetal Leydig cells (Ge and Hardy, 2007). Multiple studies have used adult Leydig cell formation and function as a biomarker of puberty. For instance, prenatal exposure to dibutyl phthalate (DBP) has been shown to delay the development of adult Leydig cells in the rat testes during puberty (Chen et al., 2017). Exposure to soy milk rich with glyphosate during pubertal development has been shown to increase the percentage of degenerated Leydig cells in male rats (Nardi et al., 2017). Furthermore, Ziram, an agricultural fungicide, delayed pubertal development of rat Leydig cells by inhibiting androgen production and steroidogenic enzyme activities within the Leydig cell (Guo et al., 2017).

Another important biomarker of puberty in males is testosterone levels. Specifically, testosterone levels in male humans increase from a prepubertal concentration of 0.2 to 6 ng/mL, which is typical for an adult man (Plant et al., 2015). Testosterone is important during puberty because it stimulates fertility and male secondary sexual characteristics (Ge and Hardy, 2007). Multiple studies have measured testosterone levels as a biomarker for puberty and have shown that EDCs can interfere with normal testosterone levels during puberty. For instance, exposure to DBP during prenatal development lowered serum testosterone levels during pubertal development in rats (Chen et al., 2017). Exposure to soy milk rich with glyphosate during pubertal development decreased serum testosterone levels in male rats (Nardi et al., 2017). In addition, maternal serum levels of dichlorodiphenyltrichloroethane (DDT) and dichlorodiphenyldichloroethylene (DDE) were inversely related to LH and testosterone levels in pubertal boys. Furthermore, polybrominated diphenyl ether (PBDE) concentrations in maternal serum were associated with increased levels of LH and testosterone in pubertal boys (Eskenazi et al., 2017).

In humans, the onset of puberty is assessed using the Tanner Scale. In males, the Tanner Scale assesses the growth of the gonads (gonadarche) and pubic hair (pubarche) (Rockett et al., 2004). Gonadarche is the dramatic increase in testicular volume from 2 to 20−25 mL due to the initiation of spermatogenesis (Plant et al., 2015). Gonadarche and pubarche are important biomarkers of puberty because they mark the physical changes associated with the cellular and hormonal changes in puberty. The Tanner Scale has five stages. Tanner stage 1 describes prepubertal gonad size and indicates no pigmented pubic hair. Tanner stage 5 describes adult testicular and penile size and adult pubic hair growth and pattern (Rockett et al., 2004). This scale is often used as a biomarker for endocrine disruption (Tanner and Davies, 1985). For example, one study has shown that peripubertal urinary levels of BPA are positively associated with an earlier onset of genital and pubic hair development, but delayed pubertal progression in boys (Wang et al., 2017).

In male rodents, biomarkers of puberty include preputial separation and the presence of motile sperm in the epididymis. Measurement of preputial separation includes the detection of the separation of the prepuce from the glans penis (Prevot, 2015). Preputial separation is an important biomarker because delayed preputial separation indicates anti-androgenic activity, impaired growth, and altered onset of puberty (Melching-Kollmuss et al., 2014). The presence of motile sperm in the epididymis is also an important indicator of puberty because it indicates proper testosterone levels and initiation of spermatogenesis (Prevot, 2015). Studies have shown that EDCs interfere with these biomarkers of puberty. For example, early postnatal exposure to pyrethroids, a class of insecticides, accelerated the onset of preputial separation in male mice (Ye et al., 2017). Ethinyl estradiol (EE2) exposure during prenatal development delayed the age of preputial separation in male rats (Ferguson et al., 2014). Furthermore, prepubertal silver nanoparticle exposure reduced the production of motile sperm and delayed the onset of preputial separation in male rats (Sleiman et al., 2013).

Male Reproductive Aging

Reproductive aging is defined as a loss of reproductive capabilities due to irreversible changes at the cellular and molecular levels over time. In males, the decline in reproductive capacity is less pronounced compared with females because males are able to father offspring throughout their life span. However, declining reproductive capacity occurs in males. Reduced endocrine function, altered testicular morphology, and declining sperm parameters are biomarkers of reproductive aging in male mammals (reviewed in Gunes et al., 2016). These biomarkers are commonly quantified to measure toxicity associated with reproductive aging in human and animal models.

The normal interactions within the HPG axis change with age. GnRH secretion from the hypothalamus and testosterone levels from the testes decrease with age; however, basal LH levels increase with age (reviewed in Araujo and Wittert, 2011). The most relevant hormone to measure as a biomarker for reproductive aging in males is total testosterone. Testosterone levels in aging men are often measured by liquid chromatography—tandem mass spectrometry (LC-MS/MS) because LC-MS/MS is considered to be a more sensitive, precise, and reliable test than RIAs and ELISAs (reviewed in Araujo and Wittert, 2011). LC-MS/MS measures the mass-charge ratio of charged particles. Specifically, the LC-MS/MS transitions solid or liquid samples into gaseous particles, ionizes vaporized samples, and detects and quantifies ions. LC-MS/MS utilizes selective reaction monitoring (SRM) to detect serum testosterone levels. SRM allows highly specific detection of testosterone with the mass-charge ratio of charged particles (Grebe and Singh, 2011). Although it is relatively easy to measure testosterone levels, few studies have used testosterone levels as a biomarker to investigate the effects of toxicant exposure on male reproductive aging. One study has shown that prenatal exposure to DEHP accelerates reproductive aging by decreasing testosterone levels and increasing LH levels in 19-month-old mice (Barakat et al., 2017).

Multiple morphological changes occur in the testis with age, and these changes can be used as biomarkers of reproductive aging. Specifically, mean testicular weight, Leydig cell responsiveness and numbers, and the numbers of germ cells and Sertoli cells in the aging testes decrease over time. Furthermore, the seminiferous tubules narrow in aging testes (Gunes et al., 2016). Changes in these biomarkers of reproductive aging in males have been exacerbated with toxicant exposure. For example, prenatal exposure to DEHP increased testicular germ cell apoptosis in 22-month-old mice compared to controls (Barakat et al., 2017). In utero exposure to DBP reduced Leydig cell function

in an age dependent manner compared to controls in rats (Motohashi et al., 2016).

In addition to morphological changes in the testis, the prostate gland, an accessory sex organ, undergoes morphological changes with age. Benign prostatic hyperplasia (BPH), an age-related disease, is a common biomarker of reproductive aging because it is associated with hyperplasia of basal cells and stromal cells around the urethra (Gunes et al., 2016). BPH can cause lower urinary tract symptoms that negatively impact the quality of life for men by creating obstructive symptoms in voiding such as increased urgency and frequency to urinate, weak urine stream, and sensation of incomplete emptying of the bladder (Bechis et al., 2014). To measure lower urinary tract symptoms caused by BPH, experimental animals can undergo a spontaneous void spot assay. In this assay, rodents are placed in a cage lined with paper for a set period of time. After this time, the animals are removed and the paper is checked for urine spots and analyzed for voiding behavior (Ricke et al., 2016). Furthermore, the prostate gland can be removed from experimental animals and histologically examined for increased cell proliferation, weight, and volume (Ricke et al., 2016; Wu et al., 2011). In humans, BPH can be detected by a general examination, hormone tests, and a digital rectal examination (Alanazi et al., 2017).

These prostate biomarkers have been used in studies that indicate toxicant exposure disrupts the aging prostate. Specifically, prenatal and lactational exposure to 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) worsened urinary dysfunction by increasing voiding behavior and prostatic proliferation in adult mice (Ricke et al., 2016). Furthermore, low doses of BPA increased the weight, proliferation, and volume of the prostate gland in adult rats (Wu et al., 2011).

Sperm parameters such as semen volume, sperm concentration, sperm motility, sperm morphology, and total sperm count are biomarkers of male reproductive function. These biomarkers are known to decline with age (Gunes et al., 2016). CASA and hemocytometer chambers are used to evaluate these parameters. Several studies have used these biomarkers of sperm to demonstrate that toxicant exposure negatively impacts sperm parameters with aging. For example, prenatal exposure to DEHP decreased sperm concentration and reduced motile sperm in 22-month-old mice (Barakat et al., 2017).

FEMALE REPRODUCTIVE BIOMARKERS

Folliculogenesis

The ovary consists of a surface epithelium, and an ovarian cortex containing ovarian follicles, stroma,

and corpora lutea. Some major functions of the ovary include maturation and ovulation of the oocyte for fertilization. Furthermore, the ovary is responsible for secreting sex steroid hormones, including estrogens, progesterone, and testosterone. Within the ovary, follicles undergo several developmental changes in a process known as folliculogenesis (Hannon and Flaws, 2015). Follicles are first formed during the later stages of fetal life in the human and during early postnatal life in the rodent (Hannon and Flaws, 2015). During early folliculogenesis, germ cells form, develop into nests, and undergo germ cell nest breakdown to form primordial follicles (Hannon and Flaws, 2015). Once the primordial follicle population is established, the follicles will become part of the follicle reserve, undergo atresia, or grow into primary follicles (Hannon and Flaws, 2015). Primary follicles consist of an oocyte surrounded by a single layer of cuboidal granulosa cells. These primary follicles then will develop into preantral follicles that contain an oocyte surrounded by multiple layers of cuboidal granulosa cells and theca cells. Preantral follicles develop into antral follicles that consist of an oocyte surrounded by numerous layers of cuboidal granulosa cells, theca cells, and a fluid-filled antrum. Changes in folliculogenesis are often used as biomarkers in female reproductive toxicology studies. Specifically, these biomarkers include examining oocyte numbers, morphological evaluation of the ovaries/oocytes/follicles, using culture systems, and measuring gene expression.

To examine oocyte numbers as a biomarker of folliculogenesis, many laboratories have adopted certain protocols to evaluate follicle numbers throughout an ovary. For example, every 10th section of the ovary is used to count all follicle types including primordial, primary, preantral, and antral follicles (Flaws et al., 1994). This procedure can be used to count raw follicle numbers or percent of each follicle type (i.e., raw number divided by the total number of follicles multiplied by 100). By calculating the percent of each follicle type, it is possible to examine shifts in the follicle pool. Another ovarian structure that can be examined as a biomarker is the corpus luteum. The presence of this biomarker is an indication that ovulation occurred in the animal. Corpora lutea are large structures containing large and small luteal cells and are counted by following the progression of the corpora lutea in each ovarian section. When examining folliculogenesis, follicle numbers have been used as a biomarker in studies that have determined that BPA, methoxychlor (MXC), TCDD, and genistein alter folliculogenesis (Patel et al., 2015). Furthermore, phthalates, particularly DEHP, have been shown to accelerate folliculogenesis (Hannon et al., 2014). Interestingly, prenatal DEHP exposure has been shown to decrease folliculogenesis in the F1 generation

of mice, but accelerate folliculogenesis in the F3 generation of mice (Rattan et al., 2017). Furthermore, when examining corpora lutea as a biomarker, DEHP decreased the volume of the corpus luteum in cows (Kalo et al., 2015).

Besides examining numbers of follicles, the morphology of ovaries and their follicles can be examined as biomarkers of female reproductive toxicology. Germ cell nest breakdown, atresia, and abnormal follicles can be detected and quantified in histological sections. Follicles are considered atretic if at least 10% of the follicle contains apoptotic bodies, and abnormal follicles include follicles with multiple oocytes, multinuclei, fragmented oocytes, and/or fragmented nuclei (Hannon et al., 2016; Zhou and Flaws, 2017). When examining the biomarker of germ cell nest breakdown, *in vitro* BPA exposure has been shown to inhibit germ cell nest breakdown in female mice (Zhou et al., 2015a). Furthermore, atresia and abnormal follicles have been used as biomarkers in studies showing that a mixture of phthalates decreased atresia in antral follicles, but induced the occurrence of oocyte fragmentation in female mice (Zhou and Flaws, 2017).

Culture systems on whole ovaries or follicles can be used to observe changes in follicle and oocyte development. Cultures can also measure follicle metabolism and steroidogenesis. Follicle cultures utilize an experimental technique designed to isolate intact follicles from whole ovaries and to measure follicle growth and metabolism (Hartshorne, 1997). In addition, whole neonatal ovaries can be cultured to examine the same parameters. When culturing follicles, ovaries from young adult rodents are ideal because they contain many antral follicles. As described by Hannon et al. (2015a), the antral follicle culture technique begins by placing isolated, untreated antral follicles into a 96-well culture plate containing unsupplemented α-minimal essential medium. Chemicals for treatment are prepared in a supplemented media that is added to the wells, and follicles are cultured in medium for 24–96 h in an incubator (Hannon et al., 2015a). At specific time points during culture, follicle size is measured and follicles and culture media are collected for further analysis (Hannon et al., 2015a).

Whole neonatal ovaries can be cultured using similar methods to those used to culture antral follicles. Ovaries are removed from neonatal pups, placed in media droplets on culture plate inserts that float on supplemented media, and placed in four-well culture plates (Hannon et al., 2015a). Chemicals for treatment are prepared in a supplemented media that is added to the wells and on top of the ovary to keep it from drying out, and supplemented medium is replaced daily (Hannon et al., 2015a). When the culture is finished, ovaries are collected for gene expression analysis, IHC, or histological

evaluation, and the media are collected for further evaluation of hormone levels (Hannon et al., 2015a).

These culture techniques have been used in studies showing that *in vitro* exposure to isoliquiritigenin inhibited antral follicle growth and altered estradiol, testosterone, and progesterone levels (Mahalingam et al., 2016). *In vitro* exposure to phthalates has been shown to inhibit antral follicle growth and alter steroidogenesis in mice (Hannon and Flaws, 2015). In another study, BPA exposure prevented germ cell nest breakdown by altering the expression of key ovarian apoptotic genes in neonatal ovary cultures (Zhou et al., 2015a). When examining gene expression using *in vitro* cultures, MEHP accelerated primordial follicle recruitment, possibly by overactivation of the ovarian phosphatidylinositol 3-kinase (PI3K) signaling pathway in a neonatal ovary culture (Hannon et al., 2014). Furthermore, MEHP increased the expression of the proapoptotic gene *Aifm1*, but decreased the proapoptotic gene *Bok* and the antiapoptotic gene *Bcl2l10* in the antral follicle culture (Craig et al., 2014).

Synthesis of Steroids, Gonadotropins, and Peptide Hormones in Females

In females, the HPG axis consists of the hypothalamus, pituitary, and the ovaries. Just as in males, GnRH is released from neurons within the arcuate nucleus of the mediobasal hypothalamus in a pulsatile manner. GnRH then travels to the anterior pituitary where it stimulates the release of the gonadotropins, LH, and FSH, into the bloodstream. LH and FSH stimulate the theca cells and granulosa cells, respectively, in ovarian follicles to produce a variety of hormones. LH stimulates theca cells to make progesterone. The progesterone is converted to androgens, which are taken up by the granulosa cells. FSH then stimulates granulosa cells to convert these androgens into estrogens. FSH also stimulates granulosa cells to produce the peptide hormones, inhibin A and inhibin B. During the majority of the female cycle, estradiol exerts negative feedback at the hypothalamic and pituitary levels to reduce the production of FSH and LH. Furthermore, progesterone exerts negative feedback directly on the hypothalamus to decrease GnRH secretion. Inhibin A and B exert negative feedback on the pituitary to reduce the release of FSH, specifically. However, as the dominant follicle(s) within the ovary produces rising levels of estradiol, a threshold is reached that leads to estradiol exerting a strong positive feedback on the pituitary, therefore causing the preovulatory LH surge needed for ovulation. After ovulation, the system resets and is controlled by the negative feedback loops. Thus, hormones in the female act through a complex network of negative and positive feedback loops to facilitate the cyclical nature of female fertility observed in a variety of species (Yen et al., 2014).

Just as in males, chemicals may affect hormone levels through a variety of mechanisms, and because female fertility depends on a carefully regulated cycle of fluctuating hormones, alteration of hormone levels can impede female fertility. Therefore, studies often use hormones as a biomarker of normal or abnormal female fertility. Using ELISAs and RIAs, many studies have examined the effects of a variety of chemicals on hormonal profiles in females. Using incubated hypothalamic samples from treated female rats, Rasier et al. (2007) found that treatment with the insecticide DDT increased secretion of GnRH *in vitro* in female rats. Carou et al. (2009) found that 4-MBC increased LH and FSH levels in the serum of female rats exposed from the gestational period through adulthood. Some studies have found that phytoestrogens decrease LH pulse amplitude and GnRH-induced LH secretion by the anterior pituitary (Dickerson and Gore, 2007). DEHP exposure has been shown to reduce progesterone and estradiol levels in rats, but has equivocal effects on LH (Ponzo and Silvia, 2013; Somasundaram et al., 2016). DEHP has also been shown to suppress the production of progesterone, testosterone, androstenedione, and estradiol in cultured antral follicles in mice (Hannon et al., 2015b). Interestingly, DBP decreased estradiol levels while increasing FSH levels in adult female mice (Sen et al., 2015). Polychlorinated biphenyls (PCBs) have also been shown to interfere with steroidogenesis in female rats exposed from gestation through lactation (Dickerson and Gore, 2007).

Female Puberty

Puberty is a period of development marked by the maturation of the genital organs, development of secondary sex characteristics, and the first occurrence of menstruation in women (Plant et al., 2015). In girls, puberty is assessed using the Tanner Scale. Specific for girls, the Tanner Scale assesses breast development (thelarche) and pubic hair growth. The age at which these developmental processes and the age at first menstruation (menarche) are also taken into consideration when determining the onset of puberty (Rockett et al., 2004). Late onset of puberty in girls is associated with decreased bone mineral density, increased risk of bone fractures, increased risk of osteoporosis later in life, and increased risk of coronary heart disease. However, early onset of puberty in girls is associated with an increased risk of breast cancer, endometrial cancer, and coronary heart disease (Zhu and Chan, 2017). In female rodents, puberty is determined by the presence of a vaginal opening and the first vaginal estrus (Prevot, 2015).

Key biomarkers that determine the timing of puberty involve the release of GnRH from the hypothalamus and the release of FSH and LH from the anterior pituitary, leading to the first preovulatory surge of gonadotropins. This surge is responsible for pubertal activation of the pituitary—ovarian axis. Levels of pituitary gonadotropins increase in association with puberty. GnRH forms pulsatile surges to facilitate the LH surge. GnRH peptides and blood gonadotropin concentrations can be measured using RIAs (Plant et al., 2015). Such measurements are used as biomarkers for puberty. One study has used these biomarkers to show that DEHP and MEHP levels in urine are associated with GnRH-dependent precocious puberty in young girls (Bulus et al., 2016).

The first ovulation is another important biomarker of puberty in females. The ability of the ovary to secrete high levels of estrogens over a short period of time (i.e., 24 h) during the estrous cycle is critical for the timing of the preovulatory GnRH/FSH/LH surge (Prevot, 2015). This surge is often linked to the age at vaginal opening. Vaginal opening is an external indicator of the onset of puberty in rodents. Following vaginal opening, rodents exhibit their first vaginal estrus (Prevot, 2015). To measure the first vaginal estrus, evaluation of vaginal cell cytology is required (Gal et al., 2014). A rodent is considered to be in estrus when most of the vaginal cells are cornified epithelial cells, diestrus when mostly leukocytes and few nucleated epithelial cells are present, and proestrus when mainly nucleated epithelial cells are visible in the lavage. Finally, a rodent is considered to be in metestrus if all three cell types are observed, usually with few nucleated epithelial cells. Several studies have used these biomarkers to evaluate the effects of EDCs on the onset of puberty. For example, studies show that neonatal diethylstilbestrol (DES) exposure accelerated the age at vaginal opening and induced abnormal estrous cyclicity in female rats (Ohmukai et al., 2017). Another endocrine disruptor, ethylene glycol monomethyl ether, delayed the age at vaginal opening in female rats (Taketa et al., 2017). Maternal exposure to fluoxetine, an antidepressant, delayed the onset of vaginal opening and first estrus in female rat offspring (Dos Santos et al., 2016).

Thelarche and menarche are important biomarkers used to assess pubertal development in girls. An abnormal onset of thelarche may indicate abnormal gonadotropin secretion that subsequently stimulates cyst formation and estradiol secretion by the ovary (Neely and Crossen, 2014). In addition, abnormal onset of menarche indicates abnormal HPG axis activation (Neely and Crossen, 2014). According to the Breast Cancer and Environment Research Program (BCERP), prepubertal exposure to various EDCs is associated with precocious or delayed thelarche and menarche in females. Specifically, high levels of enterolactone and mono(3-carboxypropyl) phthalate in urine are associated with delayed thelarche and menarche (Wolff et al., 2017). Increased levels of 2,5-dichlorophenol in urine are also associated with precocious thelarche and menarche in girls (Wolff et al., 2017). Furthermore, increased exposure to isoflavones is associated with delayed breast development in young girls (Cheng et al., 2010).

Uterus

The uterus is highly sensitive to EDC compounds and is itself a biomarker of exposure to estrogenic substances. Uterotrophic assays, histology, and gene expression profiling are complementary biomarkers of uterine sensitivity to hormones and endocrine disruptors. The mouse or rat uterotrophic assay has been used since the 1930s in pharmaceutical development of hormone-mimicking substances such as DES and more recently has been validated by the Organization for Economic Cooperation and Development (OECD) for identification of estrogen agonists and antagonists (Owens and Ashby, 2002; Owens and Koëter, 2003). The uterotrophic assay measures increases in uterine weight compared with body weight in response to estrogen receptor—mediated signaling in the presence of estrogenic substances. It is performed on immature or ovariectomized rodents without endogenous estrogens to minimize the baseline uterine weight before treatment (Owens and Ashby, 2002). The rodent uterotrophic assay has been used to identify the estrogenic activity of EDCs including BPA, DDT, the PCB mixture Aroclor 1221, and the organochlorine pesticides endosulfan and mirex (Gore et al., 2015). The synthetic estrogens DES and EE2 are typically used as positive controls. The immature mouse uterotrophic assay has also been used to identify estrogen antagonists such as dibenzyl phthalate (DBzP) (Zhang et al., 2011).

Histopathology of the uterus is another method of determining exposure to endocrine-active substances. Paired with uterotrophic assays, histologic analyses of the uterus reveal swelling of the stromal endometrium and luminal epithelium as uterine weight increases in the presence of estrogenic chemicals (Orphanides et al., 2004). However, in histological analysis of uterine tissues independent of complementary assays, it can be difficult to distinguish direct uterine toxicity from responses to changes in the overall hormonal environment of the reproductive tract or primary ovarian toxicity. Mitotic inhibitors and cytotoxins are two classes of compounds known to directly impact uterine cell populations (Li and Davis, 2007). In particular, epithelial cell height is commonly measured because it can

increase up to five-fold in rodents in response to estrogens such as EE2, DES, and BPA (Owens and Ashby, 2002; Steinmetz et al., 1998). The antibacterial agent triclosan, which has been shown to increase uterotrophic response to EE2, enhances EE2-induced epithelial cell height growth (Louis et al., 2013).

Gene expression changes in the presence of estrogens increase protein production. These changes partially contribute to the uterine growth measured in the uterotrophic assay and to the visible changes in histologic analysis of uterine tissue. Changes in expression of protein metabolism, cell cycle, proliferation, DNA replication, RNA metabolism, mRNA transcription, and blood vessel development genes have been demonstrated in the presence of estrogens, and these changes correlate with uterine weight increase and histologic changes (Orphanides et al., 2004). In addition, EDCs have been linked to distinctive patterns of gene expression. DES, BPA, and TCDD have been shown to alter the Wnt-signaling pathway (Calhoun et al., 2014; Gore et al., 2015). PBDE 99 decreased progesterone receptor expression (Ceccatelli et al., 2006). In the presence of the MXC metabolite 2,2-bis(p-hydroxyphenyl)-1,1,1-trichloroethane, gene expression changes in the mouse uterus vary by ligand specificity (estrogen-like, antiestrogen, etc.) for estrogen and androgen nuclear receptors (Waters et al., 2001).

Placenta

The placenta is a unique and important organ that controls the transfer of nutrients and other substances from the mother to the fetus during pregnancy. Placental toxicity may indicate fetal toxicity as most xenobiotics pass through the placenta on the way to the fetus, making placental biomarkers vital for monitoring fetal exposures. However, species differences in structure and function of the placenta preclude the use of most animal models for human studies (Myllynen et al., 2005).

During pregnancy, the placenta synthesizes and regulates hormones. Imbalances in endogenous hormone levels are one biomarker of placental stress due to xenobiotics. Human chorionic gonadotropin (hCG), produced throughout pregnancy, is altered by organochlorines, BPA, phthalates, smoking, heavy metals, and other estrogenic substances (Adibi et al., 2017; Myllynen et al., 2005). Phthalates have also been shown to alter androgen steroidogenesis during pregnancy (Lyche et al., 2009).

The placenta also expresses metabolic enzymes, including several cytochrome P450s (CYPs) and both phase 1 (modification) and phase 2 (conjugation) enzymes. Metabolites measured in placental tissue and cord blood are one of the most commonly used biomarkers of placental and fetal toxicity. Ethyl glucuronide, the major metabolite of ethanol, a known fetal toxicant, can be detected in placental tissue following maternal alcohol consumption (Morini et al., 2011). Metabolites of phthalates, organochlorine pesticides, PCBs, PBDEs, and other environmental contaminants are readily detected using mass spectrometry methods (Leino et al., 2013). Toxic metabolites such as epoxides that form DNA adducts can also serve as biomarkers. PAH adducts such as benzo(a)pyrene from smoking and air pollution as well as aflatoxin adducts can be detected using methods such as immunoassays, mass spectrometry, and ^{32}P-postlabeling (Carlberg et al., 2000; Partanen et al., 2010).

Gene expression changes are another biomarker of placental toxicity. Altered expression of transporter proteins, stress proteins, signaling molecules, and metabolizing enzymes have all been linked to exposures to xenobiotics (Myllynen et al., 2005; Vahakangas and Myllynen, 2009). For example, phthalate alteration of steroidogenesis can be monitored by gene expression changes of CYP (cytochrome P450) (Adibi et al., 2010). In particular, the induction of CYP1A1, the gene for enzyme responsible for biotransformation of xenobiotics, is a sensitive biomarker of exposure to environmental contaminants (Whyatt et al., 1995). CYP1A1 is regulated by the aryl hydrocarbon receptor (AhR), which is in turn responsive to xenobiotic ligands including polycyclic aromatic hydrocarbons, organochlorines, and dioxins (Mimura and Fujii-Kuriyama, 2003; Stejskalova and Pavek, 2011).

Female Reproductive Aging

Reproductive aging in women is an irreversible process that begins before birth and lasts through the menopausal transition. It consists of changes in sex steroid, peptide, and gonadotropin hormone levels, abnormal menstrual cyclicity, changes in ovarian histology and morphology, and decreases in fertility (Burger, 2006). Typically, sex steroid (estradiol, progesterone, and testosterone) and peptide hormone (inhibin B and anti-Müllerian hormone [AMH]) levels decrease, whereas gonadotropin (FSH and LH) levels increase with reproductive aging (de Kat et al., 2016; Santoro, 2002). In women, anovulatory cycles and abnormal hormone levels become more common as they progress through the menopausal transition and enter reproductive senescence (Santoro, 2002). In rodents, abnormal hormone levels lead to irregular estrous cyclicity, and eventually acyclicity (Scarbrough and Wise, 1990). In both women and animal models, ovarian histology significantly changes with aging and is characterized by a drastic decrease in the size of the primordial follicle pool

(te Velde and Pearson, 2002). In rodents, formation of ovarian cysts is common as an animal ages (Vidal et al., 2013). These changes in hormones, cyclicity, and ovarian histology lead to subfertility/infertility with age.

Many biomarkers have been used to examine the effects of toxicants on reproductive aging. One of these biomarkers is measurement of the levels of reproductive hormones such as estradiol, testosterone, progesterone, and inhibin B by ELISAs or RIAs. Hannon et al. (2016) used both ELISAs and RIAs to determine the effects of DEHP on sex steroid, peptide, and gonadotropin hormone levels in aging female mice. They showed that adult exposure to DEHP decreased the levels of inhibin B and the ratio of estradiol to progesterone in mice at 9 months of age, indicating that DEHP exposure accelerates reproductive aging. Similarly, Shi et al. (2007) used ELISAs to determine the effects of TCDD on reproductive aging in rats, and they found that TCDD decreased estradiol levels in rats at 9 months of age.

Another biomarker of reproductive aging includes the monitoring of estrous cyclicity. In rodents, estrous cyclicity is monitored by subjecting animals to daily vaginal lavage for a set amount of time (ranging from days, to weeks, to months). As rodents age, and their hormones change, this leads to irregular cyclicity, and eventually an animal becomes acyclic (Gee et al., 1983; Gore et al., 2011; Scarbrough and Wise, 1990). This biomarker has been used to show that adult exposure to DEHP altered cyclicity in mice at 6 months of age and increased time spent in diestrus/metestrus in mice at 9 months age, indicating that the mice may be exhibiting early reproductive aging (Hannon et al., 2016). Furthermore, Aroclor 1221 increased the length of estrous cycles in rats (Walker et al., 2013).

An additional biomarker for reproductive aging includes examining the morphological appearance of the ovary. Within the ovary, follicles undergo several developmental changes in a process known as folliculogenesis (Hannon and Flaws, 2015). Follicles undergo many changes beginning as germ cells, developing into germ nests, and undergoing germ cell nest breakdown to form primordial follicles. Once the primordial follicle population is established, the follicle will become part of the follicle reserve, undergo atresia, or grow into primary follicles. With normal aging, the primordial follicle pool decreases dramatically, leading to reproductive senescence (te Velde and Pearson, 2002). Several studies have used follicle counts as a biomarker for the ovarian reserve. For example, in one study, adult DEHP exposure decreased primordial follicle numbers and total follicle numbers, leading to early reproductive aging in female mice 9 months after dosing (Hannon et al., 2016). Furthermore, prenatal exposure to DEHP altered folliculogenesis in both the F1 and F3 generations of 1-year-old mice (Brehm et al., 2018).

Besides counting follicle numbers, the general morphology of an ovary can be examined as a biomarker of ovarian function. Rodents often develop cystic follicles as they spend more time in persistent estrus and have excess levels of estrogen and progesterone with age (Vidal et al., 2013). These cysts can arise from follicles, corpora lutea, rete ovarii, surface epithelium, ovarian bursae, or embryonic remnants. The presence of cysts has been used as a biomarker in studies on phthalates. For example, Zhou et al. (2017a,b) showed that a mixture of phthalates increased the occurrence of cystic ovaries at 13 months of age in both the F1 and F2 generations of female mice.

Due to the decline in follicle numbers and quality with reproductive aging, fertility decreases as well. Fertility-related indices in rodents can be analyzed by calculating different endpoints including pregnancy rate (the number of pregnant females divided by the number of breeding pairs multiplied by 100) and fertility index (the number of pregnant females divided by the number of females with a vaginal sperm plug multiplied by 100) (Ziv-Gal et al., 2015). These rates have been used as biomarkers in several studies on EDCs. For example, *in utero* BPA exposure reduced the ability of female mice to maintain pregnancies as they became older and drastically decreased the percent of fertile females at 9 months of age (Wang et al., 2014; Ziv-Gal et al., 2015). Prenatal exposure to a phthalate mixture increased pregnancy loss in the F1 generation and reduced the pregnancy rate and fertility index in mice at 9 months of age (Zhou et al., 2017b). In women, as fertility declines during the menopausal transition, occurrence of hot flashes increases. Phthalate metabolites have been associated with an increased risk of ever experiencing hot flashes and more frequent hot flashes in perimenopausal women (Ziv-Gal et al., 2016).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Measuring biomarkers is a resourceful way to observe effects of chemical exposure on different biological processes including development and reproduction (Figs. 17.2 and 17.3). Changes in spermatogenesis, folliculogenesis, puberty, and reproductive aging are measured by examining the morphology of sperm and ovarian follicles. ELISAs and RIAs are used to measure the effects of chemicals on steroidogenesis, puberty, and reproductive aging. Furthermore, the Tanner Scale is a tool to measure puberty. Finally, gene expression is used as a biomarker for changes in the uterus, placenta, folliculogenesis, spermatogenesis, and steroidogenesis.

BPA and phthalates, particularly DEHP, are commonly associated with changes in reproductive biomarkers because of their endocrine-disrupting abilities in both males and females (Fig. 17.1). BPA has been shown to affect spermatogenesis, folliculogenesis, the uterus, the placenta, and reproductive aging in both males and females. Furthermore, DEHP affects several biomarkers including spermatogenesis, folliculogenesis, steroidogenesis, reproductive aging, and puberty in both males and females. However, the mechanisms of action are often unknown. Thus, future studies are needed to examine the mechanisms of these different EDCs and how their toxicity affects the biomarkers of reproduction. Furthermore, results from human epidemiological studies are not always consistent and vary with both population and methods. Therefore, future studies are needed to better observe the effects of EDCs on biomarkers of development and reproduction in humans.

INTRODUCTION

Human placenta in between the mother and the fetus is a very special organ in many ways. In human reproduction, placenta is the gastrointestinal tract, lungs, liver, and kidneys of the fetus and its proper functioning is essential for fetal health and development as well as for the future health of the child (Burton et al., 2016)

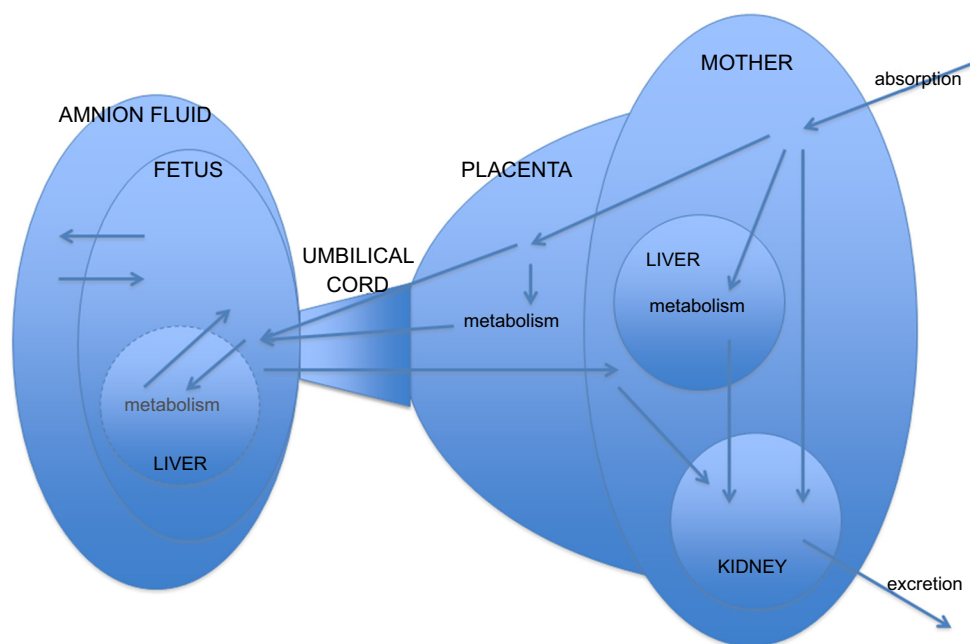
(Fig. 18.1). Furthermore, placental tissue is mainly of fetal origin and placental changes are directly related to fetal development. Placental biomarkers of toxicity may thus also reflect direct toxicity in the fetus. Biomarkers of placental toxicity have been searched for in studies using animals, trophoblastic cells lines, human placental tissue, and human blood samples. They would be useful in clinical medicine, e.g., when


FIGURE 18.1   Toxicokinetics in mother, placenta, and fetus.

303

evaluating potential drug toxicity in placenta. In toxicology, biomarkers that inform about exposure and/or significant toxic effects in the placenta would be very useful in risk assessment.

The problems in extrapolating placental studies in animals to humans are the conspicuous interspecies differences in placental structure and function and in many biochemical and molecular features, e.g., expression of enzymes. Gene expression in placenta reflects its evolutionary history. Probably due to the more recent development of placenta compared to other tissues, placental transcription factors potentially regulating xenobiotic metabolism, transporters, and other placental proteins are very different from the ones present in other tissues (Pavek and Dvorak, 2008).

At term, human discoid placenta weighs about 500 g, its diameter is about 25 cm, and it is about 3 cm thick. There is thus a lot of material and human placental tissue can be easily studied after birth. However, it is important to remember that at term placenta represents tissue at the end of its lifespan. Placenta itself goes through major anatomical, biochemical, and functional changes during the 9 months of its lifespan. This is reflected in many placental structures, functions, and expression of both proteins and RNAs. Early placentas are less frequently available for study after spontaneous or induced abortions. During pregnancy, chorionic villous biopsies can be taken only by clinical indications because of the risks for the pregnancy.

From an ethical point of view, pregnant women are regarded as a special group. Requesting the placenta, especially in the emotionally sensitive situation after abortion, creates ethical issues, which have to be considered before the actual research (Halkoaho et al., 2010). The two most important ethical issues are safety of the mother and fetus, which may be endangered if samples are taken during pregnancy, and informed consent, which should be voluntarily solicited from the mother before taking the placenta.

Various environmental chemicals can be found in human placenta and can clearly affect placental physiology and molecular pathways. Drugs and other chemical compounds can induce placental toxicity through a variety of mechanisms, which may be functional also in other tissues. A genotoxic compound has the potential to induce genomic damage also in trophoblastic and other cells of the placenta. Compounds toxic to mitochondria can be expected to damage placental mitochondria as well. Thus there are measurable entities, e.g., DNA adducts, which can be anticipated to serve as biomarkers of toxicity in any tissue, including the placenta. There are other biomarkers specific to the developmental stage, reflecting both fetal and placental function, e.g., hormone levels in blood during pregnancy. New emerging levels of regulation of cellular functions, e.g., noncoding RNA, give new possibilities for biomarker development. For instance, some microRNAs seem to be expressed primarily and extensively in the placenta.

Biomarkers of placental toxicity, analyzed in placental tissue or in another matrix, would be useful for evaluation of placental and potentially also fetal toxicity in both the clinical setting and environmental studies. On the other hand, biomarkers of toxicity in placental tissue may reflect general toxicity.

PLACENTAL DEVELOPMENT AND STRUCTURE

The development of human placenta begins 6–7 days after fertilization when the fertilized egg in the form of a blastocyst implants into the uterine wall (Benirschke et al., 2006). At this point the blastocyst contains about 100–250 cells that form the outer and inner cell mass. The inner cell mass is called the embryoblast and develops into embryo, umbilical cord, and amnion, whereas the outer cell mass, or trophoblast, develops into placenta. In the trophoblast the outer layer of cells forms the syncytiotrophoblast by the fusion of neighboring trophoblastic cells. The inner layer of cells contains cytotrophoblasts, which remain nonfused and divide to create material for the syncytiotrophoblast. The nuclei of the syncytiotrophoblast lose their capacity to divide.

The formation of a full layer of the syncytiotrophoblast is completed by 12 days after the fertilization, when the uterine epithelium closes over the deeply implanted blastocyst. About 13 days after fertilization, cytotrophoblastic proliferation increases and cytotrophoblasts together with syncytiotrophoblast form the placental primary villi (Sadler, 2004; Benirschke et al., 2006). The first fetal capillaries in the villous structure can be found about 18–20 days after fertilization. Further development of the villous capillary system gives rise to the extraembryonic vascular system and contact with the maternal circulation. Placental development continues throughout the pregnancy. For example, the syncytiotrophoblastic (syncytial) knots, which are aggregates of syncytial nuclei, increase with gestational age (Benirschke et al., 2006). Their abundance can be used to evaluate villous maturity, but also can be an indicator of poor uteroplacental circulation.

For the exchange of nutrients and gases, human placenta has a complex structure with two circulations, fetal and maternal, separated by a thin layer consisting of several cell types (Fig. 18.2). The maternal uterine surface of the placenta is called the basal plate, and the fetal (amnionic) surface of the placenta is known as a chorionic plate (Benirschke et al., 2006). Between the basal
FIGURE 18.2   Anatomy of term human placenta (figure by Dr. Chiara Mannelli).

and chorionic plates there is the intervillous space. Villous trees branching from the chorionic plate are directly in contact with maternal blood that circulates through the intervillous space. The chorionic arteries and veins from villous trees gather to form bigger vessels and, finally, the three vessels of the umbilical cord. Oxygen and nutrients are delivered to the fetus by one umbilical vein, and two umbilical arteries bring the waste products back to the maternal blood circulation via the placenta.

Term human placenta has 10–40 slightly elevated areas at the basal surface, called maternal cotyledons (Benirschke et al., 2006). Each maternal cotyledon is occupied by one or several villous trees. Maternal cotyledons correspond fairly well to the positions of the villous trees. The exchange of all compounds between maternal and fetal blood occurs through the surface of villous trees. This fetomaternal distance decreases to about one-tenth of the diffusion distance in the second month toward term. At the end of pregnancy only two cell layers (syncytiotrophoblast and the endothelial lining of fetal vessels, with some connective tissue in between) separate maternal and fetal blood (Sadler, 2004; Benirschke et al., 2006).

TOXIC AND HORMONALLY ACTIVE CHEMICALS IN HUMAN PLACENTA

Most compounds cross human placenta quite easily, although the ABC (ATP binding cassette) efflux transporters may slow down the transfer of at least some compounds (Vähäkangas et al., 2011). Compounds can also accumulate in the placenta, especially lipid-soluble chemicals (Ala-Kokko et al., 2000). Polychlorinated dibenzo-*p*-dioxin (PCDD) and polychlorinated dibenzo-*p*-furan (PCDF) congeners and Co-PCBs (dioxin-like coplanar polychlorinated biphenyls) with a high toxic equivalence factor are examples of lipid-soluble environmental compounds that accumulate in human placenta (Suzuki et al., 2005). In vivo many toxic compounds have been detected in placental and fetal samples (Table 18.1). Presence of toxic chemicals in cord blood or meconium proves that the fetus is exposed and compounds measurable in placental tissue probably have reached the fetus as well. In addition, numerous compounds measured in cord blood and/or meconium implicate placental exposure. These include legal and illegal drugs, and heavy metals (Crinnion, 2009). It is obvious that all compounds that interfere with normal placental development and function can also disturb fetal development or lead to miscarriage (Burton et al., 2016). Changes in normal placental function can occur at many levels, e.g., transport of nutrients and waste products, cell signaling, production and release of hormones and enzymes, and cellular growth and maturation (Myllynen et al., 2005).

Ethanol is a good example of a toxic compound known to affect the development of placenta and its functions (Burd et al., 2007). Ethanol can be toxic for the placenta by impairing normal transfer of amino acids, zinc, and glucose (Fisher and Karl, 1988). Together with smoking and nutritional deficiencies, prenatal alcohol exposure can lead to poor or limited placental development, and consequent placental dysfunction or abruption can even threaten fetal or maternal life. Ethanol is also directly fetotoxic and possible fetal outcomes include prematurity, growth impairment, neurocognitive problems, birth defects, and mortality. In perfused human placental cotyledon, ethanol induces vasoconstriction, which lasts as long as ethanol is present (Taylor et al., 1994). Ethanol may also induce oxidative stress in placental villi (Kay et al., 2000). This has been associated with placental toxicity in the form of impaired oxygen transport and followed by fetal acidosis (Acevedo et al., 1997).

TABLE 18.1 Chemicals, Their Fetotoxicity, and Potential Biomarkers in Human Placental Tissue or Fetal or Maternal Specimens After In Vivo Exposure

Chemical Group and Examples	Possible Fetotoxicity	Potential Biomarker	Matrix Measured
AMINES			
Acrylamide	Impaired fetal growth[1]	DNA-adducts[2]	Cord blood[2]
Glycidamide	Impaired fetal growth[1]	DNA-adducts[2]	Cord blood[2]
METALS		Compounds Themselves	
Cadmium	Reduced birth weight[3,4]	Metallothioneins, lipidperoxidases[5]	Placenta[6], cord blood[6,7], maternal blood[6,7]
Lead	Immune system effects, later in life increased risk of asthma and allergy	Metallothioneins, lipid peroxidases, ALAD[5]	Placenta[6], cord blood[6,7], maternal blood[6,7]
	Effects on neuro development[4,8]		
Mercury	Effects on neuro development[4,8]		Placenta[6], cord blood[6,7,9–11] meconium[9,10], infant's hair[9], maternal blood[6,7]
Manganese	Intrauterine growth retardation[12]	MAO-activity[13]	Cord blood[13], maternal blood[13]
MYCOTOXINS			
Aflatoxins	Low birth weight[14]; growth faltering in the first year of life[15]	DNA-adducts[16]	Placenta[16], cord blood[14,16–19], maternal blood[17,18]
Ochratoxins	NA		Cord blood[19–21], maternal blood[20], breast milk[20,21]
PAH COMPOUNDS	Gene mutations[22]	PAHs themselves[23–26]	Placenta[27], cord blood[23,26]
		DNA-adducts[27,28]	Placenta[28], cord blood[29,30]
Acenaphthylene, acenaphthene, fluorine, phenanthrene, anthracene, fluoranthene, pyrene, benz[a]anthracene, chrysene, benzo[b]fluoranthene, benzo[k]fluoranthene, benzo[a]pyrene, dibenz[a,h]anthracene, indeno[l,2,3 cd]pyrene, benzo[g,h,i]perylene,			
OTHER ENVIRONMENTAL POLLUTANTS		Compounds Themselves	
OCPs	Impaired fetal growth[31]		Placenta[32], maternal blood[23,32,33], cord blood[32,33], breast milk[23,33]
Parathion, malathion, etc.	NA		Cord blood[32,34]
PBDEs	NA		Placenta[35], maternal blood[33,36,37], cord blood[33,36,37], breast milk[33,36]
PCBs	Effects on developing neurological system and sex hormone levels; recurrent infections[8]		

TABLE 18.1 Chemicals, Their Fetotoxicity, and Potential Biomarkers in Human Placental Tissue or Fetal or Maternal Specimens After In Vivo Exposure—cont'd

Chemical Group and Examples	Possible Fetotoxicity	Potential Biomarker	Matrix Measured
PLASTICIZER			
Bisphenol A	Reduction in fetal body weight[38]		Placenta[39,40], cord blood[41–43], amniotic fluid[44], fetal liver[39], maternal blood[41–45]
SOCIAL DRUGS			
Ethanol	FASD[46]	Ethyl glucuronide[47–50], ethyl-sulfate[49,50], fatty acid ethyl esters[48]	Meconium[48,50], placenta[49], fetal tissues[49]
Nicotine	Adversely affects the development of many organ systems, especially brain and lungs[61]	Cotinine[51],	Placenta[51], cord blood[53], meconium[54]
		Trans-3′-hydroxycotinine[52]	Meconium[52]
(ILLEGAL) DRUGS			
Cocaine	Restricted fetal growth[55]	Benzoylecgonine, m-hydroxybenzoylecgonine, ecgonine methyl ester[56]	Placenta[56], umbilical cord[56], meconium[54,56,57]
Methadone	Neonatal abstinence syndrome	EDDP[56]	Placenta[56], umbilical cord[56], meconium[54,56,57]
Heroin	Impaired fetal growth; risk of neonatal abstinence syndrome[59]	6-Monoacetylmorphine[58]	Meconium[58]
Morphine	Impaired fetal growth[59]	Morphine-3-glucuronide, morphine-6-glucuronide[56]	Placenta[56], umbilical cord[56], meconium[52,54,56]
Cannabis	Adverse fetal growth trajectories[60]		Meconium[57]

Maternal cigarette smoking during pregnancy is associated with increased risk of adverse birth outcomes, such as low birth weight and infant mortality (Vyhlidal et al., 2012). In human placenta, cotinine, one of the main metabolites of nicotine, can cause vasoconstriction by activating placental phospholipase A2 and increasing the effects of prostaglandin E2 (Rama Sastry et al., 1999). Vasoconstriction in placenta is associated with increased frequency of spontaneous abortions and preterm births. Human placenta expresses at mRNA level all and at protein level at least nine nicotine receptor subtypes (α2, α3, α4, α5, α7, α9 β1, β2, and δ; Machaalani et al., 2014). In rodent placenta nicotine exposure leads to disrupted placental morphology as well as reduced 11β-hydroxysteroid dehydrogenase activity associated with poor fetal growth and health later in life (Zhou et al., 2018). Polycyclic aromatic hydrocarbons (PAHs), ubiquitous environmental contaminants, are also among the main components of tobacco smoke. Many carcinogenic and mutagenic PAHs induce oxidative stress and are suspected to have adverse effects on reproductive outcomes (Al-Saleh et al., 2013). The fetus can be exposed to PAHs and many other toxic chemicals also via maternal

food (Myöhänen and Vähäkangas, 2012). One of the most studied PAHs, carcinogenic benzo(a)pyrene (BP; Class 1; IARC, 2010), is found also in smoked, flamed, and grilled food (Miller and Ramos, 2001). BP-DNA adducts are found in human placenta (Manchester et al., 1988). Even caffeine use during pregnancy was shown to reduce birth weight of the fetus (Sengpiel et al., 2013). The doses with such effects were lower than current recommendations during pregnancy.

In human placental tissue many heavy metals, such as cadmium (Cd), copper (Cu), mercury (Hg), and lead (Pb), have been found (Kantola et al., 2000; Needham et al., 2011; Gundacker and Hengstschläger, 2012), and this may be the case with other heavy metals as well. Heavy metals affect many normal functions of human placenta (Kantola et al., 2004; Gundacker and Hengstschläger, 2012), and at least Pb and nickel (Ni) accumulate in the syncytiotrophoblast (Reichrtová et al., 1998). Accumulation of Pb leads to decreased cytochrome oxidase activity in placental cells (Reichrtová et al., 1998). Pb in maternal blood was significantly associated with a decreased uptake of calcium into isolated trophoblastic cells in the study by Lafond et al. (2004). A balance between heavy metal and selenium concentrations in maternal blood and placental tissue has suggested a protective role for selenium in restoring placental metabolic activities (Kantola et al., 2004). Therefore, in terms of adverse effects at the fetoplacental unit or within the whole body, the question may not only be of the actual heavy metal concentration but also the ratio between heavy metal burden and the amount of protecting "scavengers" present in the tissue. These markers display great interindividual and regional variation (Kantola et al., 2000, 2004).

In BeWo choriocarcinoma cells, Cd inhibits the function of the efflux transporter ABCG2 (Kummu et al., 2012), which probably has a role in transplacental transfer of many xenobiotics (Vähäkangas and Myllynen, 2009). In rats, Cd accumulates in placenta resulting in trophoblastic damage, which decreases the nutrient and oxygen transfer to fetus (Levin et al., 1981). Also in humans, Cd has been shown to accumulate in placenta (Korpela et al., 1986; Osman et al., 2000; Esteban-Vasallo et al., 2012). Kippler et al. (2010) found a link between placental Cd levels and impaired Zn transfer into the fetus, as well as increased amounts of metallothionein (MT) in placental tissue. Cd also inhibits placental transport of calcium. Furthermore, many other placental functions are disturbed by Cd as well, e.g., decidualization and hormonal balance (Gundacker and Hengstschläger, 2012). Toxicity of Hg to placenta includes at least disturbed amino acid transfer, placental oxygen consumption, enzyme activities, hormonal secretion, and membrane fluidity.

Organochlorine pesticides (OCPs) and other persistent organochlorine compounds have also been found in human placenta (Lopez-Espinosa et al., 2007; Bergonzi et al., 2011; Needham et al., 2011). The existence of OCPs in maternal blood, cord blood, and breast milk indicates that placenta, fetus, and infant are exposed to these chemicals (Al-Saleh et al., 2012; Dewan et al., 2013; Kezios et al., 2013). DDT (active p,p-DDT) is perhaps the best-studied OCP; p,p-DDT as well as its metabolites p,p-DDE and p,p-DDD have been detected in placenta, cord blood, and maternal blood (Al-Saleh et al., 2012) and can be used to evaluate exposure. Environmental pollutants, such as polybrominated diphenyl ethers (PBDEs) and polychlorinated biphenyls (PCBs), have been detected in placental tissue (Ma et al., 2012; Virtanen et al., 2012). Additionally, PBDEs, PCBs, hydroxylated metabolites of PCBs (polychlorobiphenylols; OH-PCBs), and pentachlorophenol have been detected in cord blood, maternal plasma, and breast milk (Guvenius et al., 2003; Park et al., 2009) indicating exposure of the placenta as well.

Environmental endocrine disruptors have been associated with various reproductive abnormalities (Robins et al., 2011). The plasticizer bisphenol A (BPA) has been detected in human cord blood, indicating that it crosses human placenta (Schönfelder et al., 2002; Lee et al., 2008; Wan et al., 2010). It has also been detected in human term placenta (Schönfelder et al., 2002) and various human biological fluids, such as maternal blood (Lee et al., 2008; Padmanabhan et al., 2008; Wan et al., 2010) and amniotic fluid (Yamada et al., 2002). In amniotic fluid five times higher concentrations of BPA have been measured than of other body fluids (Ikezuki et al., 2002). Also BPA metabolites have been detected in both maternal and cord sera, levels being higher in cord serum (Liu et al., 2017).

PLACENTAL FUNCTIONS AND MOLECULAR PATHWAYS INVOLVED IN TOXICITY

Xenobiotic Metabolism and Its Regulation in Human Placenta

While the liver plays a major role in xenobiotic metabolism, all tissues, including placenta, express at least some of the xenobiotic-metabolizing enzymes, although at a much lower level (for reviews, see Pasanen, 1999; Myllynen et al., 2007, 2009; Prouillac and Lecoeur, 2010). In the beginning of pregnancy placenta expresses mRNA of a wider variety of CYPs and conjugating enzymes (e.g., the UGT1A family) than at term (for a review see Myllynen et al., 2007). Functionally the most important of the xenobiotic-metabolizing CYP enzymes in placenta is CYP1A1. It is inducible, e.g., by cigarette smoking (Pasanen et al., 1988; Hakkola et al., 1996).

Kinetics of drugs and drug-metabolizing capacity as well as metabolizing enzyme profiles vary depending on the stage of pregnancy (Dickmann and Isoherranen, 2013), also in the placenta (Pasanen, 1999; Myllynen et al., 2005, 2007). Although the CYP-mediated metabolism in placenta is much more restricted than in the liver, a number of drugs and foreign chemicals are metabolized and activated. CYP1A1 activity is very low, but inducible, e.g., by cigarette smoking. In addition to CYP1A1, CYP19A1 (aromatase) has toxicological relevance and is also induced by xenobiotics. Both CYP1A1 and CYP19A1 are expressed and functional throughout the pregnancy. Other CYP enzymes expressed at protein level in human placenta include CYP11A1, CYP2J2, CYP2R1, CYP27B1, and CYP24A1. Even the CYP2 members in the placenta are evolutionarily old with only physiological substrates, and most placental CYPs are linked to steroid metabolism (Storvik et al., 2014). Of the CYP enzymes, CYP19A1 is the most highly expressed. In the placenta CYP enzymes including CYP1A1 have unique regulation mechanisms and expression patterns different from those in the liver. Aromatase is nearly undetectable in normal hepatocytes (Granata et al., 2009), but increased expression and activity have been reported in diseased liver cells (Hata et al., 2013).

In addition to CYP1A1 and some other functionalization reactions, all the main conjugation activities are also expressed in human placenta but with different isoenzyme expression profiles than in the liver or kidney. All the most important phase 2 enzyme activities (glutathione transferase, epoxide hydrolase, N-acetyltransferase, sulfotransferases and UDP-glucuronyl transferase) are also found in human placental tissue (Pasanen and Pelkonen, 1990; Paakki et al., 2000a; b; Collier et al., 2000). Protein expression of the conjugating enzymes may also in some cases respond to chemical stress (Paakki et al., 2000a; b). However, both functionalization and conjugation activities are more specifically associated with endocrine functions of placenta (Pasanen, 1999).

In human placenta, CYP1A1 catalyzing the AHH activity (aryl hydrocarbon hydroxylase, named according to the first activity found for this enzyme) is the only functionally active "traditional" xenobiotic targeting CYP form. Toxicologically CYP1A1 is interesting because it activates several procarcinogens and proteratogens (Stejskalova and Pavek, 2011). Half a century ago, Welch et al. (1968) demonstrated that placental monooxygenase enzymes can metabolize BP in vitro. Later it was shown that BP is metabolized by the placental CYP-dependent system to its ultimate carcinogenic metabolite, BP-7,8-diol-9,10-epoxide capable of DNA binding, and that the DNA binding also correlates with AHH activity (Namkung and Juchau, 1980;

Vähäkangas et al., 1989; Lagueux et al., 1999; Carlberg et al., 2000; Obolenskaya et al., 2010; Stejskalova and Pavek, 2011).

CYP19A1 in placenta is needed for estradiol production, and maintenance of pregnancy, as well as sexual differentiation of gonads and brain of the fetus. It catalyzes reactions producing estradiol from testosterone, estrone from androstenedione, and estriol from 16α-hydroxylated dehydroepiandrosterone. Interestingly, in addition to the production of estrogens from androgen derivates, CYP19A1 also metabolizes xenobiotics because it possesses a wider substrate-binding pocket than its vital function suggests. In addition, CYP19A1 can metabolize certain xenobiotics, such as buprenorphine (Deshmukh et al., 2003), and is itself inhibited by xenobiotics (Table 18.2).

CYP19A1 is very disproportionally highly expressed in placenta, compared to the liver (GEO DataSet Record GDS3113). Furthermore, among the mammalian CYP enzymes, CYP19A1 is the only one with placenta as the tissue of major expression. This high basal CYP19A1 transcription in placenta is determined by a promoter that is specific to humans (Bulun et al., 2003).

Human placental microsomal fraction, choriocarcinoma cells (e.g., JEG-3, BeWo), trophoblastic primary cells, or cells expressing recombinant CYP19A1 protein have been used to test the specificity and metabolic inhibitory potential on placental aromatase of several chemical structures (Table 18.2). In addition to classical steroids, and indole and azole-based aromatase inhibitors (Leze et al., 2004; Yahiaoui et al., 2004), several other chemical structures are capable of docking to the active center or prosthetic structures of CYP19A1 and influence the catalytic activity of the protein. For instance, BPA can directly inhibit the catalytic activity of CYP19A1 and downregulate the expression via the promoter I.1 (Watanabe et al., 2012). Aflatoxin B1 (AFB1) is a substrate for CYP19A1, and additionally affects CYP19A1 gene expression by secondary messengers (Storvik et al., 2011; Huuskonen et al., 2013).

The regulatory machineries driving the expression of CYPs in placenta mainly respond to maternal health status (Hakkola et al., 1996). The effect of maternal health may be complex and affect the enzyme activities in yet unknown ways. For example, oxidized LDLs and their PPARgamma and LXR ligands may decrease placental CYP expression due to an effect on placental development during the first two semesters (Pavan et al., 2004a; b). The best characterized regulators of CYP expression in placenta are the hormonal signals, hypoxia, proinflammatory cytokines, and certain xenobiotic compounds mimicking endogenous compounds.

Human placenta does not express most hepatic transcription factors (Storvik et al., 2014). For example,

TABLE 18.2　The Effect of Chemicals and Stress Factors on Human Placental CYP19A1

Compound	Response	Placental Test System	References
Aflatoxin B1	Substrate (aflatoxicol metabolite), induction	JEG-3 cells, microsomes	Sawada et al., 1993; Storvik et al., 2011; Huuskonen et al., 2013

CAR (NR1I3), which is one of the major inducers of liver enzymes (Wallace and Redinbo, 2013), is barely detectable in human placenta, as are also PPARα (NR1C1), PXR (NR1I2), and HNF4α (NR2A1). On the other hand, placenta does express several other nuclear factors, such as cortisol receptor (NR3C1), estrogen receptors, ERRγ, and PPARγ, LXRα (NR1H3), SHR (NR0B2), and VDR (NR1I1) (Pavek and Dvorak, 2008). In addition, the aryl hydrocarbon receptor (AHR; NR3C1) is also present in very high levels, being able to induce CYP1A1 in a classical way, but also to interact with other nuclear factors (Huuskonen et al., 2008).

The expression of the CYP19A1 gene is regulated by tissue-specific promoters upstream of tissue-specific first exons (Mendelson and Kamat, 2007). Of the existing 10 or more promoters of the gene, 3 are reported to be active in human placenta. The activation of the placenta-specific constitutively active promoter I.1 leads to induction of CYP19A1 during pregnancy, which then elevates the estrogen levels in pregnant women up to 1000 times the baseline (Bulun et al., 2003). This increase of CYP19A1 expression occurs as the cytotrophoblasts differentiate into syncytiotrophoblast in developing placenta (Mendelson and Kamat, 2007). In addition to promoter I.1, promoters I.2 and I.8 have been described to be practically placenta specific (Demura et al., 2008).

CYP11A1, the key enzyme in steroid production, producing pregnenolone from cholesterol, is present in placenta at high level. The regulation of CYP11A1 in placenta is different from most other tissues, not regulated by the binding site shared by steroidogenic factor 1 (NR5A1) and liver receptor homolog-1 (NR5A2). However, the transcription factors AP1 and SP1, together with certain tissue-specific factors, may regulate the expression of CYP11A1 in placenta (Shih et al., 2011).

CYP2J2 is expressed in placenta at a moderate level (Pavek and Dvorak, 2008). It is regulated at least by proinflammatory signals, and it produces epoxyeicosatrienoic acid derivatives from arachidonic acid. These compounds are reported to be increased in preeclampsia (PE) and have cardiovascular effects (Herse et al., 2012). The regulation of CYP2J2 expression is linked to intracellular signaling pathways leading to AP1 activation in stress conditions (Cui et al., 2010).

The regulatory pathways and CYP enzymes required in vitamin D metabolism are also expressed in placenta (Storvik et al., 2014). These include CYP2R1, which converts calciferol to calcidiol, CYP27B1 catalyzing metabolism further to calcitriol, and CYP24A1 catabolizing calcitriol. All the abovementioned CYPs are affected in preeclampsia, probably through hypoxia or oxidative stress (Ma et al., 2012).

Placental Transporters

For transport of nutrients and other compounds, there is a rather wide variety of transporter proteins expressed in placental cells, both trophoblastic and endothelial cells (for reviews see, e.g., Vähäkangas and Myllynen, 2009; Staud et al., 2012; Iqbal et al., 2012). Transporters expressed in the placenta may facilitate transfer in both the maternal and fetal directions depending on the localization and function of the transporter protein. Drug transporters in human placenta include ABC and SLC (solute carrier protein) transporter families. Of the ABC transporters ABCB1 (P-glycoprotein or p-gp, MDR1), ABCG2 (BCRP or breast cancer resistance protein), and several ABCC (multidrug resistance-associated proteins or MRP) transporters are found in human placenta. Other transporters with xenobiotics as substrates include organic anion/cation transporters. Accumulating evidence suggests that these transporters modify also transplacental transfer of pharmaceutical drugs.

Toxicologically the most studied are the ABC transporters, which in human are efflux transporters. Of the ABC transporters, ABCG2/BCRP, ABCB1/p-gp, and several of the ABCC/MRP-proteins reside in the brush border apical membrane of syncytiotrophoblast-facing maternal blood. These transporters have a potential protective role against xenobiotics because they transport drugs and compounds back to maternal blood from syncytiotrophoblast. The ABC transporters are expressed in human placenta through the pregnancy and the expression level depends on the gestational stage. The expression of ABCB1/p-gp protein has been reported to decrease toward the end of pregnancy (Matthias et al., 2005). Results on the expression of ABCG2/BCRP in human placenta have been discrepant (Matthias et al., 2005; Meyer zu Schwabedissen et al., 2006; Yeboah et al., 2006). ABCC/MRP transporters have been reported to decrease toward the end of pregnancy (Meyer zu Schwabedissen et al., 2006).

Xenobiotics may be substrates for placental transporters but they may also interfere with transporter function or affect the expression level of transporters (for reviews see Vähäkangas and Myllynen, 2009; Staud et al., 2012; Iqbal et al., 2012). Although a number of studies suggest that transporter proteins have a role in transplacental toxicokinetics, much less is known about interactions of these transporters with other xenobiotics such as environmental contaminants, food-borne carcinogens, or abused substances (Table 18.3). However, studies in animal models and cells originating from other tissues suggest that a number of environmental contaminants in fact interact also with drug transporters (Carew and Leslie, 2010; Gundacker et al., 2010; Yang et al., 2010; Pacyniak et al., 2011). For instance, PBDE congeners seem to be substrates for OATPs (Pacyniak et al., 2011) and perfluorinated compounds for OAT4 and URAT1 (Yang et al., 2010). Interestingly, there is also experimental evidence suggesting that metals such as Pb, Cd, and arsenic (As) interact with ABC transporters (see e.g., Carew and Leslie, 2010; Gundacker et al., 2010; Thévenod, 2010; Kummu et al., 2012). ABCC1, ABCC2, and ABCB1 may participate in metal efflux from the cells (Gundacker et al., 2010; Thévenod, 2010; Carew and Leslie, 2010), whereas Cd seems to inhibit ABCG2 transporter function (Kummu et al., 2012).

In addition to "drug transporters," placenta also displays high activities of a variety of transporters for nutrient transfer (for a review see, e.g., Carter, 2012). Five types of amino acid transporters have been reported in human placenta: sodium-coupled neutral amino acid transporters, high affinity glutamate and neutral amino acid transporters, sodium- and chlorine-dependent transporters, cationic amino acid transporters, and glycoprotein-associated amino acid transporters. Human placenta expresses also several glucose transporters in microvillous and basal membranes of the syncytiotrophoblast as well as in capillary endothelium. Activity of the placental glucose and amino acid transport systems is influenced by gestational age and a range of environmental factors including heat stress, hypoxia, and under- and overnutrition, as well as exposure to hormones. Implications of interference with these transporters by chemicals have also been published. Nicotine, cocaine, or their combination inhibit several amino acid transporters (Pastrakuljic et al., 2000), which is a probable mechanism for the known effects on fetal growth. Abused substances including amphetamine and delta-9-tetrahydrocannabinol have been shown to decrease

the uptake of glucose in BeWo choriocarcinoma cells (Araújo et al., 2008). In a murine model Xu et al. (2016) showed Cd-induced downregulation of the glucose transporter GLUT3 in placenta by hypermethylation of GLUT3 promoter through upregulation of DNA methyltransferases.

Placental Hormone Production

One of the most important functions of placenta is the production of steroid, protein, and peptide hormones (Table 18.4). Hormones, such as progesterone, estrogen, human chorionic gonadotropin (hCG), placental growth hormone (PGH), and human placental lactogen (hPL) are important for maintaining pregnancy and to support fetal development (Druckmann and Druckmann, 2005; Murphy et al., 2006; Cole, 2010; Newbern and Freemark, 2011). PGH and hPL have also an important role in regulating maternal insulin balance (Newbern and Freemark, 2011). More recently, leptin has appeared as an important regulator of placental growth and development (Maymo et al., 2011; Schanton et al., 2018). It induces proliferation and survival and inhibits apoptosis of trophoblastic cells. It is also important for implantation of embryo and fetal growth. Both leptin itself and all isoforms of its receptors are expressed in human placenta. Leptin secretion is induced transcriptionally

by hCG. Other hormones are inactivated in the placenta, for instance prostaglandins, catecholamines, glucocorticoids, and thyroxine (Fowden and Forhead, 2004). Placental 11β-hydroxysteroid dehydrogenase type 2 (11βHSD2) inactivates glucocorticoids and limits fetoplacental exposure to the higher maternal glucocorticoid concentrations (Seckl and Meaney, 2004).

The presence of hCG in urine or blood is used as an indicator of pregnancy because it is produced throughout pregnancy. It promotes progesterone production and fusion of cytotrophoblastic cells and their differentiation into syncytiotrophoblast at the beginning of pregnancy (Cole, 2010). Progesterone, on the other hand, maintains pregnancy by preventing the maternal immune system from attacking the fetus and stimulates maternal food intake (Druckmann and Druckmann, 2005; Newbern and Freemark, 2011). Placenta replaces the ovary as the source of progesterone during early pregnancy after about 8 weeks. The progesterone production continues to increase throughout the pregnancy. Placenta uses mainly maternal cholesterol as a precursor in progesterone biosynthesis. First cholesterol is converted in mitochondria to pregnenolone, which is further metabolized to progesterone by 3beta-hydroxysteroid dehydrogenase (Tuckey, 2005).

Placental syncytiotrophoblast synthesizes large amounts of estrogens using steroidal precursors from

TABLE 18.4   Examples of Human Placental Protein and Peptide Hormones

Hormone	Main Functions During Pregnancy
Human placental lactogen (hPL)	Induces maternal insulin resistance and facilitates the mobilization of maternal nutrients for fetal growth promotes growth of maternal tissues
Human chorionic gonadotropin (hCG)	Affects fetal and uterine growth
	Induces leptin expression in trophoblastic cells
	Promotes the maintenance of the corpus luteum during the early pregnancy
	Promotes villous trophoblast tissue formation and the development and growth of uterine spiral arteries
Adrenocorticotropin (ACTH)	Stimulates the release of cortisol and other steroids
Growth hormone variant (hGH-V)	Participates in regulation of maternal and fetal metabolism and the growth and development of the fetus.
Parathyroid hormone related protein (PTH-rP)	Regulates fetal mineral homeostasis, stimulates placental calcium (and possibly magnesium) transfer and affects mineralization of the skeleton
Relaxin	Regulates biochemical processes involved in remodeling the extracellular matrix of the cervix and vagina during pregnancy and rupture of the fetal membranes at term. Promotes uterine and placental growth and influences vascular development and proliferation in the endometrium
Inhibins	Inhibit FSH secretion, inhibit steroidogenesis and production of hCG by the syncytiotrophoblast, involved in the control of the fetomaternal communication required to maintain pregnancy
Activins	Stimulate production and/or secretion of hCG, human placental lactogen, progesterone, and estradiol, potentially involved in cytotrophoblast fusion and syncytialization. Immunomodulatory functions
Gonadotropin releasing hormone (GnRH)	Regulates hCG production, Inhibits the formation of progesterone and estrogen
Placental corticotropin-releasing hormone (CRH)	Stimulates adrenocorticotropin (ACTH) release. Modulates glucose transporter (GLUT) proteins in placental tissue. Role in the timing of birth
Somatostatin	Inhibits hormone secretion and nutrient transport
Ghrelin	Stimulates growth hormone release
Leptin	Regulates implantation as well as fetal and placental growth and development. In placenta regulates survival, proliferation, angiogenesis, and immunomodulation of trophoblast

maternal and fetal blood. C19-steroids dehydroepiandrosterone (DHEA) and its sulfate metabolite dehydroepiandrosterone sulfate (DHEA-S), originating from both maternal and fetal circulations, serve as precursors for estrogen biosynthesis. In human placenta, neither cholesterol nor progesterone can serve as a precursor for estrogen synthesis due to the lack of CYP17 enzyme. Conversion of C19-steroids to estrogens is catalyzed by placental aromatase (CYP19) (Mendelson and Kamat, 2007), which is known to be affected by a number of xenobiotics (Table 18.2). Estrogens produced in the syncytium preferentially enter maternal circulation. Estrogenic hormones increase uteroplacental blood flow, enhance steroid production, stimulate the development of mammary glands, and increase prostaglandin synthesis (Sadler, 2004; Newbern and Freemark, 2011).

Environmental contaminants and lifestyle-associated factors such as smoking and alcohol consumption affect placental hormone production (Table 18.5). Most of the studies have been carried out using in vitro cultured primary trophoblasts or the three most commonly used choriocarcinoma cell lines (BeWo, JEG-3, JAr) and the most commonly studied end point has been hCG production. In addition, hormone concentrations have been measured from placental tissue as well as from maternal and cord blood samples. For instance, smoking has been associated with decreased hCG and PGH secretion. On the other hand, the results regarding leptin and hPL secretion are controversial (Boyce et al., 1975; Spellacy et al., 1977; Mochizuki et al., 1984; Helland et al., 2001; Stasenko et al., 2010). Concentration measurements of hormones from maternal blood can easily be conducted throughout the pregnancy if a suitable biomarker for exposure or placental toxicity can be established.

Molecular Stress Protein Pathways Involved in Toxicity of Human Placenta

Any proteins, such as structural proteins, receptors, enzymes, transporters, and hormones can be targets of toxicity in the placenta. Relatively few studies are available on toxic mechanisms of environmental contaminants in human placenta or placental cells, but some changes in proteins associated with exposure to toxic agents and/or placental pathology have been clearly identified. From a biomarker point of view, these are naturally of the most immediate interest. Also, various environmental factors can affect the same signal transduction pathways, which are involved in some pathological conditions during pregnancy, such as intrauterine growth restriction (IUGR), PE, and HELLP

(hemolysis, elevated liver enzymes, and low platelet) syndrome.

Apoptosis is an important mechanism of toxic cell death. For instance BPA, an endocrine disruptor, has been shown to increase procaspase-3 cleavage to caspase-3, a key event in apoptosis induction, in human first trimester placental explants (Mørck et al., 2010). One of the key proteins in apoptosis induction is the tumor suppressor protein p53. It has an important role in cell toxicity because, in addition to apoptosis, it regulates various other cellular processes including the cell cycle, and it is commonly activated by chemical stress (Vähäkangas, 2003).

There are only a few in vitro studies in human placental cells available that have tried to pursue the role of p53 and related signal transduction pathways in toxicity caused by common environmental contaminants. For instance, data on 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) toxicity in human placental cells are still discrepant. Chen et al. (2010) showed that TCDD damages mitochondria in human trophoblastic JAr cells and induces p53-mediated apoptosis associated with Bax induction, cytochrome *c* release, and caspase-3 activation. On the contrary, TCDD or BP did not cause apoptosis in JEG-3 cells, another human trophoblastic cell line, in the study by Drukteinis et al. (2005). In these cells, TCDD has also no effect on cell proliferation while BP inhibits it (Zhang and Shiverick, 1997; Drukteinis et al., 2005). BP-induced inhibition may be associated with downregulation of epidermal growth factor receptors (EGFRs) (Zhang and Shiverick, 1997) and cell cycle arrest by activation of p53 through Ser-15 phosphorylation. Consequently, there is induction of the p53 target p21 with reduction in the expression of cyclin-dependent kinase 1 (CDK1) (Drukteinis et al., 2005). Preimplantation factor (PIF), secreted by viable embryos inhibits trophoblastic apoptosis through the p53 pathway and is lower in placentas from PE and IUGR pregnancies (Moindjie et al., 2016). Thus, the p53 protein seems to be involved in pathological conditions during pregnancy related to placental function. As with many other proteins, the

level of p53 protein changes during pregnancy (Rolfo et al., 2012) and according to our own unpublished studies there is a very high interindividual variation in the level of p53 protein in human placenta. In cultured primary cytotrophoblasts isolated from normal human placenta, the expression of p53 has been shown to be higher under hypoxia (2% O_2) than under normal oxygen concentration (20%) (Hung et al., 2012). Recently, it has been shown that in human placentas associated with IUGR, the levels of p53 protein are higher than in placentas after normal pregnancy (Hung et al., 2012; Rolfo et al., 2012). In contrast to IUGR, Rolfo et al. (2012) observed that the amount of p53 protein is lower in PE placentas than in normal placentas. It is a well-known fact that smoking is associated with IUGR (e.g., Campbell et al., 2012) and increases the risk of IUGR by ethanol (Aliyu et al., 2009). The interesting inverse association between smoking and PE, related to changed balance of vasoactive factors, e.g., the soluble vascular endothelial growth factor receptor, fms-like tyrosine kinase-1 (sFlt-1), and placental growth factor (PlGF) by cigarette smoke condensate, nicotine and cotinine (Mehendale et al., 2007; Romani et al., 2011), seems to be dependent on the stage of pregnancy (Engel et al., 2013). Although the data are still discrepant, in many studies IUGR has been associated also with other chemical and environmental exposures, such as persistent organochlorine compounds (Bergonzi et al., 2011 and references within), air pollution particulates and nitrogen oxides (van den Hooven et al., 2012 and references within), endocrine disruptors (Meeker, 2012), and laboratory work (Halliday-Bell et al., 2010). Air pollution has also been shown to change the expression of sFlt-1 and PlGF in human placenta (van den Hooven et al., 2012).

Menai et al. (2012) suggested that one of the mechanisms by which tobacco smoking causes fetal growth restriction is accumulation and transplacental transfer of Cd. Heavy metals such as Hg, Pb, and Cd cross the human placenta, and Cd in particular, also accumulate in placenta (Esteban-Vasallo et al., 2012 and references within). Many studies indicate that smoking increases Cd levels in human placenta and this is associated with increased expression of metallothioneins (MTs) (Ronco et al., 2005, 2006; Sorkun et al., 2007). Ronco et al. (2006) specified that smoking induces especially the MT-2 isoform in human term placenta. MTs are probably the most important metal-binding proteins but also can act as antioxidants (Gundacker and Hengstschläger, 2012). Induction of MTs by Cd and Zn has been shown earlier also in primary human trophoblasts (Lehman and Poisner, 1984) and trophoblastic JAr cells (Wade et al., 1986; Powlin et al., 1997).

Cd is toxic in human placental trophoblastic cell lines (Valbonesi et al., 2008; Kummu et al., 2012). Cell death by Cd was associated with phosphorylation of ERK1/2, JNK1/2, and p38 mitogen activated protein kinases (MAPKs) in human immortalized HTR-8/SVneo trophoblasts (Valbonesi et al., 2008). These proteins are important regulators of various cellular processes such as proliferation, survival, apoptosis, and differentiation (for an extensive review see Cargnello and Roux, 2011). Also other agents may affect MAPK signaling pathways in placental cells. Saulsbury et al. (2008) suggest that p38 MAPK has a protective role against chlorpyrifos in human trophoblastic JAr cells because inhibition of the p38 MAPK pathway increases cytotoxicity caused by this organophosphate pesticide. The importance of p38 as a regulator of normal functioning of placenta is emphasized by the finding that the expression of p38 is reduced in placentas of women having HELLP syndrome during pregnancy (Corradetti et al., 2010). HELLP results from impaired trophoblast invasion and is present in about 10%−20% of women with severe PE (Jebbink et al., 2012). Migration and invasion of extravillous trophoblasts are key steps in the normal development of placenta (Knöfler, 2010). It is possible that this process is disturbed by toxic environmental compounds, such as Cd. Alvarez and Chakraborty (2011) showed that Cd, at concentrations that have no effect on cell viability, prevents migration of immortalized human HTR-8/SVneo trophoblastic cells. This may be due to actin cytoskeletal disorganization via caspase activation.

The signaling pathway of growth arrest and DNA damage-inducible 45 (Gadd45a), a stress sensor member of the Gadd45 family of genes, seems to be an important mediator in pathogenesis of human PE (Xiong et al., 2009, 2013; Luo et al., 2011). Gadd45a can be induced by various environmental stresses such as radiation, hypoxia, and oxygen radicals (Siafakas and Richardson, 2009). Luo et al. (2011) showed that Gadd45a expression and activation of p38 MAPK is higher in preeclamptic placenta than in placentas from pregnancy without any complications. This is supported by Xiong et al. (2013) who showed that in explants of human term placenta, various stresses associated with PE, including angiotensin II, hypoxia, and cytokines, increase the expression of Gadd45a and the release of sFlt-I. Similar results have been observed in rats with induced PE (Uddin et al., 2011). Increased levels of sFlt-1 and soluble endoglin (sEng) have been measured in serum of women with PE (Luo et al., 2011). It has been suggested that sFlt-1 and PlGF can be used as predictors of PE (Leaños-Miranda et al., 2012). The induction of Gadd45 is associated with

activation of two MAPKs: p38 and JNK (Xiong et al., 2013). Also other factors, such as activin A and 8-isoprostane levels, are increased in the circulation of women with PE (Mandang et al., 2007). They are also produced more in human placental explants exposed to oxidative stress.

Possibilities for Studying Pathways and Proteins Involved in Toxicity of Human Placenta

To reveal human placental toxicity and the mechanisms behind helpful biomarker development, relevant models have to be utilized because of the uniqueness of human placenta when compared to other species (Benirschke et al., 2006). All existing models have restrictions and some are very difficult in practice to set up and manage. Trophoblastic cancer cell lines originating from human choriocarcinoma, such as BeWo, JEG-3, and JAr, have appeared very useful for mechanistic studies (Vähäkangas and Myllynen, 2006; Myllynen and Vähäkangas, 2013). In addition to trophoblastic cell lines, changes in cellular macromolecules and pathways as a result or mechanism of toxicity can be studied in cultured placental tissue explants or primary trophoblasts isolated from newly born placentas. Acute responses to toxic agents can also be studied in human placental perfusion where placental tissue can be retained viable for hours. If placental tissue is used for experimental purposes, production of hCG can be used as a marker of viability of the tissue (Partanen et al., 2010; Woo et al., 2012).

Ex vivo perfusion of a human placental cotyledon has appeared very useful to study transplacental transfer of chemical compounds, such as drugs and environmental contaminants (Schneider et al., 1972; Ala-Kokko et al., 2000; Vähäkangas and Myllynen, 2006; Myren et al., 2007; Hutson et al., 2011; Myllynen and Vähäkangas, 2013). In addition, the role of various transporters in transplacental transfer can be studied in placental perfusion. Specific inhibitors of transporters combined with a radioactively labeled compound can be utilized to find out whether a certain transporter is involved in the transfer (e.g., Myllynen et al., 2008; Karttunen et al., 2010; Woo et al., 2012). Radioactively labeled compounds are most widely used because radioactivity can be easily and sensitively measured using scintillation counting. Mechanisms of transplacental transfer can be modeled also by using a Transwell system with two chambers separated by a layer of trophoblastic cells forming tight junctions (Woo et al., 2012). Only a few studies exist to date and the cell line mostly used in Transwell studies is the human BeWo b30 cell line. Single nucleotide polymorphisms (SNPs) and other mechanisms of individual genetic variation can affect the activity of metabolizing enzymes and transporters, increasing or decreasing toxicity (Vähäkangas and Myllynen, 2009). SNPs in placental transporters can be functionally significant as shown in placental perfusion studies. As an example, Rahi et al. (2007) have shown in a perfusion model that the ABCB1/p-gp polymorphism 3435C/T in exon 26 affects transplacental transfer of the antipsychotic drug quetiapine.

In placental tissue or cells of placental origin, expression of various types of proteins, such as stress proteins (e.g., p53), cell cycle regulators (e.g., p21 and CDK1), and other signal transduction proteins (e.g., Wnt-signaling proteins β-catenin and E-cadherin), metabolizing enzymes (e.g., CYP1A1), and transporters (e.g., ABCC2/MRP2 and ABCG2/BCRP), has been shown using various immunological methods (Drukteinis et al., 2005; Hnat et al., 2005; Nakanishi et al., 2005; Myllynen et al., 2008; Storvik et al., 2011; Tsang et al., 2012; Woo et al., 2012; Huuskonen et al., 2013). Xenobiotics can change the expression level of proteins or their posttranslational modifications. It is important to remember that expression of proteins in choriocarcinoma cell lines does not reflect in all cases the in vivo situation in the placenta (Vähäkangas and Myllynen, 2006).

In addition to proteins, corresponding gene expression at the mRNA level can be studied by reverse transcription polymerase chain reaction (RT-PCR) or quantitative real-time reverse transcription PCR (qRT-PCR) (Myllynen et al., 2008; Avissar-Whiting et al., 2010; Suter et al., 2010; Tsang et al., 2012; Huuskonen et al., 2013). Modern high-throughput microarray methodologies provide possibilities for gene expression profiling and "fishing" for mechanistically interesting candidate biomarkers (Huuskonen et al., 2008; Avissar-Whiting et al., 2010; Maccani et al., 2010). The omics techniques using various commercially available platforms enable analysis of the whole genome, transcriptome, proteome, or part of the epigenome (e.g., all known microRNAs) at the same time (for a review see Fowler, 2012). These methods are expensive and require special expertise, and studies pursuing their use in the development of biomarkers are in general at a very early stage of development. As to placental toxicity, very few studies exist to date.

POTENTIAL BIOMARKERS OF EXPOSURE AND TOXICITY IN HUMAN PLACENTA

Toxic Compounds and Their Metabolites as Biomarkers

Chemicals as well as their metabolites can be measured from placental tissue, cord blood, and fetal specimens (Table 18.1) and can be used as biomarkers

of placental and fetal exposures. Theoretically they can also be pursued as biomarkers of placental and fetal toxicity. The ideal specimen probably varies based on the timing and duration of the exposure (Colby, 2017). Meconium, the stool produced during gestation, is usually used to assess longer term exposures because it reflects exposures occurring from the end of the second trimester through the third trimester. Cord tissue reflects more recent exposures than meconium, including exposures that happen just prior to or during delivery.

OCPs and other persistent organic pollutants, and their metabolites, have been detected in human placenta and can be used to demonstrate exposure. Cholinesterase activity in both maternal blood and placental tissue is lower in mothers living on Spanish farms, indicating potential placental toxicity of organophosphate pesticides (Vera et al., 2012). Decreased placental and/or maternal blood acetylcholinesterase activity may thus serve as an exposure biomarker of placental exposure to organophosphates.

Metabolites of ethanol have been suggested as biomarkers of ethanol exposure. Ethyl glucuronide (EtG), a primary metabolite of ethanol, has been detected in first trimester placental tissue (Morini et al., 2011) and is formed in perfused placenta (Matlow et al., 2013). In addition, another metabolite of ethanol, ethyl sulfate (EtS), has also been detected in first trimester placental tissue (Morini et al., 2011). Both are detectable in meconium of infants born to mothers who have consumed excessive amounts of alcohol during pregnancy (Pichini et al., 2009). Fatty acid ethyl esters (FAEE) are formed after ethanol consumption from free fatty acids and lipids in blood and Bakdash et al. (2010) have detected FAEE in meconium. They suggest that the combination of FAEE and metabolites of ethanol (e.g., EtG) in meconium increases the accuracy of fetal alcohol exposure assessment.

Cotinine is a major metabolite of nicotine and is used as a biomarker of nicotine exposure. It can be measured in several tissues or biological matrices including placenta, meconium, and cord blood (Ostrea et al., 1998; Vyhlidal et al., 2012). Cotinine levels in placenta correlate with the gene expression of xenobiotic-metabolizing enzymes (mRNA of CYP1A1 and CYP1B1) in fetal lung and liver tissue. Thus, placental cotinine is considered to be a reliable biomarker of fetal nicotine exposure (Vyhlidal et al., 2012). Also, another nicotine metabolite, trans-3′-hydroxycotinine, can be measured in meconium as a biomarker of fetal exposure (Gray et al., 2010). Additionally, it has been suggested that maternal or neonatal cadmium blood levels could be used as a potential biomarker for tobacco toxicity on fetal development. Cd, a toxic heavy metal present in large amounts in cigarettes, is accumulated in placental tissue (Al-Saleh et al., 2011) and

transferred through the placenta (Butler Walker et al., 2006; Al-Saleh et al., 2011). Its levels in placenta, maternal blood, and urine are negatively correlated with birth weight (Kippler et al., 2010; Menai et al., 2012).

Levels of heavy metals in placental tissue prove the exposure of the placenta and have been suggested as markers of fetal exposure as well (Gundacker and Hengstschläger, 2012). However, at least in some cases, other markers are more useful for fetal exposure. Pb can be detected in placenta (Yoshida, 2002) and cord blood (Ding et al., 2013; Wu et al., 2013), but maternal blood levels have been suggested to be a more reliable indicator of fetal exposure (Iyengar and Rapp, 2001). The chemical form of Hg affects its cellular uptake and transfer through the placenta: Hg vapor and the methylated form cross the placenta easily (Ask et al., 2002), but inorganic Hg is more likely to be trapped in placental tissue (Yoshida, 2002). Human hair (from both mother and fetus) seems to be a more reliable matrix for the evaluation of mercury exposure than placenta (Iyengar and Rapp, 2001). As to arsenic, its levels in placenta correlate with maternal urinary levels and thus use of both urine and placenta could increase reliability when evaluating fetal exposure to arsenic.

Illicit drugs and opioids as well as their metabolites can be measured in placenta, meconium, and other biological specimens and be used as possible biomarkers of fetal exposure (Gray et al., 2010). Methadone and its metabolite 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine have been detected in placenta, umbilical cord, cord blood (de Castro et al., 2011, 2013), and meconium (Ostrea et al., 1998; Gray et al., 2010). However, there are contradictory results as to whether their presence correlates with fetal birth outcome (e.g., birth weight, length, head circumference) or the severity of neonatal abstinence syndrome (Gray et al., 2010; de Castro et al., 2011). Of the other opioids, morphine, codeine, and hydromorphone have been detected in meconium, which is positively correlated with their presence in maternal urine (Ostrea et al., 1998; Gray et al., 2010). The presence of a heroin metabolite, 6-monoacetylmorphine, was detected in meconium in one study (Pichini et al., 2009), but not in another (Gray et al., 2010). Metabolites of cocaine have been detected in placenta, umbilical cord, and meconium: ecgonine methyl ester and hydroxybenzoylecgonine (BE-OH) in placenta (de Castro et al., 2013); benzoylecgonine in umbilical cord (de Castro et al., 2013); and benzoylecgonine and m-hydroxybenzoylecgonine in meconium (Ostrea et al., 1998; Gray et al., 2010). The presence of cocaine and its metabolites benzoylecgonine and m-hydroxybenzoylecgonine in meconium is associated with maternal urine positive for cocaine (Ostrea et al.,

1998; Gray et al., 2010). Cannabinoids can be also measured in meconium to assess fetal exposure (Bar-Oz et al., 2003).

Aflatoxins have been detected in maternal and cord blood as well as in breast milk of mothers living in contaminated areas, proving that fetus and infants are exposed to this toxic and carcinogenic mycotoxin (De Vries et al., 1989; Denning et al., 1990; Hsieh and Hsieh, 1993; Abdulrazzaq et al., 2002). Another mycotoxin, ochratoxin A, has been detected in maternal and fetal serum, cord blood, and also in breast milk, indicating early exposure of the fetus and placenta also to this mycotoxin (Breitholtz-Emanuelsson et al., 1993; Zimmerli and Dick, 1995; Rosner et al., 2000; Postupolski et al., 2006; Galvano et al., 2008; Biasucci et al., 2011).

PAHs have been detected in placenta and cord blood, indicating exposure at early stages (Yu et al., 2011; Al-Saleh et al., 2013). However, because they require metabolic activation to DNA-binding—activated metabolites, their DNA-adducts as biologically relevant biomarkers have been studied much more than the compounds themselves.

Placental DNA Adducts as Biomarkers

Metabolic activation is a key step for the toxicity of most genotoxic carcinogens (Miller and Miller, 1975; Pelkonen and Vähäkangas, 1980). These toxic metabolites, e.g., epoxides or methylcarbonium ions, may covalently bind to DNA and induce mutations (Fig. 18.3) (Dipple, 1995; Klaassen, 2001). Therefore, DNA adducts are biomarkers of an early, detectable, and critical step of carcinogenesis and can be used as biomarkers of exposure to reactive metabolites of genotoxic carcinogens. The predominant binding site in DNA is the guanine base, but compounds may also bind to other DNA bases (Beach and Gupta, 1992; Dipple, 1995; Poirier et al., 2000). Several organs, including placenta, contain capacities to repair covalent DNA adducts by, for example, nucleotide excision repair (Cheng et al., 1999). However, DNA adduct repair is substance- and organ-specific. Placental DNA adducts can be analyzed from in vivo exposed placental tissue, as well as from experimentally exposed placental tissue, trophoblastic cell lines, and primary trophoblasts(Table 18.6).

Since 1980s, many studies have demonstrated PAH-DNA adducts in human placental tissue (e.g., Manchester et al., 1988; Hansen et al., 1993; Arnould et al., 1997; Sram et al., 1999; Perera et al., 1999; Sanyal et al., 2007; Pratt et al., 2011a,b; Dodd-Butera et al., 2017), or in DNA incubated with placental microsomes (Vaught et al., 1979; Pelkonen and Saarni, 1980; Vähäkangas et al., 1989). PAH exposure from smoking (Everson et al., 1988; Hansen et al., 1992, 1993; Gallagher et al., 1994; Daube et al., 1997) and air pollution (Reddy et al., 1990; Manchester et al., 1992; Topinka et al., 1997;
FIGURE 18.3   Benzo(a)pyrene and aflatoxin B1 DNA-adduct formation.

Whyatt et al., 1998; Sram et al., 1999) is associated with increased incidence of DNA adducts in human placenta, suggesting the transfer of pollutants and carcinogens in cigarette smoke from maternal to fetal tissues. PAH-DNA adducts seem to be localized especially in the cytotrophoblasts and syncytiotrophoblast knots lining the chorionic villi (Pratt et al., 2011a,b).

The presence of BPDE-DNA adducts in human placenta perfused with BP (Karttunen et al., 2010) indicates that PAHs can be metabolized in vivo in placental tissue. Trophoblastic cells contain metabolizing CYP enzymes and have been shown to contain the highest concentrations of PAH-DNA adducts among placental cells. PAH-DNA adducts have been proposed to be indicative for, or act as biomarkers of, harmful fetal outcomes, miscarriages, and placental pathologies (Perera et al., 1998, 1999; 2002; Obolenskaya et al., 2010). That nutritional status of mothers can affect the DNA-adduct levels, is implicated by the study of Dodd-Butera et al. (2017), who showed an inverse correlation between maternal serum folate levels and total PAH-DNA adduct levels. It has been suggested that the combination of placental PAH-DNA-adducts, placental CYP1A1 induction, and placental glutathione status could serve as a general biomarker for environmental chemical stress (Carlberg et al., 2000; Obolenskaya et al., 2010).

Aflatoxin-albumin adducts have been detected in both maternal and cord blood (Hsieh and Hsieh, 1993; Turner et al., 2007) and AFB1-DNA adducts in placental tissue and cord blood (Hsieh and Hsieh, 1993). AFB1 can be metabolized to its carcinogenic metabolite, aflatoxicol, by placental tissue fractions (Partanen et al., 2010). Some studies have tried to detect placental DNA adducts after exposure to compounds requiring CYP2E1 activation. However, after placental exposure to such genotoxic compounds, e.g., nitrosodimethylamine or acrylamide, no DNA adducts in placental tissue were found (Annola et al., 2008, 2009).

DNA adducts can be analyzed by several techniques (Table 18.7). The most common technique, due to its sensitivity and versatility, used in various laboratories for detecting DNA adducts in human placenta or other tissues, is the ^{32}P-postlabeling method originally developed by Randerath et al. in 1981 (Randerath et al., 1981) and further developed and used by many other groups (e.g., Spencer-Beach et al., 1996; for reviews see Jones, 2012; Phillips, 2013). The first demonstration of smoking-related bulky DNA adducts in human placenta, which was later confirmed by the same and other groups, was presented by Randerath's group in 1986 using this method (Everson et al., 1986, 1988; Reddy et al., 1990; Hansen et al., 1992; Gallagher et al., 1993; Daube et al., 1997; Pratt et al., 2011a,b). Other

TABLE 18.7	Advantages and Limitations of Analytical Methods for Measuring DNA and Protein Adducts

Method	Advantages	Limitation	References
Immunoassays	Reliable and inexpensive	Poor specificity, high amount of DNA needed	Farmer et al., 2005
^{32}P-postlabeling	High sensitivity	The efficiency of phosphorylation may be unknown or uncontrolled	Randerath and Randerath, 1994
LC-MS/MS or GC-MS	High specificity and sensitivity, possibility for chemical characterization of the adducts	Several pretreatments such as derivatization, vaporization, and ionization	Poirier and Weston, 1996; Farmer and Singh, 2008
Fluorescence spectroscopy, e.g., SFS	High specificity and sensitivity, rapid, and inexpensive	Requirement of a fluorescent adduct	Vähäkangas et al., 1985
Atomic absorbance spectrometry	High sensitivity to detect metal ions in DNA	Detection of metal ions with electrochemical conductance, there may be problems finding proper chromatographic separation for selective detection	Phillips, 2005
Analysis of radioactivity in DNA	Simple and inexpensive	Experimental only; does not tell about the types of adducts; requires radioactively labeled chemical	Myllynen et al., 1998

SFS, synchronous fluorescence spectrophotometry.

methods used to detect DNA adducts are immunoassays (Poirier et al., 1993), synchronous fluorescence spectrophotometry (Vähäkangas et al., 1985), LC- or GC/MS (Shuker et al., 1993; Farmer et al., 2005), atomic absorbance spectrometry (Reed et al., 1988), and electrochemical conductance (Floyd et al., 1986). Because of labor intensity, price, and other restrictions, none of the above methods is used in routine exposure analysis in any tissues. One of the latest techniques described in the literature is immunohistochemistry using the Automated Cellular Imaging System (Pratt et al., 2011a,b).

All in all, there are several robust and reliable analytical possibilities for studying placental adducts, which, however, at this stage are not practical in routine exposure or effect assessment. Studies of placental DNA adducts have mainly focused on PAH-compounds (e.g., BP and its derivates) or AFB1, as they are metabolized by CYP1A1 found in human placenta.

Xenobiotic-Metabolizing Enzymes, Placental Hormones, and Stress-Related Proteins as Biomarkers of Exposure and/or Toxicity in Placenta

As in other organs, many proteins in the placenta react with toxic compounds. One of the best studied groups so far is the xenobiotic metabolizing enzymes. Their activities may be modified in human placenta by maternal drug therapies and environmental and occupational factors (Myllynen et al., 2007). Most of the existing information concerns the CYP1A1 protein, the induction of which can be regarded as a general marker of exposure to xenobiotics. Also aromatase activity responds to environmental compounds, especially to those with hormonal activity.

Maternal cigarette smoking and environmental PAH exposure (Pasanen, 1999; Huuskonen et al., 2008; Suter et al., 2010), drug abuse (Paakki et al., 2000a,b), organochlorine exposure (Lagueux et al., 1999), and radiation (Obolenskaya et al., 2010) have been associated with CYP1A1 induction (for reviews see Pasanen et al., 1990; Collier et al., 2002, 2003). BP increases the expression of CYP1A1 protein in human placental JEG-3 cells (Drukteinis et al., 2005). CYP1A1 is one of the key enzymes in metabolic activation of PAH compounds (Xue and Warshawsky, 2005) and its activity is regulated by AhR (Stejskalova and Pavek, 2011). Also other environmental contaminants have been shown to increase the expression of CYP1A1 in human placental cells. TCDD increased CYP1A1 at mRNA (Tsang et al., 2012) and protein (Augustowska et al., 2007) levels in JEG-3 cells and at mRNA level in BeWo cells (Tsang et al., 2012). A mixture of PCDD and PCDF increases CYP1A1 protein levels in JEG-3 cells (Augustowska et al., 2007). In these cells, AFB1 induces CYP1A1 at mRNA level (Storvik et al., 2011; Huuskonen et al., 2013). Smoking modifies the levels of many placental transcription factors and proteins. With simultaneous CYP1A1 and 4B1 induction, smoking significantly

upregulated the proteins SERPINA1, EFHD1, and KRT8 and downregulated SERPINB2, FGA, and HBB. Transcript expression of CYP1A1 and CYP4B1 were induced, whereas mRNA of HSD17B2, NFKB, and TGFB1 were repressed by smoking (Huuskonen et al., 2016). Clinical significance of these wide-spread changes by smoking in placenta need to be studied further.

Maternal glucocorticoid therapy suppresses placental xenobiotic metabolizing enzymes and aromatase activity (Paakki, 2000a). Interestingly, results on placental conjugating enzyme responses to exogenous chemical stress (cigarette smoking, environmental PAH compounds) are contradictory (Pasanen et al., 1990; Paakki, 2000b; Collier et al., 2002; Obolenskaya et al., 2010). This implicates that placental conjugation capacity does not detoxify all harmful reactive chemicals/intermediates that may target the fetoplacental unit.

The pregnancy-associated plasma protein-A (PAPP-A) is a product of the placenta and decidua and is secreted into the maternal circulation during human pregnancy. PAPP-A has recently been identified as an IGF binding protein-4 protease. Although PAPP-A is commonly analyzed clinically, there is very limited information available on the association of PAPP-A with environmental exposures. PAPP-A values have been reported to be somewhat lower in the blood of smoking than in nonsmoking mothers (Chelchowska et al., 2008), but the finding was not reproduced in another study (Ball et al., 2013). PAPP-A and hCG measured from maternal blood are used in prenatal screening for Down's syndrome. According to a relatively recent metaanalysis of these proteins in the first trimester, an unexplained low PAPP-A and/or a low hCG are associated with an increased frequency of adverse obstetrical outcomes (Gagnon and Wilson, 2008). Furthermore, during the second trimester, an unexplained elevation of maternal serum alfa-fetoprotein (AFP), hCG, and/or inhibin-A, or a decreased level of maternal serum AFP and/or unconjugated estriol, seem to be associated with an increased frequency of adverse obstetrical outcomes (Gagnon and Wilson, 2008). Maternal circulating inhibin A is mainly produced by the placental trophoblasts during pregnancy.

Production of hormones, such as progesterone and hCG, is a potential target of toxicity in placenta (Kawai et al., 2002; Nakanishi et al., 2005; Augustowska et al., 2007; Wójtowicz et al., 2007a,b; Stasenko et al., 2010). Many environmental endocrinologically active contaminants can affect the production or metabolism of hormones in placental cells (Augustowska et al., 2007; Storvik et al., 2011; Huuskonen et al., 2013) as shown in the studies on hCG in various placental models (Table 18.5). Different models may provide contradictory results as with Cd (Boadi et al., 1992; McAleer

and Tuan, 2001b). Cd decreases progesterone secretion in cultured human trophoblasts isolated from term placentas (Kawai et al., 2002). This is associated with a decline in the mRNA expression of P450 cholesterol side-chain cleavage (P450$_{scc}$) and 3β-hydroxysteroid dehydrogenase (3β-HSD) enzymes involved in placental steroidogenesis. However, as to the activity of these enzymes, Cd inhibited only the activity of P450$_{scc}$. AFB1 increased the expression mRNA of steroid-metabolizing HSD enzymes 3B1 and 17B1 (Huuskonen et al., 2013). In addition, AFB1 induces CYP19A1 mRNA (Storvik et al., 2011; Huuskonen et al., 2013) and aromatase activity in JEG-3 cells (Storvik et al., 2011). Another class of stable environmental contaminants with endocrine disruption potential is PCBs. PCB28, a non—dioxin-like PCB (NDL-PCB) compound, and also hydroxyl-metabolites of NDL-PCB180, inhibit aromatase activity in human placental microsomes (Antunes-Fernandes et al., 2011).

Oxidative stress is currently believed to have a significant role in the pathophysiology of many complications of human pregnancy such as spontaneous miscarriage, early onset PE, and IUGR (Burton and Jauniaux, 2011). Also, gestational diabetes has been associated with enhanced placental oxidative stress (Gauster et al., 2012). Several environmental exposures have been shown to induce placental oxidative stress. Increased lipid peroxidation (LPO) in human placenta has been measured as a marker of oxidative stress after metal exposure. Levels of many metals (Cd, Zn, Ni, Pb, Cr) are positively correlated with LPO (Serafim et al., 2012). Also, TCDD, endrin, and lindane increase LPO in the placenta (Hassoun and Stohs, 1996). TCDD, endrin, and lindane also increase superoxide anion production and single strand breaks in DNA (Hassoun and Stohs, 1996). Smoking increases oxidative stress in the placenta, as shown by the increased levels of hydroxyl-2-nonenal (4-HNE) and 8-hydroxyguanosine (8-OHdG) (Sbrana et al., 2011). Furthermore, ethanol increases oxidative stress in in vitro cultured villous tissues as measured by nitrotyrosine, hydroxyl-2-nonenal, and 8-hydroxyguanosine staining (Kay et al., 2006).

Circulating cell-free nucleic acids analyzed from maternal plasma and serum are new promising potential biomarkers. Several studies have suggested that changes in the amount of cell-free fetal (cff) DNA may serve as an indicator of developing PE (for a review see Hahn et al., 2011). The increased levels of cffDNA before the onset of symptoms in PE may be due to hypoxia/reoxygenation within the intervillous space leading to oxidative stress in the tissue and increased placental apoptosis and necrosis. In addition, cell-free placental RNA is another potentially useful biomarker for PE. However, cffDNA or cell-free placental RNA as biomarkers of environmental

compounds causing oxidative stress in the placenta awaits further studies.

To assess adverse effects of metal exposure in placenta, biological responses in placental tissue to metals have been tested as potential biomarkers of exposure and early effects. Some enzymes, such as ALAD, a key enzyme in hemoglobin synthesis, are inhibited by environmental contaminants and can thus be used as potential biomarkers (Serafim et al., 2012). For example, levels of the metals Cd, Cu, Zn, Ni, Pb, and Cr are negatively correlated with ALAD. Monoamine oxidase (MAO) activity in placenta is induced by metals in experimental animals and thus it may be a potential biomarker also in humans. In human placenta, MAO activity is positively correlated with manganese (Mn) concentrations in maternal and cord blood and has been suggested as a potential marker of Mn toxicity in human placenta (Abdelouahab et al., 2010).

Metallothioneins (MTs) are cysteine-rich proteins that are involved in metal metabolism. MT expression in placenta may serve as a biomarker for metal exposure (Sorkun et al., 2007; Zhang et al., 2011b; Serafim et al., 2012). In a recent Portuguese study, levels of many metals (Cd, Zn, Ni, Pb) in placenta were positively correlated with elevated levels of MTs when metal levels were within the range found in most European countries (Serafim et al., 2012). MT expression was also associated with cadmium but not lead concentration in placenta in a highly polluted area in Guiyu, China (Zhang et al., 2011b). These results suggest that induction of MT in placenta is an indicator of heavy metal exposure during pregnancy. In the study by Zhang et al., Cd exposure was also associated with lower expression of S100P. The S100 proteins, including S100A, -B, and -P, are Ca^{2+}-binding proteins, which can also bind other divalent ions. S100P is worth further studies as a potential biological indicator of Cd exposure (Zhang et al., 2011b).

Epigenetic Changes in Human Placenta as Potential Biomarkers of Toxicity

Epigenetics deals with molecular changes that affect gene and mRNA activity but are not due to changes in the genetic code (genetic changes) (Novakovic and Saffery, 2012). The most studied of the epigenetic phenomena are DNA methylation and modifications in histone proteins that regulate transcription. More recently, regulation of translation at the level of mRNA by a variety of noncoding RNA molecules has been revealed as a new important level of epigenetic regulation of protein expression. Noncoding RNAs have their own genes but are not translated into proteins.

It is by now well known that environmental chemicals can induce a variety of epigenetic changes (for reviews see Hou et al., 2012; Kim et al., 2012), and such changes are also linked to various adverse reproductive conditions, such as IUGR (Robins et al., 2011). Arai et al. (2011) studied in murine embryonal stem cells the effect of 25 environmental chemicals in relevant concentrations found in human cord blood serum, and found many of them capable of inducing changes in heterochromatin structure and DNA methylation. However, further research is required to establish the persistence and potential accumulation of epigenetic changes (Hou et al., 2012). It is also important to note that epigenetic changes are tissue- and cell-type specific and due to the novelty of the field a lot of discrepant data exist. Thus, the studies on how epigenetic changes can serve as biomarkers of toxicity in placenta are at an early stage, and studies on potential biomarkers have so far mainly concentrated on disease diagnosis and prognosis (Maccani and Marsit, 2009; Novakovic and Saffery, 2012; Fu et al., 2013).

In human placental epigenetics, considerable variation between placentas has been found, putatively due to environmental effects in addition to internal reasons (Yuen and Robinson, 2011). Such adaptation of the placenta according to changes in the maternal physiology and other environmental influences is naturally important for the optimal support of fetal health (Mouillet et al., 2011). Epigenetic alterations in the placenta are probably better tolerated than in the fetus, and placenta has been suggested to protect the fetus from environmental epigenetic influences (Yuen and Robinson, 2011).

What makes the situation difficult from the biomarker point of view is that, in addition to developmental, sex, and interindividual variation in placental epigenetics (Novakovic and Saffery, 2012), there is also intraplacental variation suggested to reflect localized effects in the placenta and its environment in the uterus (Yuen and Robinson, 2011). Grigoriu et al. (2011) compared methylation patterns in human placental trophoblastic cells and fibroblasts and showed differences between these cell types. They also concluded that the methylation profile of placenta is mainly due to the methylation pattern of cytotrophoblasts. Especially, in line with the extensive proliferation of cytotrophoblasts, promoters of many tumor suppressor genes were hypermethylated in the placenta.

In connection with environmental influences, the best studied are methylation changes, both global methylation and methylation of the promoter of some specific genes. Typically, methylation of CpG islands in the promoter region of a gene inhibits its transcription. Methylation patterns vary between different types of tissues and are susceptible to environmental influences

(Christensen et al., 2009). In human placenta, global methylation is lower than in other tissues (2.5%–3% vs. 4%–5%) (Novakovic and Saffery, 2012), for instance lower than methylation of maternal blood (Chu et al., 2011). Chu et al. (2011) found in the placenta tissue-specific differentially methylated regions, which were enriched within genes having tissue-specific functions. Methylation is dependent on placental development, so that global methylation increases by gestation (Novakovic et al., 2011). Sitras et al. (2012) have found specific gene groups, e.g., genes related to cell proliferation, upregulated in first trimester and other groups (e.g., genes related to G-protein–mediated signaling, ion transport, and neuronal activities) upregulated in third trimester placentas. Variation between the placentas increases also toward the end of pregnancy, implicating increasing impact by environmental factors. Both maternal nutrition and smoking have been shown

to affect placental gene methylation (Table 18.8). For instance, CYP1A1 activity and protein induced by cigarette smoke, BP, or other PAH-like compounds seem to be associated with hypomethylation of regulatory elements of the CYP1A1 gene (Suter et al., 2010).

Another important level of epigenetic regulation is the microRNAs (miRNAs), small noncoding RNA molecules, which, by binding to mRNA, regulate translation, RNA processing, and RNA stability (Rosario et al., 2012). Micro RNAs regulate all the different cellular functions related to placental development, including trophoblast differentiation, proliferation, apoptosis, invasion, and angiogenesis, and are thus essential for proper development and function of the placenta (Fu et al., 2013). Aberrations in the miRNA expression are associated with some placental pathologies such as preterm labor (Fallen et al., 2018; for reviews see Chen and Wang, 2013; Fu et al., 2013).

TABLE 18.8 Examples of Epigenetic Changes in Human Placenta or Human Primary Trophoblasts Associated With Environmental Influences

Chemical/Exposure	Model	Epigenetic Changes	References
Tobacco smoking	In vivo exposure; human placental tissue	Downregulation of microRNA (miRs-16, 21 and 146a)	Maccani et al., 2010
Tobacco smoking	In vivo exposure; human placental tissue	Hypomethylation of CYP1A1 promoter region	Suter et al., 2010
Tobacco smoking	In vivo exposure; human placental tissue	Methylation changes, especially in genes GTF2H2C and GTF2H2D	Chhabra et al., 2014
Hypoxia	Primary human trophoblasts	Downregulation of miR-424	Mouillet et al., 2015
Hypoxia	Primary human cytotrophoblasts	Hypermethylation of functionally relevant genes including CP, ITGA5, SOD2, XDH, and ZNF2	Yuen et al., 2013
Air pollution	In vivo exposure, placental tissue analyzed for chemicals	Positive correlations: PBDE 209 with miR-188-5p PCBs with miR-1537 Cd with miR-1537 Negative correlation: PBDE 99 with let-7c	Li et al., 2015
Air pollution, PM2.5	Estimated in vivo exposure, placental tissue	Decrease of methylation of leptin gene promoter	Saenen et al., 2017
Phthalates	In vivo exposure, human placental tissue	Upregulation of lncRNAs	Machtinger et al., 2018
Lead	Human cord blood	Global hypomethylation	Pilsner et al., 2009
Mercury	In vivo exposure, human placenta	Hypomethylation of EMID2 gene	Maccani et al., 2015
Assisted reproductive technologies	Chorionic villous samples	Hypermethylation of imprinted genes; hypomethylation of nonimprinted genes	Zechner et al., 2010
In vitro fertilization	Placenta, cord blood	Higher mean methylation in placenta, lower in cord blood	Katari et al., 2009

Considering the fact that placenta expresses a wide variety of miRNAs, more than 600 identified so far, some of them unique to placenta (Chen and Wang, 2013), chemicals that affect placental miRNAs may be associated with placental toxicity (Mouillet et al., 2011). An important primate-specific genomic cluster in chromosome 19 (chromosomal region 19q13.4 or C19MC) seems to give rise to the most abundant placenta-specific miRNAs. It is transcribed as one large transcript that is processed into mature miRNAs. Among placental cells, C19MC is exclusively expressed in trophoblast-derived cells. Interestingly, C19MC is also expressed in human embryonic stem cells, with reduction of the expression by differentiation. Furthermore, aberrant expression of miRNAs encoded by this locus is found in some aggressive cancers. All these data implicate the important role of the miRNAs from C19MC in proliferation and differentiation. Some miRNAs are also abundantly expressed in placental mesenchymal stromal cells and some of the placenta-specific miRNAs are also found in maternal blood during pregnancy (Chen and Wang, 2013) implicating possibilities for biomarker development, and also for placental toxicity.

Hypoxia is related to placental pathology, such as preeclampsia, and many placental miRNAs are differentially expressed in preeclamptic placentas (Mouillet et al., 2011). MiR-210 is upregulated by both physiological and malignant hypoxia, and it is also significantly increased in preeclamptic placenta. MiR-424 is highly expressed in the placenta and is downregulated by hypoxia (Mouillet et al., 2013). MiR-205, which is specific to epithelium and linked to epithelial—mesenchymal transition and cancer, is upregulated in primary human trophoblasts by hypoxia (Mouillet et al., 2010b). Many drugs and chemicals (e.g., tobacco smoking; Zdravkovic et al., 2005) are known to induce hypoxia in the placenta. Thus such chemicals most probably also affect hypoxia-related miRNAs. Whether such miRNAs could serve as biomarkers for the exposure or effects of hypoxia-inducing chemicals remains to be studied.

Toxicologically, an interesting miRNA is miR-146a, which is downregulated in SV-40 transformed human trophoblasts by several environmental chemicals, for instance nicotine and BP (Maccani et al., 2010). It is also downregulated in placentas from smoking mothers, making it a candidate biomarker for the effects of smoking-related chemicals (Maccani et al., 2010). The fact that the same miR-146a is strongly induced by BPA (Avissar-Whiting et al., 2010) implicates further studies on the specificity of its downregulation as a biomarker of smoking-related toxicity in the placenta. MiR-146a is also responsive to folate deficiency and As. Its expression is related to cancer, with

tumor suppressive or oncogenic effects, depending on the type of cancer. Its overexpression in the first trimester villous cells 3A increased proliferation of the cells as well as their sensitivity to bleomycin, a DNA-damaging cancer drug (Avissar-Whiting et al., 2010). All in all, miR-146a is an attractive candidate biomarker for environmental influences in the placenta. Other miRNAs downregulated by smoking, miR-16 and miR-21 (Maccani et al., 2010), are also clearly and markedly reduced in babies with a low birth weight (Maccani et al., 2011).

Dependence of miRNA changes on the developmental stage of the placenta was implicated by Avissar-Whiting et al. (2010) who used human placental cell lines, representing first and third trimester placentas. Although miR-146a was upregulated in the cells from first trimester, its expression was not detectable in the cell line from third trimester placenta.

MicroRNAs are found in blood within various microparticles or bound to nucleophosmin 1, which putatively protects them from ribonucleases (see Mouillet et al., 2011). During pregnancy, C19CM-derived miRNAs are found consistently in maternal blood and increased in fetal growth restriction (Mouillet et al., 2010a). Whether such changes are reflected in fetal blood is not yet known. In any case, it is an attractive idea to study the placenta-specific circulating miRNAs as possible biomarkers for placental and fetal toxicity. At this point, the whole field of epigenetics and, especially, miRNAs, is under lively development including the methodologies. Mouillet et al. (2011) justly remind us of the difficulties in normalization of the miRNA array data and poor concordance of the results by high-throughput platforms with RT-qPCR measurements.

USE OF PLACENTA IN REGULATORY TOXICOLOGY—CONSIDERATIONS BY ECVAM AND OTHER ORGANIZATIONS

Obviously, because developmental toxicity is such an important part of toxicity testing, and exposure of the developing individual is an important factor in the outcome, methods to measure placental transfer of foreign chemicals have been considered in the regulatory circles for quite some time.

OECD Guidelines

Reproductive and developmental toxicity studies have been regulated for a long time by the OECD guidelines. These studies are performed using experimental animals, rats, and rabbits, and, consequently

due to interspecies differences, extrapolation of the results presents particular problems. In in vivo animal studies it is difficult to evaluate the contribution of the placental transfer or toxicity in the final developmental outcome. Obviously placenta itself may be the target of xenobiotics, resulting in disturbances in placental function or penetration. Low placental weight or other toxicity to placenta may have direct effects on the condition of pups. However, placental toxicity cannot explain all the effects, e.g., serious malformations observed in pups.

However, it is of interest that even if placental transfer controls the access of a chemical to the fetus and thus may influence the fetal adverse outcomes, only rather short sections concerning placenta can be found in appropriate OECD guidelines. Placental weights and sometimes placental condition are examined in the standard TG 414 test (developmental toxicity study in mice) as an additional end point. In TG 416 (two-generation reproductive toxicity study in mice), related to dosing, it is stated: "Information regarding placental distribution should be considered when adjusting the gavage dose based on weight."

The OECD TG 443 (Extended One-Generation Reproductive Toxicity Study in mice) contains a couple of statements about placenta. In relation to dosing, the following statement concerns placental transfer: "If TK data indicate a low placental transfer of the test substance, the gavage dose during the last week of pregnancy may have to be adjusted to prevent administration of an excessively toxic dose to the dam." Related to evaluation of the test results: "The physicochemical properties of the test substance, and when available, TK (toxicokinetic) data, including placental transfer and milk excretion, should be taken into consideration when evaluating the test results." However, it is not clear from where the TK data are supposed to come.

Recently, the OECD has developed so called Adverse Outcome Pathways (AOP), to increase knowledge of how chemicals induce adverse effects in humans and wildlife (https://aopwiki.org/aops). Also placenta is included in several OECD AOP proposals, as one of the events involved in the pathways, especially those related to vascular function/angiogenesis and induction of developmental toxicity; see, e.g., AOP 151: AhR signaling leading to placental vascular disruption and AOP 43: Disruption of VEGFR Signaling Leading to Developmental Defects. There is still room for identifying or reporting more AOPs where placenta plays a role in induction of an adverse effect.

Role of European Center for the Validation of Alternative Methods

ECVAM (European Center for the Validation of Alternative Methods)[1], which is responsible for the development and validation of alternative methods to replace in vivo animal tests, has considered placental models in its surveys and reviews on developmental toxicity. Moreover, there is a currently ongoing validation process for several methods to study adverse effects of xenobiotics on the placenta.

In 2005, ECVAM published an extensive survey on alternative methods available or under investigation for all major toxicities, including a chapter on reproductive and developmental toxicity (Bremer et al., 2005). The survey contains a short section on placental toxicity, including the placental barrier, and mentions both trophoblast cell lines and the human placental perfusion system. The chapter on toxicokinetics and metabolism (Coecke et al., 2005) includes some sections on bioaccumulation and distribution of chemicals across membranes and barriers, but it does not directly address the placental barrier. However, from the toxicokinetics point of view, it was envisaged that placental transfer studies would estimate the exposure of the fetus to a chemical under study. From the placental toxicity perspective, placental studies would reveal direct toxic effects of a compound under study on placental biochemistry, morphology, and functional status.

Adler et al. (2011) published an extensive survey to assess the status and prospects of alternative methods to animal testing for five toxicological areas (toxicokinetics, repeated dose toxicity, carcinogenicity, skin sensitization, and reproductive toxicity). This review contained two assays on placenta or placenta-derived cells, which were regarded as promising tools to study some aspects of fetal exposure to chemicals and mechanistic background for kinetics and toxicities. They were also seen potentially contributing as 3R tools[2] to OECD reproductive toxicity guidelines.

One of the aims of the EU Integrated Project ReProTect was to develop and optimize in vitro tests in reproductive toxicology, including tests using human placental models, to detect key events and mechanisms and to use these tests as building blocks in the integrated testing strategies (Bouvier d'Yvoire et al., 2012). Studies pursuing prevalidation of human placental perfusion (Myllynen et al., 2010; Mose et al., 2012; Karttunen et al., 2015) have indicated good intra- and interlaboratory comparison and transferability of the system.

[2] 3R is an acronym for refinement, reduction, and replacement of use of animals in toxicity studies.

Experimental Methods Concerning Placenta

Regarding the human placental perfusion assay, an ex vivo human placental perfusion provides an opportunity to carry out research without ethical difficulties. Other advantages of the placental perfusion method include the retention of in vivo placental organization and assessment of binding to placental tissue (Vähäkangas and Myllynen, 2006; Mose et al., 2008; Myllynen and Vähäkangas, 2013). However, the application of this assay is limited due to placenta to placenta variations and the limited relevance of the term placenta for the period of embryonic development. Because of the complexity of the assay, it is not applicable to routine testing of high numbers of test compounds. The trophoblast cell assay serves as an in vitro model of the rate-limiting barrier to maternal—fetal exchange and also for basic cellular and molecular investigations on toxicity mechanisms (Mørck et al., 2010).

It is clear that studies on isolated perfused human placenta as well as on properly characterized placental cells and cell lines would provide crucial information about the exposure of the fetus and placental toxicity and, in addition, basic characterization of enzymes, transporters, and targets of toxicity in the placenta. The use of human placenta obviates one of the most important problems in extrapolation and prediction of toxicity to humans, i.e., interspecies differences. The use of placental cells (and placentas if technically feasible and necessary) from animal species used for developmental toxicity studies would provide background for comparisons and extrapolation between animals and humans.

On the basis of the above argumentation, it would be of considerable advantage to include the option of placental studies in guidelines for reproductive and developmental toxicity studies.

According to the current views of regulatory toxicology, placental perfusion or other in vitro/ex vivo placental test methods can only be used in a tiered strategy and/or test battery. However, regulatory toxicology in general is shifting more toward the tiered or integrated testing strategies to minimize the use of animals and to get a more comprehensive picture of toxicity of the compounds. Therefore, as an example, the human placental perfusion study may have a key role in the integrated testing strategy, especially in a case when the compound is not transferred through the human placenta. It may thus prevent the need for conducting standard animal testing for the purpose of predicting developmental toxicity in humans.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

A biomarker can be defined as a chemical, biochemical, or molecular entity that is, preferably quantitatively, associated with exposure, tissue change, or a condition. For the development of a biomarker one needs a measurable molecule (or a group of molecules), a method to analyze it with, and a matrix to measure it from. The method of analysis of the putative biomarker and its usefulness as a biomarker in humans have to be validated separately (Vähäkangas, 2008). This means that we need to know that what we measure is real, and thereafter, that it works in the selected matrix and, finally, in in vivo situations. Before these validation steps it would be best to talk of a potential biomarker. In the literature, there is unfortunately a lot of discrepancy concerning the validation.

Placenta has appeared potentially useful not only as a matrix for placental exposure and toxicity, but also for fetal, and even general, exposure and toxicity. New exciting possibilities for biomarkers indicating placental toxicity are being searched for among newly identified small noncoding RNAs and by high-throughput methodologies, such as genomics platforms for mRNA profiles. Their usefulness, especially for regulatory toxicology, remains to be studied.

1. Biomarkers of placental exposure and toxicity: The presence of a xenobiotic, e.g., heavy metal or PCB, or their metabolites or DNA-adducts in the placenta is a very clear proof of placental exposure. To develop biomarkers for placental toxicity is a more complex issue. Exposure or even accumulation of a xenobiotic in the placenta does not necessarily mean that it is toxic to the placenta. A change in placental biochemistry, e.g., in the level of certain protein, should preferably be mechanistically linked to the toxic effect in the placenta. A well-known indication of placental exposure to cigarette smoke or PAH compounds is the classical triad: induction of CYP1A1, resulting in increased amount of PAH-DNA adducts in placental tissue, followed by glutathione depletion and increased oxidative stress (Obolenskaya et al., 2010). This glutathione depletion may not only be restricted to chemical compounds but can reflect also radioactive-induced stress (Obolenskaya et al., 2010). Additionally, increased PAH load has resulted in human placenta in decreased aromatase activity (Kitawaki et al., 1993; Huuskonen et al., 2008). However, these connections to maternal overall hormonal balance have not been evaluated prospectively. Endocrine disruption by various environmental contaminants or even medicines is an important toxic end point in placenta.

Better knowledge of the pathways involved, including metabolizing enzymes, in endocrine disruption may, therefore, help to develop biomarkers of placental toxicity. Changes in CYP19 mRNA and protein can already be regarded as a qualitative, general biomarker of exposure to endocrine disrupters.

2. Placenta as a matrix of biomarkers for fetal toxicity: Because placenta is mainly of fetal origin, it is feasible to expect an association between placental and fetal exposure and toxicity. Indeed, in some cases a correlation between placental and cord blood and/or meconium levels of xenobiotics has been shown. The level of PAH-DNA adducts in both placental tissue and cord blood is higher than in maternal blood, and the level of these adducts correlates with fetotoxicity (Perera et al., 1999).

3. Placenta as a matrix of biomarkers for general toxicity: Binding to macromolecules of genotoxic compounds in the placenta is a clear sign of genotoxic potential in human tissue, and implicates adducts and genotoxic effects also in other tissues. Heavy metals in the placenta serve as biomarkers of metal exposure. They induce expression of MTs. MT in placenta is the best candidate as a placental biomarker of exposure to cadmium, and putatively other heavy metals during pregnancy, apart from showing the heavy metals themselves. Some old biomarkers seem to be relevant also when analyzed from placental tissue. Organophosphate pesticides decrease blood cholinesterase activity. Such a decrease can be seen after the exposure also in placental tissue, which may serve as a general biomarker. Recent examples of changes in placental proteome due to smoking, and miRNAs and methylation due to environmental chemicals, strengthen the hypothesis of the role of placenta as a biomonitoring target to explore placental changes as indicators of the well being of fetus or child. From the regulatory point of view in the future there are some critical issues to be resolved. Placenta has the same role throughout various species: nutrition, energy supply to fetus, barrier for inflammatory diseases, hormonal production, and other "housekeeping" functions. However, it does exhibit a huge species-dependent variation in its organization, anatomy, and histology that has never been taken into account when interpreting data obtained in animal studies. Obviously, such differences between the species are probably reflected in placental mechanistically relevant cellular responses. A good example is transport of immunoglobulin fractions from maternal to fetal circulation, which varies significantly between the species (Pentsuk and van der Laan, 2009).

Early Biomarkers of Acute and Chronic Pancreatitis

Bhupendra S. Kaphalia

Department of Pathology, University of Texas Medical Branch, Galveston, TX, United States

INTRODUCTION

Early detection and prevention of pancreatic injury progressing to inflammation and fibrosis, maybe pancreatic cancer (PC), should be critical for the success of both clinical and surgical interventional therapies. Although a significant literature available on biomarkers of pancreatic diseases is focused on various forms of PC, identification of biomarkers for early pancreatic injury and precancerous stages should be the key to early prevention and therapy. Therefore, summarizing reliable and probable biomarkers identified for acute and chronic pancreatic toxicities/pancreatitis rather than PC is the focus of this chapter.

Both biliary duct disease and chronic alcohol abuse constitute 70%–75% of the etiologies of acute and chronic pancreatitis; remaining one-third may be idiopathic including those caused by chemical exposure, pesticide and metal poisoning, infections (viral, bacterial, and fungal), autoimmune and anatomical conditions, and the use of certain drugs. Congenital abnormalities, generally rare and asymptomatic, are related to two important events during embryological development of the gland, rotation and fusion. Anatomical disorders, deposition of cholesterol and related substances, obstruction of pancreatic duct due to tumor, and cyst formation could be rare (Lankisch and Banks, 1998; Kaphalia, 2011).

Pancreatic toxicity generally characterized by dysregulation of lipid metabolism and edema in early reversible stages followed by massive necrosis resulting into inflammation with or without fibrosis (scaring of the tissue) at the advanced stages. Irrespective of etiological agents, sequel of pancreatic injury follows a similar pattern for most of the etiologies. Some patients with pancreatitis can also develop PC. Overall, chronic pancreatitis and PC are serious diseases with great social, economic, and psychological impact and significant morbidity. The prognosis of pancreatitis and PC is very poor, and many patients die before reaching the clinical stage of the disease. Therefore, identification of biomarkers for prepancreatitis and postpancreatitis stages could be important for clinical interventions.

ANATOMICAL, PHYSIOLOGICAL, AND METABOLIC CONSIDERATIONS FOR PANCREATIC INJURY

Pancreas is an important digestive and glandular organ in vertebrates consisting of endocrine and exocrine components. About 85% of the gland consists of exocrine pancreas populated by acinar cells and a few duct cells. While endocrine pancreas secretes insulin hormone needed to control the body's glucose, exocrine pancreas synthesizes and stores zymogens (inactive form of digestive enzymes such as trypsinogen) required for the digestion of food. The digestive enzymes are secreted in the upper part of the intestine and activated by a gut hormone (enterokinase) for the digestion of food as detailed in several text books and reviews. An activation of zymogens within exocrine acinar cells in the gland triggers massive necrosis followed by inflammation with or without fibrosis, commonly termed as pancreatitis, and classified as acute pancreatitis and chronic pancreatitis.

ACUTE PANCREATITIS

Clinically, acute pancreatitis is characterized by an acute abdominal pain accompanied by elevated

pancreatic enzymes in the blood or urine, or both. Acute pancreatitis could be a single episode, or it may reoccur and is induced by the release of activated proteases from the pancreatic acinar cells and is often hemorrhagic. It occurs suddenly and lasts for a short period of time and usually resolves by itself in most of the cases. Severity of acute pancreatitis depends on histologic evaluation and may vary from mild (fat necrosis with enlarged gland [edema]) to severe (large confluent foci fat necrosis around the pancreas, focal hemorrhage, and acinar cell necrosis).

CHRONIC PANCREATITIS

Chronic or calcifying pancreatitis is a continuing inflammatory response characterized by severe morphological changes (such as irregular sclerosis and permanent loss of exocrine parenchyma), which may be focal, segmental, or diffused. Clinically, chronic pancreatitis is characterized by recurrent or persisting abdominal pain, although chronic pancreatitis may also present without pain. Chronic pancreatitis does not resolve by itself and could progress to a slow destruction of the pancreatic gland. Irrespective of etiology, the clinical pattern of chronic pancreatitis is characterized by the recurrent episodes of acute pancreatitis in early stages followed by pancreatic insufficiency, steatorrhea, pancreatic calcification and may be diabetes mellitus at the chronic stage. However, an intra-acinar activation of zymogens in the gland itself is the primary cause of pancreatic injury and pancreatitis (Lankisch and Banks, 1998).

BIOMOLECULAR BASIS OF PANCREATITIS

A large number of digestive enzymes are synthesized and stored by exocrine pancreas to be released into the upper part of intestine for digestion. Metabolic composition of the pancreas, particularly exocrine pancreas, has been previously detailed (Kaphalia, 2011). Activation of zymogens within the acinar cells is potentially damaging to the gland and causes autodigestion of exocrine pancreas and surrounding tissue. This process involves several extra-acinar cellular events, both in the pancreas and elsewhere in the body, due to the generation of inflammatory mediators such as cytokines, chemokines, and growth factors. It is also generally known that lipid degradation by-products produced due to oxidative stress are involved in various target organ pathogenesis. Clinically, disease can be evident by noninvasive tests and by conventional physical and clinical symptoms only after inflammation (pancreatitis) has occurred due to a massive necrotic cell death. Having both exocrine and endocrine components in the pancreatic organ system, many patients with chronic pancreatitis also present overt diabetes mellitus as manifestation of either exocrine or endocrine pancreatic insufficiencies, or both. It is possible to have combined biomarkers of endocrine and exocrine pancreatic injury to evaluate chronic and advanced stages of pancreatitis and fibrosis, which involve both components of the gland. Therefore, identification and development of biomarkers of early pancreatic injury even before inflammation should have great translational and clinical benefits for interventional therapies.

Like other key gastrointestinal organs, exocrine pancreas is also metabolically an active organ, and expresses various phase I and phase II enzymes [oxidative, reductive and conjugation enzymes including fatty acid ethyl ester (FAEE) synthase] (Kaphalia, 2011). Such metabolic organization of the gland might also bioactivate and/or biotransform drugs and chemicals damaging to the gland itself. Therefore, certain proteins and peptides specific to the exocrine pancreas secreted in to the blood and/or excreted via urine during injury can be reliable and specific biomarkers of pancreatic injury/toxicity/inflammation.

BIOMARKERS OF ACUTE AND CHRONIC PANCREATITIS

Clinically, two types of biomarkers described are (1) those specific and related to target organ function detected in the blood and excreted through urine are termed as endogenous and (2) various chemical(s)/agent(s) and their metabolite(s) and infectious agents involved in initiation and progression of the disease are called exogenous biomarkers. Except for known cases of chemical poisoning and history of abuse (alcohol or drug) or occupational exposure, it is generally very difficult to pin point the agent responsible for the injury. In such cases patient information could be critical. Global approaches such as proteomics, metabolomics, and genomics could be important for biomarker discovery, but such approaches are generally not cost-effective and may require confirmation using Reverse transcription-polymerase chain reaction (RT-PCR), Liquid chromatography-mass spectrometry (LC-MS), and/or Gas chromatography-mass spectrometry (GC-MS) analyses.

A biomarker candidate should be measurable via noninvasive methods. Several such matrices as plasma, serum, urine, saliva, hair, feces, or sweat can be used for identification and levels of the etiologic agent(s)

and its metabolite(s). Several biomarker candidates identified in experimental acute pancreatitis models can be developed using translational research approaches. Physical examination, imaging (endoscopic ultrasound, chest radiography, and barium sulfate X-rays), direct pancreatic function tests, and analysis of serum/plasma/urine for markers of pancreatic injury/pancreatitis should be gold standard for routine and less-expensive diagnosis (Table 19.1).

ABDOMINAL IMAGING TECHNIQUES

Abdominal ultrasound can be done with routine evaluation of acute pancreatitis; however, severity of pancreatitis can rarely be ascertained by the abdominal ultrasound. A less-invasive endoscopic ultrasonography and computed tomography (CT) and more invasive endoscopic retrograde cholangiopancreatography (ERCP) are better diagnostics for the gallstones in the common bile duct. ERCP is used primarily to diagnose and treat conditions of the bile ducts and main pancreatic duct, including gallstones, although the development of safer and relatively noninvasive investigations such as magnetic resonance cholangiopancreatography (MRCP), and endoscopic ultrasound has meant that ERCP is now rarely performed without therapeutic intent. Multimodal imaging systems such as single-photon emission computed tomography (SPECT)–CT, positron emission tomography (PET)–CT, and PET–magnetic resonance imaging (MRI) combine the best of both conventional diagnostic and molecular modalities, with the high resolution and high sensitivity of molecular imaging paired with anatomical or functional information of conventional diagnostic imaging. Currently, endoscopic ultrasound, CT, MRI, and ultrasonography form the conventional core imaging methodologies for pancreatic diseases (Dimastromatteo et al., 2017). Therefore, patient history and imaging results should be meaningful along with markers of pancreatic function tests in the plasma, urine, and/or saliva keeping in view the acute and chronic nature of the disease.

FUNCTIONAL BIOMARKERS OF ENDOCRINE AND EXOCRINE PANCREATITIS

Most available biomarkers of pancreatic injury are limited to acute pancreatitis. Markers of chronic pancreatitis necessarily do not correspond to those identified for acute pancreatitis. Elevated titers of autoantibodies directed against amylase α-2A are suggested a novel specific serologic biomarker to help identify patients at risk for autoimmune pancreatitis (AIP) and

TABLE 19.1 Biomarkers of Acute and Chronic Pancreatitis

Matrix	Biomarkers and/or Biomarker Candidates
Serum/plasma	**Indirect pancreatic functional biomarkers** Amylase, isoamylase, and total amylase Lipase Carbohydrate-deficient transferrin Trypsinogen activation products • Trypsinogen activation peptide (TAP) • Trypsin-1 and 2 and their conjugates with α-antitrypsin (trypsin-1-AAT and trypsin-2-AAT) C-reactive protein (CRP) Elastase-1 and phospholipase A_2 Procalcitonin (precursor of calcitonin) Proteins (proteomics, 2-dimensional gel electrophoresis (DGE), and MALDI-TOF/TOF) Lipids (lipidomics, NMR, GC-MS, and LC-MS) Metabolites (small-molecule metabolomics using LC-MS and GC-MS) Inflammatory cytokines and chemokines microRNAs (miR-216a and miR-217) Peptides (RA1609 and RT2864) IgG4 d-Dimer and angiopoietin-2 **Direct analysis of suspected etiologic agent(s)** Alcohol and alcohol metabolites (FAEEs, EtS, EtG, and PEt), pesticides and metal poisoning and suicide cases, drugs and occupational exposure to chemicals), and infectious agents
Urinary	Amylase, isoamylase, TAP, CAPAP, phospholipase A_2
Fecal	Elastase-1
Pancreatic juice	Cathepsins B, L, and S (lysosomal hydrolases) (CAPAP)
Pancreatic tissue specimens	Differential expression of genes, proteins and microRNA, and altered metabolomics, inflammatory cytokines and chemokines, and growth factors
Breath analysis	Breath analysis for H_2S, N_2O, and 66U substance
Direct visualization	**Imaging techniques** Endoscopic ultrasound, CT, ERCP, MRI, SPECT-CT, PET-CT, PET-MRI

Note: The biomarkers of acute pancreatitis may not be applicable for chronic pancreatitis, which can be confirmed by imaging techniques (ultrasound, CT, MRCP, and/or ERCP) in conjunction with clinical symptoms consistent with chronic pancreatitis.
CAPAP, carboxypeptidase activation peptide; *CT*, computed tomography; *EtG*, ethyl glucuronide; *EtS*, ethyl sulfate; *FAEE*, fatty acid ethyl ester; *ERCP*, endoscopic retrograde cholangiopancreatography; *MRCP*, magnetic resonance cholangiopancreatography; *MRI*, magnetic resonance imaging; *PEt*, phosphatidylethanol; *SPECT*, single-photon emission computed tomography; *PET*, positron emission tomography; *TAP*, trypsinogen activation peptide.

fulminant type 1 diabetes for early prevention and therapy (Wiley and Pietropaolo, 2009). However, low serum levels of CD44, CD44v6, and neopterin as indicators of immune dysfunction in chronic pancreatitis could not be specific or selective (Schlosser et al., 2001). Similarly, oxidative stress—related lipid peroxidation products proposed as biomarkers of acute pancreatitis may have limited success due to lack of specificity (Col et al., 2010). Correlation between lipid peroxidation products such as malondialdehyde in plasma/serum/urine with severity of acute pancreatitis need to be established. A number of biomarkers of pancreatitis (acute or chronic) identified in the plasma/serum are described as following:

AMYLASE

All amylases (glycoside hydrolases) catalyze the breakdown of complex sugars (such as starch) and act at α-1,4-glycosidic bonds. Pancreatic and salivary amylase can be of several orders of magnitude than those in other tissues/organs such as lungs, tears, sweat, and human milk. However, amylases can also be found as minor genetic variants. α-Amylase, faster acting than other isozymes, is the major form present in both human pancreas and salivary glands with a half-life time in the serum of ~ 10 h. The levels can return to the normal within 24 h after pancreatic injury is resolved and/or if enzyme is not being added to the serum (Nord et al., 1973).

Amylase levels can show a variable response depending on the etiologic agent(s) involved in the pancreatitis, and its lower levels have been reported on admission in patients with alcohol-induced acute pancreatitis. About 50% of the patients with abdominal pain and hyperlipidemia considered to have acute pancreatitis as confirmed by CT show no significant elevation of either serum or urinary amylase levels (Toskes, 1990). Therefore, sensitivity of serum amylase estimation compromises the gold standard for the diagnosis of acute pancreatitis and pancreatic trauma (Lankisch and Banks, 1998; Moridani and Bromberg, 2003; Herman et al., 2011). Total serum amylase levels can be altered by changes in either pancreatic or salivary amylases (Tietz, 1988). Although measuring total amylase after inhibition of salivary amylase is suggested being more accurate diagnostic marker, the assay adds up more steps and cost of the test. Even, reducing the amylase ordering has been suggested for the emergency departments (Volz et al., 2010). Macroamylasemia due to binding of amylase with serum globulin can also mislead the amylase levels (Wilding et al., 1964). The precision of total amylase versus pancreatic amylase appears to be identical (Moridani and Bromberg, 2003). Therefore, a straight forward approach to measure total amylase is cost-effective and saves time.

Elevated urinary amylase is also a sensitive indicator of acute pancreatitis and increased in almost 95% of patients with pancreatitis and remains elevated longer than the serum amylase activity. An elevated urinary amylase (>3 folds) than the upper limit of normal is a clear diagnosis of acute pancreatitis. However, elevated urine amylase can also be seen in salivary gland disease, bowel perforation, and ketoacidosis (Lankisch and Banks, 1998). An abnormal urinary amylase—creatinine clearance ratio can be a proof of acute pancreatitis. Although urinary amylase has not been widely used, elevated urinary amylase and serum amylase both can be considered as diagnostic biomarkers of acute pancreatitis.

ISOAMYLASE

Any of several isoenzymes of α-amylase catalyzes the hydrolysis of 1,6-α-glycosidic branch linkages in glycogen and amylopectin and their β-limit dextrins. The ratio of the amounts of pancreatic and salivary isoamylases in the urine is proposed as an index of insufficient exocrine pancreatic functions (Hobbs et al., 1967). However, urinary isoamylase levels have not been used by the clinics so far.

LIPASE

Unlike amylase, lipase mainly is of pancreatic origin; a small amount can also be produced in the liver, stomach, and tongue. Lipase catalyzes the breakdown and hydrolysis of fats and acts at specific position on the glycerol backbone of lipid substrate (A1, A2, or A3). Pancreatic lipase is the main enzyme that converts triglycerides to monoglycerides and fatty acids. As compared with serum amylase and other markers so far been used, serum lipase appears to be a sensitive marker for acute pancreatitis. Serum lipase is highly sensitive, can be detected for several days, and is sensitive even with normal amylase levels. Most hospitals use serum lipase for the diagnosis of acute pancreatitis, and its specificity is considered to be excellent and can significantly reduce the cost to the hospitals (Ismail and Bhayana, 2017). Evidence-based guidelines also recommend the use of serum lipase over amylase, although both lack ability to distinguish severity and etiology of acute pancreatitis. However, the diagnosis of acute pancreatitis may require at least two or three diagnostic criteria such as characteristic abdominal pain, elevated serum lipase and/or amylase, and radiological evidence of pancreatitis.

CARBOHYDRATE-DEFICIENT TRANSFERRIN

Transferrin, a serum protein, is a polypeptide with two N-linked polysaccharide chains, which are branched with sialic acid (monosaccharide carbohydrate) residues. Transferrin carries iron through the bloodstream to the bone marrow, as well as to the liver and spleen. Correlation between carbohydrate-deficient transferrin (CDT) and mean corpuscular volume has been reported statistically significant with excessive alcohol consumption (Basterra et al., 2001; Aparicio et al., 2001; Sharpe, 2001). Elevated CDT found in the blood of chronic alcoholics can also be seen in various medical conditions (ARIP Laboratories, 2010). The CDT levels are shown to be correlated with alcohol consumption and possibly to acute pancreatitis in alcoholic patients (Jaakkola et al., 1994). Overall, CDT appears to have some clinical utility but could not be used by clinics for the diagnosis of acute or chronic pancreatitis, probably due to specificity and cost of analysis reasons.

ACTIVATION BY-PRODUCTS OF PANCREATIC TRYPSINOGEN AND CARBOXYPEPTIDASE B

Proenzyme trypsinogen occurs in two major isoenzymes in humans (trypsinogen 1, i.e., cationic trypsinogen form, and trypsinogen 2, i.e., anionic trypsinogen form), which are activated to trypsin by enterokinase (EK) in the gut for protein digestion. However, activation of trypsinogen within acinar cell plays a key role in pathogenesis of acute pancreatitis because conversion of trypsinogen triggers a cascade of reactions that activates the remaining zymogens resulting in autodigestion of the surrounding tissue (Rinderknecht, 1986). Trypsin rapidly gets inactivated by 1-α-antitrypsin (AAT), a neutralization process. High serum concentrations of trypsin-1-AAT and trypsin-2-AAT have been reported in acute pancreatitis (Borgström and Ohlsson, 1978; Hedström et al., 1994).

Trypsinogen activation peptide (TAP) is a by-product of trypsinogen activation process. Trypsin is a serine protease found in the digestive system of many vertebrates, where it hydrolyzes proteins at carboxyl side of the amino acids, lysine or arginine. Trypsin produced due to premature trypsinogen activation in the pancreas ideally fulfills criterion of organ specificity of a biomarker. The activation peptide at the amino terminus of vertebrate trypsinogen contains the sequence Asp-Asp-Asp-Asp-Lys (D_4K, highly conserved during vertebrate evolution) as the carboxy-terminal moiety. These peptides are generally liberated in the proximal small intestine during digestion, after recognition and cleavage at the lysine carbonyl by a small gut hormone, EK.

Intra-acinar activation of trypsinogen releases TAP into circulation, which is rapidly cleared by kidneys for excretion in urine because of its small size. TAP can be quantitated by an enzyme-linked immunosorbent assay (ELISA) in the plasma and urine using specific antibody to TAP (Wu et al., 2008). Only early acute or severe pancreatitis as compared with mild acute pancreatitis correlated with serum and urinary levels of TAP, which are rapidly depleted to undetectable levels. A quick collection and analysis of samples needs attention and results may differ depending on etiology of acute pancreatitis (for e.g., alcohol- versus gallstone-induced [Lempinen et al., 2003]). Serum TAP appears to have close correlation to severity of pancreatic injury and can be used as an early marker of acute pancreatitis.

As compared with serum TAP, urinary TAP has more consistent relationship with early acute pancreatitis. It has been reported that plasma TAP increased immediately after the induction of pancreatitis as compared with delayed excretion of TAP in the urine by several hours in experimental pancreatitis model (Wang et al., 2001). About 30% of the patients with acute pancreatitis had normal TAP values on admission (Gudgeon et al., 1990). There are contradictory reports regarding the utility of serum and urinary TAP, and its levels can remain undetected in mild cases of acute pancreatitis. Therefore, TAP levels only reflect severe acute pancreatitis (Kylänpää-Bäck et al., 2002; Johnson et al., 2004). However, the methods of analysis of trypsin and TAP are time-consuming and difficult and also not cost-effective for the routine clinical use.

Likewise TAP, procarboxypeptidase B has an activation peptide, carboxypeptidase activation peptide (CAPAP), which is a larger peptide and more stable in the serum and urine than other peptides (Burgos et al., 1991; Abu Hilal et al., 2007; Deng et al., 2015). Serum and urinary levels of CAPAP were found to correlate well with severe acute pancreatitis based on a study conducted in a small number of patients (Appelros et al., 2001; Pezzilli et al., 2000). Both TAP and CAPAP could serve the markers of early and severe form of acute pancreatitis at the time of admission to hospitals. Both serum and urinary CAPAP have the potential to act as a stratification marker on admission in predicting severity of acute pancreatitis. Therefore, utility of both markers needs to be tested in larger cohorts.

ELASTASE AND PHOSPHOLIPASE A2

Pancreatic elastase is a form of elastase and a subfamily of serine proteases (referring to chymotrypsin-like

elastase family, member 3B [CELA3B]) that hydrolyze many proteins in addition to elastin. Human pancreatic elastase-1 (E1) is quite stable and remains undegraded during intestinal transit. Therefore its concentration in feces reflects exocrine pancreatic function. During an inflammation of the pancreas, E1 is released into the bloodstream. Thus the quantification of pancreatic elastase-1 in serum and feces allows diagnosis or exclusion of acute pancreatitis (Domínguez-Muñoz et al., 2006; Naruse et al., 2006). Urinary excretion of elastase-1 has been shown to increase in all patients with chronic pancreatic disease regardless of neoplastic or inflammatory nature of the disease (Fabris et al., 1989). Unfortunately, determination of elastase-1 does not provide additional advantage over combination of lipase and amylase for the diagnosis of acute pancreatitis and may not be a specific biomarker candidate.

Phospholipase A2 specifically recognizes the sn-2 acyl bond of phospholipids and catalytically hydrolyzes the bond releasing arachidonic acid and lysophospholipids. However, phospholipase A2 can be found in several other organs and induced in chronic liver cirrhosis thus lacking target organ specificity (Vishwanath et al., 1996). Urinary excretion of phospholipase A2 in chronic pancreatic diseases particularly during relapse and in other physiological conditions has been reported (Fabris et al., 1992). Like trypsin and TAP, the elastase and phospholipase A2 increase in serum and feces in acute pancreatitis but could not be used as conventional diagnostic biomarkers for acute pancreatitis probably due to cost considerations and intricate analysis protocols.

PROCALCITONIN

Procalcitonin is a precursor of calcitonin and serum procalcitonin as measured using chemoluminescent immunoassay was found to be a simple promising biomarker with accuracy similar to acute physiology and chronic health examination (APACHE)-II score, in predicting severity of acute pancreatitis (Woo et al., 2011). However, precalcitonin can be useful only in predicting the severity of acute pancreatitis and comparable to other biomarkers such as APACHE-II, C-reactive protein (CRP), lactate dehydrogenase (LDH), and urea.

C-REACTIVE PROTEIN AND PANCREATITIS-ASSOCIATED PROTEIN

CRP, an acute-phase proteins primarily synthesized in the liver, is a class of proteins whose plasma concentrations increase (positive acute-phase proteins) or decrease (negative acute-phase proteins) in response to inflammation. Determination of the severity of acute pancreatitis is difficult in the early phase after onset and often encounters difficulties in making decisions to initiate intensive care during the early phase. CRP values increase significantly in early stages of necrotic pancreatitis (Imamura et al., 2002). It is an important prognostic marker of pancreatic necrosis with the highest sensitivity and negative prognostic value given the cutoff is at 110 mg/L. The patients with CRP values below 110 mg/L are at low risk to develop pancreatic necrosis (Barauskas et al., 2004). Measurement of acute-phase proteins, especially CRP, is a useful marker of inflammation in both medical and veterinary clinical pathology. It correlates with the erythrocyte sedimentation rate. However, CRP is a marker of inflammation (proinflammatory cytokines), and higher CRP may also indicate liver failure (Ananian et al., 2005).

Pancreatitis-associated protein (PAP), an acute-phase protein such as CRP, is overexpressed in acute pancreatitis and detected in pancreatic juice from 49 patients with chronic pancreatitis. However, higher level of PAP also detected in 15 control subjects discredited the significance of the PAP as a reliable biomarker of chronic pancreatitis (Motoo et al., 2001).

Serum CRP, procalcitonin, and LDH have been used for the diagnosis of pancreatic necrosis, but any conclusions regarding the diagnostic test accuracy could not be arrived due to methodological deficiencies and uncertainty of the results (Komolafe et al., 2017). Summary of available data on diagnostic usefulness of markers of endothelial dysfunction and activated coagulation in early prediction of severe acute pancreatitis has been reviewed using the results of experimental studies and clinical trials targeting coagulation—inflammation interactions in severe acute pancreatitis. Among laboratory tests, d-dimer and angiopoietin-2 measurements have been found useful predictors of severe acute pancreatitis (Dumnicka et al., 2017).

CATHEPSINS

Pancreatitis is shown to be associated with increase in active form of cathepsins B, L, and S, which regulate premature activation of trypsinogen within pancreatic acinar cells (Lyo et al., 2012). Cathepsins are lysosomal proteases and postulated to play a role in the initiation of pancreatitis (van Acker et al., 2006). The levels of aforementioned cathepsins have been shown to increase in the pancreatic juice from patients with chronic pancreatitis. In case of ethanol-induced pancreatic injury, cathepsins respond to FAEEs (nonoxidative metabolites of ethanol-induced pancreatic lysosomal fragility) (Haber et al., 1993). However, lack of

specificity and analysis of cathepsins mostly using fluorimetric are simply not cost-effective (Barrett, 1980).

PEPTIDES

Walgren et al. (2007) identified two peptide markers (RA1609 and RT2864) of pancreatic toxicity that are target organ specific using a model pancreatic toxin cyanohydroxybutene. These markers were verified in the serum of patients diagnosed with pancreatitis, and changes in serum RA1609 and RT2864 were indicative of and specific to pancreatitis. The human sera analyzed in this study were from patients with pancreatitis, which was not defined as acute or chronic. Moreover, clinical use of such markers has yet to be established for a routine analysis.

INFLAMMATORY CYTOKINES AND CHEMOKINES

Necrosis of exocrine pancreas, the primary cause of acute and chronic pancreatitis, can be identified by contrast-enhanced computerized tomography and magnetic resonance imaging. Massive necrotic cell death follows strong inflammatory responses and infection. Proinflammatory cytokines and chemokines such TNF, IL1α, IL1β, IL6, IL8, IL12, and MCP-1 have been identified to serve as biomarkers of acute and chronic pancreatitis (Papachristou, 2008; Achur et al., 2010). However, ability to predict which patients will develop severe disease is limited. Large prospective studies are still needed to address these questions by identifying risk factors for acute pancreatitis and serum biomarkers of severe disease conditions.

Correlation of specific serum inflammatory cytokines and chemokines increased or decreased with severity of pancreatitis need to be established before embarking on cytokines and chemokines as potential biomarkers of acute or chronic pancreatitis. Chronic pancreatitis is chronic inflammatory disease. However, a caution should be exercised to use certain or combination of inflammatory cytokines and chemokines in view of broad inflammatory response in chronic diseases of diverse nature. Secondary target organ toxicity is also one of the potential interference in such determinations.

Various laboratory markers for predicting acute pancreatitis including cytokines, activation peptides of pancreatic proteases, antiproteases, adhesion molecules, and several leucocyte-derived enzymes have been reviewed time and again, but due to their low accuracy, use of cumbersome laboratory analysis techniques, and high cost of analysis, a quest for finding new markers of acute pancreatitis continues.

BIOMARKERS OF ENDOCRINE AND AUTOIMMUNE PANCREATITIS

Endocrine functional impairment with insulin resistance can be used as an index of endocrine pancreatitis (Wu et al., 2011). Type 1 diabetes mellitus (loss of insulin-secreting capacity) is now classified as autoimmune (Type 1A) or idiopathic (Type 1B). Presence or absence of glutamic acid decarboxylase antibodies can differentiate type 1 diabetes. Some patients with idiopathic type 1 diabetes may also have nonautoimmune and remarkably abrupt onset and high serum pancreatic enzyme levels (Imagawa et al., 2000). Presence of elevated titers of autoantibodies directed to amylase α-2A may represent a novel specific biomarker of AIP and fulminant type 1 diabetes. The characteristic features of AIP are increased IgG4, lymphoplasmacytic sclerosing pancreatitis (abundant infiltration of IgG4+ plasmacytes and lymphocytes, storiform fibrosis, and obliterative phlebitis), and the involvement of other organs indicating a complex pathologic mechanism and biomarker identification (Okazaki and Uchida, 2015). Generally, endocrine pancreatic gland is well preserved even after an acute pancreatic insult (Bhopale et al., 2017b). However, glucagon, insulin, somatostatin, and polypeptides produced by endocrine pancreatic gland have not been target as reliable markers of acute endocrine pancreatic injury other than pancreatic endocrine insufficiency. A correlation between urinary p-aminobenzoic acid (PABA, a split product of n-benzoyl-1-tyrosyl-p-aminobenzoic acid) excretion and plasma glucagon concentration suggests that in chronic pancreatitis there is collateral impairment of exocrine and endocrine functions (Keller et al., 1984).

ETHANOL METABOLITES AND CONJUGATES

Ethanol is one of the major etiologic agents for acute and chronic alcoholic pancreatitis after biliary duct disease (Lankisch and Banks, 1998; Kaphalia, 2011). Acetaldehyde, an oxidative metabolite of ethanol, could not go beyond oxidative stress as a global toxicity endpoint. On the other hand, nonoxidative metabolism of ethanol to FAEEs is most prevalent ethanol metabolism in the pancreas frequently damaged during chronic alcohol abuse (Laposata and Lange, 1986). These esters are lipophilic and shown to cause selective pancreatic acinar cell toxicity (Werner et al., 1997; Kaphalia and Ansari, 2001; Gukovskaya et al., 2002; Vonlaufen et al., 2007; Wu et al., 2008). The plasma/serum levels of FAEEs are generally high and correlate well with blood alcohol concentration particularly during chronic alcohol abuse (Laposata and

Lange, 1986; Kaphalia et al., 2004). Our studies in the deer mouse model of chronic ethanol feeding have shown that increased levels of plasma FAEE correlate well with those in the pancreas (Kaphalia et al., 2010). However, an interrelationship between plasma/serum levels of FAEEs and severity of pancreatitis in patients with acute or chronic pancreatitis needs to be established.

Other nonoxidative metabolite of ethanol, which correlates with blood alcohol levels in the blood, is phosphatidylethanol (PEt) formed by phospholipase D−catalyzed reaction (Aradottir et al., 2006). A good clinical efficiency of PEt and its pancreatic toxicity has not been demonstrated so far for detecting chronic heavy drinking (Viel et al., 2012). Ethyl glucuronide (EtG) and ethyl sulfate (EtS) levels are typically used to determine whether an individual has been exposed to alcohol (ethanol) (Nanau and Neuman, 2015). Accuracy of the test is greater when both EtG and EtS are included. EtG in contrast to EtS may also be produced in vitro when ethanol-producing bacteria are present in the urine specimen; so detection of EtS indicates in vivo alcohol presence, thereby improving the specificity of the test. An EtG concentration >500 ng/mL is considered positive for alcohol presence only if the EtS concentration is ≥100 ng/mL. EtG may be present in the urine for up to 80 h after ethanol ingestion. EtS may be detectable for 24 h or more after the ethanol ingestion. The validity of the markers depends on the cutoff used for the test and the patient's metabolic rate and the time and duration of alcohol exposure. Although chronic alcohol abuse is one of the major causes of acute and chronic pancreatitis, the ethanol metabolites as markers can be limited to ethanol exposure, which can also be supported by the patient history of alcohol abuse and used in combination with some functional markers such as lipase and patient symptoms.

DIFFERENTIALLY ALTERED PROTEINS, METABOLITES, SMALL MOLECULES, AND MICRORNA

Direct functional tests can be conducted by identifying the proteins, metabolites (small molecule), and microRNAs differentially altered in the pancreatic juice and duodenal contents from proteins with acute or chronic pancreatitis. Omic and array research is a systemic global approach and provides a unique "fingerprint," which varies with time or stresses, that a cell or organism undergoes. High-resolution ^{1}H-NMR analysis of plasma and urine samples and data analysis as

determined by principal component analysis using metabolomic modeling of L-arginine−induced exocrine pancreatitis suggest metabolomics a valuable approach, which can distinguish patients with pancreatitis from healthy controls (Bohus et al., 2008; Lusczek et al., 2013). Lipid profiling of serum and pancreatic fluid conducted in chronic pancreatitis using the LC-ESI-MS/MS system in five controls and six patients of mild and five of severe chronic pancreatitis was shown to increase the levels of oxidized fatty acid products suggesting their utility as biomarker candidates for the diagnosis of chronic pancreatitis (Stevens et al., 2012). However, the specificity and analysis cost-effectiveness of such biomarkers need to be established.

Identification of proteins has been done only in the pancreas in acute pancreatitis models (Zhang et al., 2012; Fétaud et al., 2008: García-Hernández et al., 2012). Therefore, significant efforts should be directed for profiling both plasma and pancreatic proteins differentially expressed in acute and chronic pancreatitis in animal models followed by their validation in the plasma of patients with acute or chronic pancreatitis. Proteomic profiling using SELDI-TOF-MS has been done in the serum as a predictor of severity of acute pancreatitis from 21 patients with mild and 7 patients with severe acute pancreatitis (Papachristou et al., 2007). Various other proteomic studies (separation of proteins by 2-dimensional polyacrylamide gel electrophoresis and identification by MALDI-TOF/TOF) done in the pancreatic fluid, plasma, serum, and pancreatic tissue from patients with chronic pancreatitis provide significant lead to further pursue the studies in larger cohorts (Chen et al., 2007; Hartmann et al., 2007). Recent papers from our laboratory have identified a number of proteins differentially expressed in the pancreas and plasma of a chronic ethanol feeding model of hepatic alcohol dehydrogenase (ADH)−deficient (ADH⁻) deer mice (Bhopale et al., 2017a,b). Proteins differentially expressed in the pancreatic tissue of ethanol-fed mice are mainly amylase 2b precursor, 60-kD heat shock proteins, and those involved in ATP synthesis and blood pressure. Plasma proteins differentially expressed were mainly serine protease inhibitor A3A precursor, creatine kinase M-type, and transport protein, apolipoprotein E. These findings also suggest that chronic ethanol feeding does not provide a plasma profile that can be found for acute pancreatitis. While gene profiling studies can also identify biomarker candidates, studies are limited to target organ and in experimental models. Pathway analysis and system's biology approaches generally done to infer relationships between genes, protein, and small molecules (metabolomics) are important for identification of biomarkers and may be a future direction in the

biomarker field. Therefore, novel concepts such as genetic, transcriptomic, and proteomic profiling as systems approach to pancreatitis or PC along with functional imaging for identification of specific disease pattern need to be introduced at least to find out the target molecules of interest.

MicroRNAs (miRs) are functional, 22 nt, noncoding RNAs that negatively regulate gene expression and play a role in the initiation and progression of certain diseases. However, identity of differentially altered target microRNA should be confirmed. Hierarchical clustering and principal component analysis of the data sets can distinguish pancreatic tissue of patients with pancreatitis from normal control tissue. Only a handful of studies are available to identify microRNAs as biomarkers in the experimental rat model of acute or chronic pancreatitis and in PC (Bloomston et al., 2007; Lee et al., 2007; Kong et al., 2010). Kong et al. (2010) identified plasma miR-216a as a potential marker of pancreatic injury in the rat model of acute pancreatitis. Like amylase and lipase, increased expression of miR-216a in the plasma was restricted to acute pancreatitis at 24 h after the insult. Serum miR-216a and miR-217 in rats fed with exocrine pancreatic toxicants (cerulean or 1-cyano-2-hydroxy-3-butene) are reported sensitive and specific biomarkers of acute exocrine pancreatic toxicity as compared with amylase and lipase and may add value to the measurement of classical pancreatic biomarkers (Wang et al., 2017b). Both miR-216a and miR-217 are claimed to be of pancreatic origin, correlated better with microscopic findings within the exocrine pancreas. Conversely, neither microRNA was increased in rats administered a proprietary molecule known to cause a lesion at the pancreatic endocrine—exocrine interface or in rats administered an established renal toxicant. Circulating miRNAs such as miR-488-5p and miR-938-5p have been suggested to have an important role in discriminating pancreatic ductal adenocarcinoma (PDAC) from healthy subjects and those with chronic pancreatitis (Ebrahimi et al., 2016). The miRNA—mRNA regulating network in chronic pancreatitis has been identified based on significant functional expression (Wang et al., 2017a). However, such miRNA-based markers need to be confirmed in patients with acute and chronic pancreatitis. In one study, two dozens of microRNAs have been shown to be differentially altered in the pancreatic tissue from patients with chronic pancreatitis (n = 42) as compared with that in adjacent normal tissue as control (Bloomston et al., 2007). These studies are very preliminary and need further investigations to establish their utility as biomarker candidates in clinical diagnostics. Even if microRNA microarray technologies identify some promising biomarkers of disease/injury, cost and precision are other factors to be considered.

COMPARISON OF BIOMARKERS BETWEEN ACUTE AND CHRONIC PANCREATITIS

Basic laboratory tests for diagnosing acute and chronic pancreatitis are vastly different because former one is short term largely indicated by significant increases for amylase, isoamylase, lipase, TAP, trypsin, elastase-1, phospholipase A2, CDT, CRP, PAP, CAPAP, procalcitonin in serum, plasma and/or urine, and other markers such as cathepsins in pancreatic juice. The indirect pancreatic function tests in serum or urine can be evident in early stages of chronic pancreatitis, but a number of biomarkers as mentioned previously may be in the normal range or fluctuate depending on the chronicity of the pancreatitis because slow destruction of the exocrine gland results in exocrine pancreatic insufficiency. Therefore, testing exocrine pancreatic insufficiency is still recommended when chronic pancreatitis is suspected. When the pancreatic injury progress to fibrosis following the activation of stellate cells as often noticed in chronic pancreatitis, a shift in cellular phenotype may also bring new markers of injury in picture. Although several tests including secretin test, Cerulean test, and Lundh test have been described in detail by Lankisch and Banks (1998), fecal tests for trypsin, chymotrypsin, and elastase-1 can also provide some clues for presence of chronic pancreatitis. Most of methods used are either titrimetric estimation or ELISA. Moreover, fecal chymotrypsin estimation is not novel. Most of these tests are not even sensitive to diagnose mild-to-moderate exocrine pancreatic insufficiency. Fecal fat estimation, particularly when stimulated lipase and protease output fall below 10% of the normal, is a safe biomarker for steatorrhea (DiMagno et al., 1973). However, fecal fat contents were of no value for differential diagnosis of pancreatic and nonpancreatic steatorrhea (Roberts et al., 1986).

Pancreas-specific chymotrypsin splits N-benzyl-L-tyrosyl-p-aminobenzoic acid to p-aminobenzoic acid (NBT—PABA) in the duodenum. Estimation of p-aminobenzoic acid (PABA) cannot be true because some gut bacteria also splits NBT—PABA causing a false normal test results. Chronic pancreatitis can be diagnosed by serum, urinary, and fecal biomarkers of pancreatic functions in conjunction with patient history and imaging (CT, MRCP, ERCP) results. In view of available biomarkers and nature of pathology, a single biomarker should not be sufficient to diagnose chronic pancreatitis. Identification and development of metabolomic-, proteomic-, and microRNA-based biomarkers should be undertaken in experimental models followed by in patients at various stages of acute and chronic pancreatitis.

BIOMARKERS FOR EARLY DETECTION OF PANCREATIC CANCER

Although focus of this chapter is biomarkers of pancreatitis (acute and chronic), early detection of PC is also critical for the success of interventional and surgical therapies. PC is most devastating and fatal disease without any overt symptoms at initial stages. Most common exocrine PCs are PDAC followed by adenosquamous carcinomas and broad-based pancreatic cystic neoplasma. However, pancreatic neuroendocrine tumors constitute a small number of cases ~1% of the all PCs. Endocrine pancreatic tumors have been variously called islet cell tumors, pancreas endocrine tumors (PETs), and pancreatic neuroendocrine tumors (PNETs). On the other hand, serum IgG4 was found to have high specificity and relatively low sensitivity in differential diagnosis of AIP from PC using meta-analysis of 11 studies comprising 523 AIP and 771 PC patients (Dai et al., 2018).

The annual clinically recognized incidence is low, about five per one million person/years. However, autopsy studies incidentally identify PETs in up to 1.5%, most of which would remain inert and asymptomatic. The majority of PNETs are usually categorized as benign, but the definition of malignancy in pancreas endocrine tumors has been ambiguous. The more aggressive endocrine PCs are known as pancreatic neuroendocrine carcinomas (PNECs). Similarly, there as likely been a degree of admixture of PNEC and extrapulmonary small cell carcinoma. Most of biomarkers of PCs, identified for PDAC, are carcinoembryonic, carbohydrate antigen (CA19-9), and mucin family (MUC), the later being most commonly used along with circulating tumor cells, markers in pancreatic juice, and signaling pathway have been extensively reviewed (Tanase et al., 2009; Poruk et al., 2013; Chakraborty et al., 2011). Elevated CA19-9 by itself is sufficient for differentiating pancreatic carcinoma and chronic pancreatitis. Early detection of PC offers promise of improved mortality rates through surgical resection. Therefore, biomarkers should be determined for the early stages of PC to improve the prognosis and mortality rates by using intervention therapies. For further details on biomarkers of PC, readers are referred to Chapter 49. In fact, a large number of miRNAs have been identified as putative biomarkers and therapeutic targets for an early detection of PC (Gayral et al., 2014; Calvano et al., 2016; Young et al., 2018). Innovative initiative and new approaches need to be undertaken to identify and validate the biomarkers for an early detection of PC (Kenner et al., 2017). It is expected that an early detection of PC can be very cost-effective with greater prognostic and clinical outcomes.

BREATHE ANALYSIS

Human-exhaled breath contains many molecules either present as gases or occurring in a soluble form in the vapor of the breath and can rapidly and easily assess the presence of volatile compounds (hydrogen sulfide, nitric oxide, and molecular mass 66 u substance) in the exhaled breath of chronic pancreatitis patients (Morselli-Labate et al., 2007). Although study was conducted in 11 patients with chronic pancreatitis and 31 healthy subjects and appears novel, no significant differences were found between patients and healthy controls.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Reliable and sensitive biomarkers of acute and chronic pancreatitis and PCs are needed, as current available biomarkers have limitations and lack specificity. Serum total amylase and lipase in combination or individually remains to be a gold standard for functional clinical diagnostics of acute pancreatitis if the test is conducted on admission of the patients to the hospital. Definitely, lipase assay has advantage over amylase in clinical diagnostics and has more specificity for diagnosing acute pancreatitis. However, imaging technologies are strong support for diagnosis of both acute and chronic pancreatitis. Identification and development of biomarkers of chronic pancreatitis remains to be investigated and is challenging because several indirect pancreatic functional biomarkers are inconclusive primarily because of impaired secretory components of exocrine pancreas due to slow destruction of the gland in chronic pancreatitis, particularly at later stages. The focus of future research lies in identification of molecular biomarkers by utilizing proteomic, metabolomic, and circulating microRNA array technologies by using very well-defined patient populations at various stages of the disease.

INTRODUCTION

The skeletal muscles account for nearly half of mammalian body weight. The muscles are targets of toxicity for many drugs and chemicals for three major reasons. First, the muscles receive proportionately large amounts of toxicants; second, muscle metabolism is highly active; and third, the muscles are enriched with many reactive and binding sites, such as receptors, neurotransmitters, neurotropic and growth factors, enzymes, and other proteins. In addition, the muscles have drug transporter systems. Chemicals from various classes interact with these critical molecules and exert their toxic effects. Under strenuous conditions, such as chemical intoxication, skeletal muscles generate excess reactive oxygen species (ROS)/reactive nitrogen species (RNS), thereby causing oxidative/nitrosative stress leading to muscle toxicity. Chemicals of different classes can induce apoptosis, necrosis, or autophagy, resulting in muscle weakness, loss of muscle mass, atrophy, myopathy, or paralysis. Currently, drug-induced myopathy is among the most common causes of muscle disease. The target molecules are often used as biomarkers of exposure and/or effects of chemical/drug toxicities. In addition to drugs and chemicals, muscle toxicity occurs because of envenomations by poisonous snakes, scorpions, and other spiders. The distinct features of slow and fast muscles are the most fascinating aspects of skeletal muscle research because they can respond differently to each chemical. This chapter describes biomarkers of exposure and effects of drugs, chemicals, and biotoxins in skeletal muscles of experimental animals and humans and their relationship to clinical perspectives.

MUSCLE TYPES

Originally, muscles were characterized as having three different myofibers: type I myofibers (red, slow and aerobic muscles), and types IIA and IIB (white, fast and glycolytic muscles). Fiber type analysis by actomyosin ATPase reaction shows that the soleus is composed predominately of type I fibers with a few type IIA and IIB fibers. In contrast, the extensor digitorum longus (EDL) is composed predominately of type IIA and IIB fibers, with a few type I fibers. In the rat, total fiber numbers are approximately 1800 for soleus and 2500 for EDL (Gupta et al., 1985, 1986). Recently, types IC, IIC, IIAC, and IIAB, which have intermediate myosin ATPase–staining characteristics, have been identified in human muscles. Recently seven human muscle fiber types have been identified based on myosin ATPase–histochemical staining (from slowest to fastest): types I, IC, IIC, IIAC, IIA, IIAB, and IIB. Effects of toxic chemicals have rarely been studied on these fiber types, but chemicals such as organophosphate (OP) pesticides and nerve agents are known to have different effects on specific fiber types. The fast and slow muscles differ qualitatively and quantitatively in terms of biochemical constituents, and accordingly, these muscles are affected differently by various chemicals.

PESTICIDES

Cholinesterase Inhibitors

Next to the brain, skeletal muscles are major targets for the toxicity of OP and carbamate (CM) compounds. Understanding the skeletal muscle system in the context of OP/CM poisoning is interesting, yet very complex because muscles containing different fiber types often respond differently, even to the same OP or CM compound (Gupta et al., 2015). Skeletal muscles contain cholinergic as well as noncholinergic elements, which are directly or indirectly modulated by OP/CM compounds, and this influences overall toxicity outcome accordingly.

Behavioral Effects

In general, experimental animals acutely intoxicated with an OP (pesticide or nerve agent) or CM pesticide exhibit the onset of toxicity, such as salivation, lacrimation, muscle tremors, and fasciculations within 5−15 min. The signs of maximal severity are observed within 30−60 min and usually last for 2−6 h with increasing propensity. Thereafter, the intensity is reduced to a mild form and toxicity may still be observed after 24 h of exposure. With some OP insecticides, such as chlorpyrifos or parathion, occurrence of toxic signs is delayed. Toxic signs are less severe and last for a shorter period with CMs than with OPs. It needs to be pointed out that some OPs and CMs produce pronounced CNS effects, whereas others produce peripheral effects (Gupta et al., 1986, 1987a,b, 2015; Misulis et al., 1987; Gupta and Kadel, 1989, 1991).

Cholinergic Effects

All skeletal muscles contain major elements (a neurotransmitter ACh, an enzyme acetylcholinesterase (AChE) that hydrolyzes ACh, and an enzyme ChAT that synthesizes ACh) of the cholinergic system, but quantities of these elements vary from muscle to muscle. The fast fiber−containing muscle (EDL) has greater values of these cholinergic elements than the slow fiber muscle soleus or the mixed fiber muscle diaphragm (Gupta et al., 2015). OP and CM compounds exert muscle toxicity primarily by virtue of AChE inhibition at the neuromuscular junction (NMJ). Normally at the cholinergic synapse, AChE is essentially required for the removal of ACh from the synaptic cleft. But a marked inhibition of AChE by OPs or CMs profoundly modifies neuromuscular transmission by accumulated ACh, causing muscle hyperactivity, fasciculations, weakness, and muscle cell death by necrosis or apoptosis. Time-course studies of AChE inhibition in skeletal muscles have been reported for many OPs and CMs (Gupta et al., 1985, 1986, 1987a,b, 1991a,b, 2015; Gupta and Kadel, 1991; Thiermann et al., 2005). Evidently, AChE inactivation occurs to a varying degree in slow and fast muscles by each OP/CM compound. For example, Gupta et al. (1987a) demonstrated that selective inhibition of AChE activity in skeletal muscles was apparent within 1 h of soman administration (100 μg/kg, sc) in rats when soleus showed the maximum inhibition (87%), whereas EDL showed the least inhibition (47%). EDL-AChE was also less inhibited by other OP nerve agents, such as sarin, tabun, and VX (Gupta et al., 1987b, 1991a,b). However, with DFP (1.5 mg/kg, sc) AChE inhibition was maximal in EDL (80%), followed by diaphragm, and least in soleus (63%) (Gupta et al., 1986). It needs to be mentioned that AChE inhibition of 70% or greater is required to cause muscle hyperactivity. The observable toxic effects usually do not persist for more than 4−6 h, whereas recovery of AChE activity occurs at a much slower rate (i.e., days or weeks) depending on the muscle and the AChE inhibitor.

Skeletal muscles have also been characterized for molecular forms of AChE. Qualitative and quantitative variations exist among different species, as well as young versus adult (Massoulie and Bon, 1982; Barnard et al., 1984; Patterson et al., 1987, 1988). In the rat EDL, the G_1 (4S), G_4 (10S), and A_{12} (16S) molecular forms are predominant, whereas in soleus and diaphragm a fourth major molecular form is also present, the A_8 (12S). In rat soleus, the majority of the total AChE activity is contributed by the 12S and 16S forms, whereas in the diaphragm it is from 4S and 10S and in the EDL it is from 4S (Patterson et al., 1987; Gupta et al., 2015). The 16S form is found in high concentration at the endplates, and it is thought to be involved in neuromuscular transmission. The different molecular forms of AChE in soleus and EDL have apparent K_m values similar to that previously found in the diaphragm muscle. There appears to be no difference between catalytic sites of the molecular forms of AChE in fast EDL and slow soleus muscles, despite the different molecular form patterns and activity in these muscles.

After 1 h of soman administration (100 μg/kg, sc), all molecular forms of AChE were reduced to less than 10% of control (100%) in soleus and diaphragm. In EDL the 16S form, mainly localized at the NMJ, was not affected at this time, whereas the 10S form was completely inhibited and the 4S form was reduced to 50%. Further inhibition was seen after 24 h but even then the 16S form was least inhibited in EDL. In similar experiments, Gupta et al. (1986, 1987b, 1991) also reported differential inhibition of AChE and its molecular forms in various skeletal muscles of rats intoxicated with DFP (1.5 mg/kg, sc), tabun (200 μg/kg, sc), sarin (110 μg/kg, sc), and VX (12 μg/kg, sc).

Petrov et al. (2011) demonstrated different sensitivities of rat skeletal muscles to an anti-ChE agent, alkylammonium derivatives of 6-methyluracil (ADEMS) because of different sensitivities of molecular forms. The rat respiratory muscle diaphragm had markedly lower sensitivity than the locomotor muscle EDL to ADEMS. The intermuscular difference in sensitivity to ADEMS is partly explained by a higher level of mRNA and activity of 1,3-bis[5(diethyl-o-nitrobenzylammonium)pentyl]-6-methyluracildibromide (C-547)−resistant BuChE in the diaphragm. Moreover, diaphragm AChE was found to be more than 20 times less sensitive to C-547 than that from the EDL. The A_{12} form present in muscles appeared more sensitive to C-547. Some of the intermuscular differences are explained based on AChE and BuChE mRNA levels. For example, the ratio of AChE and BuChE mRNA level in the EDL was

4.6 and in the diaphragm it was 1. It appears that BuChE might be more significant for ACh hydrolysis in the diaphragm than in the EDL.

Morbidity and mortality associated with OP or CM intoxication is due to the effects on skeletal muscles in general and muscles of respiration in particular. Deaths from an overdose of OPs and CMs are due in part to respiratory paralysis by depolarizing neuromuscular blockade (Misulis et al., 1987; Besser et al., 1989; Karalliedde and Henry, 1993).

Inhibition of AChE and BuChE in skeletal muscles can be used as biomarkers of exposure and effect of OPs and CMs. But interpretation should be made with great caution, and factors such as species, sensitivity of AChE and BuChE to its inhibitor in a specific muscle, and different sensitivities of molecular forms of AChE and BuChE in that muscle should be taken into account. Following acute exposure, OPs and CMs have not been shown to alter the levels of ChAT or ACh in skeletal muscles.

Noncholinergic Effects

Excitotoxicity and Oxidative/Nitrosative Stress

Excitotoxicity caused by OPs and CMs is mediated by overstimulation of nicotinic acetylcholine (nACh) and NMDA receptors, leading to increased Ca^{2+} uptake (Gupta et al., 1986; Inns et al., 1990; Karalliedde and Henry, 1993). Lipid peroxidation, mitochondrial dysfunction/damage, loss of energy metabolites, reduction of cytochrome-c oxidase (COx) activity, and increased xanthine oxidase (XO) activity support the contention that AChE inhibitor—induced hyperactivity causes muscle injury by excessive formation of ROS and RNS (Yang and Dettbarn, 1998; Gupta and Goad, 2000; Jeyarasasingam et al., 2000; Gupta et al., 2002; Milatovic et al., 2000, 2005, 2006). Yang and Dettbarn (1998) demonstrated that in rats within 30−60 min of

DFP injection (1.5 mg/kg, sc) COx activity was reduced by 56%, XO activity was increased by 56%, and a significant muscle fiber breakdown had occurred in the diaphragm. These findings suggested that ROS is produced during DFP-induced muscle hyperactivity, initiating lipid peroxidation and subsequent myopathy.

Acute toxic effects of AChE inhibitors on skeletal muscles are thought to involve oxidative and nitrosative stresses with increased generation of free radicals, such as ROS and RNS. Muscle hyperactivity with its increased oxygen and energy consumptions appears to be the primary cause of oxidative stress. Control values were not significantly different in soleus and EDL muscles of rats for biomarkers of oxidative stress, F_2-isoprostanes (F_2-IsoPs, 1.142 ± 0.027 and 1.177 ± 0.092 ng/g), nitrosative stress, and citrulline (469.7 ± 31.8 and 417.8 ± 18.5 nmol/g). However, the values were different for biomarkers of mitochondrial dysfunction (ATP, 3.66 ± 0.11 and 5.85 ± 0.14 µmol/g; and phosphocreatine, 7.91 ± 0.26 and 13.14 ± 0.31 µmol/g, in soleus and EDL, respectively).

Rats acutely intoxicated with a CM pesticide carbofuran (1.5 mg/kg, sc) showed signs of maximal toxicity including muscle hyperactivity within 60 min of exposure. At this time, F_2-IsoPs (177% and 153%) and citrulline (267% and 304%) levels were significantly increased (Figs. 20.1 and 20.2, respectively), whereas ATP (46% and 43%) levels were decreased in soleus and EDL (Milatovic et al., 2005). With this level of ATP depletion, muscle fiber damage is likely to occur as a result of metabolic catastrophe.

In a similar study, Gupta et al. (2002) determined citrulline, ATP, and phosphocreatine (PCr) levels in skeletal muscles of rats acutely intoxicated with DFP (1.5 mg/kg, sc). Within 15 min of DFP exposure, with an onset of fasciculations, citrulline levels were significantly elevated in the muscles (soleus, EDL, and
FIGURE 20.1 Effect of carbofuran (1.5 mg/kg, sc) on F_2-IsoPs levels in extensor digitorum longus (EDL) muscle of rats. Values are Means $\pm$ SEM (n = 4−6). [a]Significant difference between control and carbofuran-treated rats ($P < .05$).
FIGURE 20.2 Effect of carbofuran (1.5 mg/kg, sc) on citrulline levels in soleus and extensor digitorum longus (EDL) muscles of rats. Values are Means ± SEM (n = 4–6). [a]Significant difference between control and carbofuran-treated rats ($P < .05$).

diaphragm). Maximum increases in citrulline (272% −288%) were noted 60 min after DFP injection. At this time point, AChE activity was reduced by 90%−96% (soleus < diaphragm < EDL). The levels of ATP and PCr were maximally reduced (30%−43%) and total adenine nucleotides (TAN) and total creatine compounds (TCC) showed declines. The findings revealed that the increase in NOS activity and nitric oxide (NO) was greater than the decrease of ATP and PCr.

NO has been linked to many pathological conditions, including deleterious effects of ChE inhibitors in skeletal muscles (Jeyarasasingam et al., 2000; Gupta et al., 2002; Milatovic et al., 2005, 2006). During DFP-induced muscle hyperactivity, the increased Ca^{2+} influx is associated with nicotinic ACh receptor (nAChR) activation at the NMJ. This finding was supported by previous studies showing that increased muscle contractility generates significantly greater quantities of ROS and RNS (Yang and Dettbarn, 1996; Clanton et al., 1999). Increased muscle contractility may also involve the activation of glutamate machinery (glutamate, glutamate receptors, and glutamate transporters) present at the NMJ mediated through increased calcium and NO. Increased NO exerts cellular toxicity primarily by depleting energy stores through a couple of mechanisms: (1) prolonging poly-(ADP-ribose) polymerase (PARP) activation and (2) inhibiting enzymes involved in mitochondrial respiration (cytochrome oxidase, aconitase, and mitochondrial CK) and glycolysis (phosphofructokinase). NO directly and specifically inhibits mitochondrial respiration by competing with molecular O_2 for binding to COx, thereby causing inhibition of ATP synthesis. Even at a nanomolar concentration, NO can directly inhibit COx activity, and cells producing large quantities of NO can inhibit their own respiration as well as the respiration of neighboring cells. Yang and Dettbarn (1998) found a 50% reduction of COx activity in diaphragm muscle caused by DFP-induced muscle hyperactivity, which

could be due to the inhibitory effect of NO, the magnitude of which was increased by a factor of threefold. In essence, inhibition of COx appears to be the primary mechanism for ATP depletion because COx is the terminal and rate-limiting enzyme of the mitochondrial respiratory chain, which generates ATP by oxidative phosphorylation.

NO appears to regulate the coupling between energy supply and demand; it increases skeletal muscle blood flow and glucose transport and inhibits glycolysis and mitochondrial respiration (Kaminski and Andrade, 2001). The findings of Fukushima et al. (1997) and Gultekin et al. (2000) further supported the contention that the AChE-inhibiting OP insecticides cause lipid peroxidation and inhibition of oxidative phosphorylation. Gupta et al. (2002) demonstrated that the degree of NO elevation (threefold) was much greater than the declines of high-energy phosphates (30%−40%), suggesting the NO/NOS system to be a much more sensitive marker of nitrosative injury in skeletal muscles. Other factors, in addition to NO elevation, that contribute to the energy loss may include damage to mitochondria by AChE inhibitors (Laskowski et al., 1975; Gupta et al., 1999) and a higher rate of ATP utilization needed to generate NAD in the ADP-ribosylation of nuclear proteins, resulting in a decline of TAN and TCC.

OP-/CM-induced changes, such as increases in XO, F_2-IsoPs, and citrulline and decreases in COx, ATP, and PCr in skeletal muscles, can be used as biomarkers of oxidative stress and mitochondrial dysfunction.

Creatine Kinase and Creatine Kinase Isoenzymes

Creatine kinase (CK) catalyzes the synthesis of ATP and phosphocreatine (PCr) in a reversible Lohmann reaction (Creatine + ATP ↔ PCr + ADP). Data presented in Table 20.1 show the normal distribution of CK and its isoenzymes in the skeletal muscles of untreated control rats. Maximal CK activity was found in the EDL,

TABLE 20.1   Normal Distribution of CK and CK Isoenzymes in Skeletal Muscles and Serum of Rats

	Total CK	CK Isoenzymes		
		CK-BB (CK-1)	CK-MB (CK-2)	CK-MM (CK-3)
Soleus	2,062,800 ± 71,065 (100)	ND	ND	2,062,800 ± 71,065 (100)
EDL	4,659,125 ± 185,583 (100)[a,b]	ND	ND	4,659,125 ± 185,583 (100)[a,b]
Diaphragm	3,018,240 ± 110,777 (100)	ND	ND	3,018,240 ± 110,777 (100)
Serum	3769 ± 240 (100)	576 ± 45 (15.3)	148 ± 17 (3.9)	3086 ± 209 (80.8)

Values expressed in terms of IU/L are presented as Means ± SEM (n = 4–6). Numbers in parentheses are percentages of isoenzymes to total CK activity (100%). *CK,* creatine kinase; *EDL,* extensor digitorum longus; *ND,* none detected.
[a]*Significant difference between EDL and soleus (P < .001).*
[b]*Significant difference between EDL and diaphragm (P < .001).*

followed by diaphragm, with lowest activity in the soleus. The levels of energy metabolites (ATP and PCr) are reflected in these muscles according to the levels of CK (e.g., EDL having higher CK level had greater energy metabolites). Furthermore, during normal activity, fast-twitch fibers fire over a short period at higher rates than slow-twitch fibers, and for that reason, the EDL needs a greater amount of ATP and PCr (immediate precursor for ATP synthesis) than the soleus.

Electrophoretic separation of CK isoenzymes in all three muscles revealed the existence of only the CK-MM isoenzyme (Gupta et al., 1994). Further separation of the CK-MM isoenzyme for subforms showed only CK-MM3 in all three muscles. Serum had very little CK activity compared to muscles; however, the CK consisted of three distinct isoenzymes: CK-BB (15.3%), CK-MB (3.9%), and CK-MM (81.8%). Further separation of CK-MM isoenzyme by electrophoresis revealed the presence of three subforms: CK-MM1 (6.3%), CK-MM2 (24%), and CK-MM3 (69.7%). It is well known that the CK-MM3 subform is secreted from muscles into the plasma, where it converts into the MM2 and MM1 subforms by carboxypeptidase-N2 (CPN2).

Rats acutely intoxicated with a CM insecticide carbofuran (1.5 mg/kg, sc) showed significant increase in CK activity in diaphragm, a decrease in soleus, and no change in EDL, at the time of maximal severity (1 h post exposure). At the same time, activities of CK and all three CK isoenzymes were significantly elevated in serum. Carbofuran toxicity caused a shift in the serum CK-MM subform (i.e., higher sequential conversions of CK-MM3 subform to CK-MM2 and CK-MM2 to CK-MM1) possibly due to enhanced CPN2 activity.

Lactate Dehydrogenase and Lactate Dehydrogenase Isoenzymes

Lactate dehydrogenase (LDH) catalyzes the synthesis of lactate and pyruvate in a reversible reaction and is commonly used as a biomarker of cell damage or death. Normal distribution of LDH and its isoenzymes in skeletal muscles of rats revealed that in controls, LDH activity was found to be highest in the EDL, followed by diaphragm, and lowest in the soleus (Table 20.2). The enzyme activity was meager in serum compared with that of muscles (Gupta et al., 1994). It was interesting to note that all three muscles and serum

TABLE 20.2   Normal Distribution of LDH and LDH Isoenzymes in Skeletal Muscles and Serum of Rats

	Total LDH	LDH Isoenzymes				
		LDH-1 HHHH	LDH-2 HHHM	LDH-3 HHMM	LDH-4 HMMM	LDH-5 MMMM
Soleus	72,720 ± 2484 (100)	14,962 ± 476 (20.7)	19,054 ± 617 (26.3)	16,118 ± 692 (22.2)	14,254 ± 1332 (19.5)	8316 ± 890 (11.3)
EDL	207,300 ± 22,945 (100)[a,b]	7290 ± 1890 (3.5)[a,b]	12,300 ± 2033 (5.9)[a,b]	18,105 ± 1498 (8.7)	40,420 ± 4100 (19.5)[a,b]	129,870 ± 15,298 (62.6)[a,b]
Diaphragm	129,120 ± 4828 (100)	17,020 ± 504 (13.2)	17,498 ± 571 (13.5)	16,190 ± 780 (12.6)	26,738 ± 1080 (27.7)	51,680 ± 3081 (40.0)
Serum	740 ± 28 (100)	9.8 ± 1.4 (1.3)	17.4 ± 2.0 (2.3)	10.2 ± 1.2 (1.4)	38.0 ± 3.8 (5.2)	643 ± 65 (87.0)

Values expressed in terms of IU/L are presented as Means ± SEM (n = 4–6). Numbers in parentheses are percentages of isoenzymes to total LDH activity (100%). *EDL,* extensor digitorum longus; *LDH,* lactate dehydrogenase.
[a]*Significant difference between EDL and soleus (P < .01).*
[b]*Significant difference between EDL and diaphragm (P < .01).*

contained all five LDH isoenzymes, although with varying quantities. Each muscle presented a characteristic LDH isoenzyme pattern. For example, EDL contained a large proportion of LDH-5 (62.6%) and very little LDH-1 (3.5%). Soleus, on the other hand, had a very small amount of LDH-5 (11.3%) and about 20% each of the other four isoenzymes (LDH-1 through LDH-4). In general, values of LDH isoenzymes in diaphragm were intermediate to the EDL and soleus. Diaphragm had predominantly LDH-5 and LDH-4 (40% and 27.7%, respectively). In serum, isoenzyme LDH-5 was 87% of the total LDH activity (100%).

Carbofuran acute toxicity caused significant enhancement of LDH activity in EDL, diaphragm, and serum. Marked elevation of all five isoenzymes in serum occurred with maximum increases in LDH-1 and LDH-4 (threefold). Unlike serum, muscle LDH isoenzymes depicted variable patterns with carbofuran toxicity. A significant decline in ATP appears to be the mechanism involved in leakage of cytoplasmic/mitochondrial enzymes into circulation (Gupta et al., 1994). The fact that ATP is essential for retaining intracellular enzymes by maintaining cell membrane permeability and integrity was strongly reinforced by earlier investigations, demonstrating that depletion of ATP results in cell membrane damage, and ATP can be used as a biomarker of cell damage/death (Andreoli, 1993).

Histopathological Alterations

In general, the greater the AChE inhibition (during the initial 24−48 h period), the higher the number of lesions found in skeletal muscles (Gupta et al., 2015). The time courses of AChE inhibition and number of necrotic lesions in skeletal muscles of rats intoxicated acutely with DFP (1.5 mg/kg, sc) are presented in Table 20.3. With acute AChE inhibitors, the earliest lesions are focal areas of abnormality in the subjunctional

area of the muscle fiber (Laskowski et al., 1977; Patterson et al., 1987, 1988). These focal changes progress to a breakdown of subjunctional fiber architecture followed by phagocytosis. Longitudinal sections reveal that the necrosis affects only a small segment of fiber lengths. During later stages, progressively greater lengths of muscle fibers are affected. Serial cross-sections of 10-μm thickness indicate that the number of lesions correlates with the greatest density of end-plates. A significant increase in blood CK activity coincides with appearance of myonecrosis, indicating destruction of the muscle membrane (Gupta et al., 1991a,b, 1994, 2015). CMs, such as aldicarb and carbofuran, caused cell swelling, loss of myofibrillar structure, cytoplasmic clearing, and necrosis. Electron microscopic changes included mild focal loss of myofibrillar structure, intermyofibrillar clearing (fluid accumulation), and swelling of mitochondria (Fig. 20.3) (Gupta et al., 1999). Recently, Holovská et al. (2017) reported that a CM insecticide bendiocarb induced ultrastructural alterations in gastrocnemius muscles of rabbits receiving daily treatment (5 mg/kg body wt, po) for 20 days. Electron microscopy revealed dilatation of sarcoplasmic reticulum and myofilament disorganization. The most important alteration was the disruption of the sarcomeres due to the lysis of both thick and thin myofilaments. Muscle fibers also showed prominent mitochondrial swelling, and many mitochondria lacked cristae thus appearing as large membrane-bound cytoplasmic vesicles.

Despite the diversity in structures of the AChE inhibitors, the induced myopathic changes are the same, suggesting a common mechanism, i.e., muscle hyperactivity (Adler et al., 1992; Gupta and Dettbarn, 1992; Gupta et al., 2015; Jeyarasasingam et al., 2000). This mechanism is an excess of ACh and its prolonged interactions with nAChRs are associated with an excess of Ca^{+2}

TABLE 20.3   AChE Inhibition and Number of Necrotic Fibers Following a Single Sublethal Injection of DFP (1.5 mg/kg, sc)

Time After DFP Administration	Soleus		EDL		Diaphragm	
	AChE	Lesions	AChE	Lesions	AChE	Lesions
Control	100%	0	100%	0	100%	0
1 day	24%	27 ± 6[a]	17%	64 ± 11[a]	13%	308 ± 58[a]
2 day	24%	39 ± 9[a]	14%	71 ± 12[a]	13%	333 ± 63[a]
3 day	39%	5 ± 1[a]	31%	49 ± 5[a]	25%	174 ± 35[a]
7 day	65%	0	53%	0	69%	0

Values of AChE activity are expressed as % remaining activity of control (100%).
Numbers of lesions are presented per cross section from the mid-belly region of muscle.
Data are presented as the means ± SEM (n = 5−10).

and not a direct action of these inhibitors on the muscle (Gupta et al., 1986; Inns et al., 1990; Bright et al., 1991; Karalliedde and Henry, 1993).

Strychnine

Strychnine, obtained from the plants *Strychnos nux-vomica* or *Strychnos ignatii*, has been used as a rodenticide for more than a century. It has been involved in accidental poisonings in humans and malicious poisonings in animals. In small amounts, strychnine is known to be added to "street drugs," such as LSD, heroin, cocaine and others.

Strychnine is a potent convulsant. The convulsant action of strychnine is because of interference with the postsynaptic inhibition that is mediated by the amino acid glycine. Glycine is an inhibitory transmitter to motor neurons and interneurons in the spinal cord. Strychnine acts as a selective competitive antagonist to block the inhibitory effects of glycine at the glycine receptors. Studies suggest that strychnine and glycine interact with the same receptor (a ligand-gated chloride channel) but at different sites. There is also evidence of an increase in brain levels of glutamic acid, an amino acid that acts as a transmitter for excitatory nerve impulses that excites muscle contraction. The result of these effects is that skeletal muscles become hyperexcitable.

Roy et al. (2012) showed embryotoxicity of strychnine in zebrafish with long-term behavioral impairment in adults, possibly because of synaptic changes. Polymerase chain reaction analysis revealed indications that strychnine exposure altered expression of some genes related to glycinergic, GABAergic, and glutamatergic neuronal synapses during embryonic development.

The LD_{50} of strychnine in most species lies in the range of 0.4—3 mg/kg body wt (Gupta, 2018). Following the ingestion of strychnine, symptoms of poisoning usually appear within 15—60 min. Strychnine has profound toxic effects on the skeletal muscles. The initial clinical signs of poisoning include nervousness, restlessness, twitching of the muscles, and stiffness of the neck. As poisoning progresses, the muscular twitching becomes more pronounced and tetanic convulsions suddenly appear in all the striated muscles. The limbs are extended and the neck is curved to opisthotonus. As death approaches, the convulsions follow one another with increased rapidity, severity, and duration. Death results from asphyxia because of prolonged paralysis of the respiratory muscles, especially the diaphragm (Patocka, 2015). The main morphologic change following prolonged muscle contraction is rhabdomyolysis. Release of intracellular proteins may lead to myoglobinuric nephrosis, which in turn may result in renal failure for those who survive the acute tetanic phase. The presence of typical strychnine crystals can be identified using microscopy. Of course, chemical identification and confirmation of strychnine in the gastrointestinal content or body tissues/fluids by GC-MS is considered the best biomarker of strychnine toxicity (Gupta, 2018). The other characteristic laboratory findings, which can be used as secondary biomarkers of strychnine poisoning, include elevation of serum enzymes (GOT, CK, and LDH), lactic acidosis, hyperkalemia, and leukocytosis.

Paraquat

Paraquat, a commonly used herbicide, is known to cause myopathy in humans examined at both biopsy and necropsy. A few cases of paraquat poisoning and myopathy are described here in brief. Dinis-Oliveira et al. (2008) reviewed the toxicity of this herbicide in detail. Koppel et al. (1994) reported extensive myonecrosis in a postmortem specimen of intercostal muscle from a 52-year-old woman who had ingested an unknown dose of paraquat. A patient who died 5 days after ingestion of paraquat showed paraquat levels higher in the skeletal muscle, and an increase of CK levels appeared on the fourth day after admission. Tabata et al. (1999) observed degeneration of skeletal muscles (mainly rectus abdominis, psoas major, and diaphragm). Plasma CK values were highest on day 5 (1700 mU/mL) and 900 mU/mL on day 8. In an in vitro study, paraquat was shown to damage the mitochondrial membrane, disrupt oxidative phosphorylation, and halt the electron transport chain (Yamamoto et al., 1987). The presence of paraquat in muscle or body fluids can be used as biomarker of paraquat exposure and its toxic effects. Toxicity and biomarkers of paraquat and related herbicides are described in detail in Chapter 27 of this book.

METALS

Some metals are highly toxic to the biological system, specifically targeting skeletal muscle. Skeletal muscle regeneration is a known adaptive response to muscle injury that occurs through a process of myofiber degeneration, inflammation, and new fiber formation, resulting from satellite cell proliferation and differentiation (Kawai et al., 1990; Hurme and Kalimo, 1992). However, fibrosis that also develops during the healing process may hinder muscle regeneration. Yen et al. (2010) investigated the effects of arsenic trioxide (As_2O_3) on the myogenic differentiation of myoblasts in vitro (C2C12 myoblasts and primary mouse and human myoblasts) and skeletal muscle regeneration in vivo using a mouse model. Myogenesis involves three major steps: (1) withdrawal of myoblasts from the cell cycle, (2) subsequent expression of myotubes-specific genes, and (3) formation of multinucleated myotubes. Also, Akt is an important signaling pathway involved in myogenesis. Yen et al. (2010) demonstrated that low-dose As_2O_3 ($0.1-0.5\ \mu M$) dose-dependently inhibited in vitro skeletal muscle differentiation as assessed by myogenin and myosin heavy chain expression, CK activity, and formation of multinucleated myotubes without apparent effects on cell viability. As_2O_3 significantly and dose-dependently inhibited skeletal myogenic differentiation (myogenin expression) by inhibiting phosphorylation of Akt protein and its downstream targets, mTOR and p70s6k. As_2O_3 also suppressed skeletal muscle differentiation and regeneration after glycerol-induced myopathy in the soleus in an in vivo mouse skeletal muscle regeneration model. Diaz-Villasenor et al. (2007) reported that arsenic exposure alters the expression or activity of different genes and proteins expressed in skeletal muscle and fat tissue. However, the precise mechanism of action of arsenic on skeletal myogenic differentiation remains unknown.

Muscle toxicity can also be induced by other metals, such as mercury, cadmium, lead, etc. (Gasparik et al., 2010; Tymoshenko et al., 2016). Recently, Tymoshenko et al. (2016) reported that high concentrations of Cu, Pb, Fe, Zn, Cr, and Mn caused swelling and activation of sclerotic and atrophic processes in the striated muscles of rats. These authors also observed enlarged muscle fibers and layers of connective tissue, deformation of their shapes, homogenous sarcoplasma, and hypochromic nuclei. The ultramicroscopic findings revealed multiple-dot hemorrhages with irregular cross section, deformed myofibril and hydropic and swollen mitochondria with destroyed inner membrane and deformed cristae.

Metals residue and microscopic and ultramicroscopic changes in the skeletal muscles usually serve as biomarkers of exposure and effects, respectively.

THERAPEUTIC DRUGS

Drugs of many classes are known to induce myotoxicity directly or indirectly, and their mechanisms of action are different and poorly understood. Drug-induced myopathy ranges from myalgias to chronic myopathy with severe weakness or massive rhabdomyolysis.

Lipid-Lowering Drugs

Currently, more than 25 million Americans use statins. Statins are 3-hydroxy-3-methylglutaryl-CoA reductase inhibitors, which attenuate cholesterol biosynthesis and are therefore widely used to manage hypercholesterolemia (Di Stasi et al., 2010). These medications have a number of additional important pleiotropic properties, such as improving endothelial function, enhancing the stability of atherosclerotic plaques, decreasing oxidative stress and inflammation, and inhibiting the thrombogenic response (Koch, 2012). The antiinflammatory effects of statins are thought to be neuroprotective. Furthermore, statins have beneficial extrahepatic effects on the immune system, CNS, and bone (Liao and Laufs, 2005). Statins are classified into two groups based on their solubility: lipophilic (e.g., atorvastatin, cerivastatin, fluvastatin, lovastatin, pitavastatin, and simvastatin) and hydrophilic (e.g., pravastatin and rosuvastatin). Each statin can be further classified into its lactone or acid forms, and both forms for all statins interconvert to achieve equilibrium in vivo (Skottheim et al., 2008). Lipophilic statins can pass through the cell membrane by passive diffusion and therefore can be widely distributed in a variety of cells and tissues, whereas hydrophilic statins are membrane-impermeable and therefore require drug transporters to enter cells. Statin transporters (Oatp1a4 and Oatp2b1) can carry both hydrophilic and lipophilic statins across the membranes.

Statins are generally well tolerated but can produce a variety of skeletal muscle-associated dose-dependent adverse effects (Schachter, 2005; Westwood et al., 2005; Sakamoto and Kimura, 2013; Norata et al., 2014). The major adverse effects of statins can range from muscle pain, cramping, soreness, fatigue, weakness, and myotoxicity, including rhabdomyolysis, myalgia, muscle fiber breakdown, and myositis (Mukhtar and Reckless, 2005; Di Stasi et al., 2010; Kurnik et al., 2012; Sakamoto and Kimura, 2013). In rare cases, statins can cause rapid muscle breakdown and rhabdomyolysis that can lead to death (Thompson et al., 2003; Antons et al., 2006).

Statin-induced myopathy appears to be multifactorial, including impaired signal transduction, cell trafficking, gene transcription, structural protein formation

and regulation, and oxidative phosphorylation (Oh et al., 2007; Klopstock, 2008; Norata et al., 2014). Abnormal fat oxidation or mitochondrial dysfunction may be the primary mechanism underlying statin-induced myopathy (Kaufmann et al., 2006; Phillips and Haas, 2008). Other possible mechanisms are reduced sarcolemmal cholesterol and isoprenoids involved in muscle fiber apoptosis (Dirks and Jones, 2006; Klopstock, 2008; Sakamoto and Kimura, 2013; Norata et al., 2014). Lipophilic statins exert a concentration-dependent adverse effect on muscle cell viability and promote cell disruption via proteolysis and apoptosis. Also, lactone forms of statins exert more extensive myopathic effects compared with their respective acid forms. The higher myopathic potential of the lactone forms of statins may be due to their lipophilic nature, which increases their passive transport across the muscle membrane, yielding a greater propensity for muscle damage (Thompson et al., 2003).

In vitro studies confirm that lipophilic statins have greater myopathic effects than hydrophilic statins (Kobayashi et al., 2008; Vaklavas et al., 2008). Kaufmann et al. (2006) investigated mitochondrial toxicity of four lipophilic statins (cerivastatin, fluvastatin, atorvastatin, and simvastatin) and one hydrophilic statin (pravastatin). In L6 cells (rat skeletal muscle cell line), the four lipophilic statins (100 μmol/L) induced death in 27% −49% of the cells. Pravastatin was not toxic up to 1 mmol/L. Cerivastatin, fluvastatin, and atorvastatin (100 μmol/L) decreased the mitochondrial membrane potential by 49%−65%, whereas simvastatin and pravastatin were less toxic. In isolated rat skeletal muscle mitochondria, all statins, except pravastatin, decreased glutamate-driven state 3 respiration and respiratory control ratio. Beta-oxidation was decreased by 88% −96% in the presence of 100 μmol/L of the lipophilic statins, but only at higher concentrations by pravastatin. Lipophilic statins caused mitochondrial swelling, cytochrome c release, and DNA fragmentation in L6 cells.

Kaufmann et al. (2006) suggested that statin-induced myopathy may be attributed to its effect on coenzyme Q10 (CoQ10), which is a component of the inner mitochondrial membrane required for oxidative phosphorylation. By inhibiting CoQ10 biosynthesis, statins impair oxidative phosphorylation and energy production (Marcoff and Thompson, 2007; Vaklavas et al., 2008). It needs to be pointed out that statin intolerance in humans may be associated with a genomic variation in the CoQ10 pathway (Oh et al., 2007).

Hanai et al. (2007) reported that lovastatin induced the expression of atrogin-1 (a key gene involved in skeletal muscle atrophy) in humans with statin myopathy, in zebrafish embryos, and in murine skeletal muscle cells in vitro. Based on in vitro animal and human experiments, there is evidence that statins induce muscle damage by induction of the muscle-specific E3 ubiquitin ligase atrogin-1. Findings revealed that atrogin-1 may be a critical mediator of the muscle damage induced by statins.

Interestingly, Sakamoto et al. (2008) noted a discrepancy in the adverse effects of statins between clinical reports and in vitro studies using skeletal muscle cell models. In an in vitro study, Sakamoto and Kimura (2013) highlighted that statins cause depletion of isoprenoids and inactivation of small GTPases (especially Rab GTPases), which are critical for statin-induced myotoxicity, and can be used as biomarkers. In clinical reports, both lipophilic and hydrophilic statins caused myotoxicity, whereas in in vitro experiments using cell lines of myoblasts, lipophilic but not hydrophilic statins exerted myotoxicity. In the skeletal myofibers, both pravastatin and fluvastatin induced vacuolation and cell death, whereas in the mononuclear cells only fluvastatin, but not pravastatin, was toxic. mRNA of the organic anion— transporting polypeptides Oatp1a4 and Oatp2b1 were expressed in the skeletal myofibers, but not in mononucleate cells. The statin transporters Oatp1a4 and Oatp2b1 are expressed in rat skeletal myofibers but not in satellite cells, fibroblasts, or L6 myoblasts. This explains why hydrophilic pravastatin affects skeletal muscle but not skeletal myoblasts.

Creatine kinase (CK) has commonly been used as a biomarker of statin-related myopathy (Thompson et al., 2006). But in some cases of statin-myopathy, serum CK is found to be normal (Phillips et al., 2002). Therefore, CK level alone as a biomarker can be misleading, as elevated CK levels can occur without myopathic effects and are often seen as a result of exercise (Di Stasi et al., 2010). Therefore, in statin therapy, CK results should be interpreted with great caution. Elevated myoglobin is another biomarker used to identify damage to myocytes and often accompanies elevated circulatory CK levels (Thompson et al., 2003). Statins are also known to cause elevation of transaminases in the absence of muscle symptoms. Slade et al. (2006) reported elevation of phosphodiesters in myopathy with statin use because of accelerated myocytes membrane turnover or reduction in cholesterol synthesis. Thus, testing of phosphodiesters may assist physicians in identifying those patients who may have adverse effects due to statin use.

Dobkin (2005) suggested evaluation of skeletal muscle composition and function to assess the presence of myopathy in statin users. Muscle biopsies are an invasive procedure that may be used in research to assess histochemical and morphological alterations, but they are not clinical tests for myopathy (Di Stasi et al., 2010). Biopsies from statin users showed myopathic

effects, including diffuse lipid droplet accumulation vacuoles, cytochrome oxidase—negative myofibers, and an increased number of ragged-red fibers (Phillips et al., 2002). Dobkin (2005) suggested measurement of muscle performance, alternative to muscle biopsies, to identify the myopathy. Findings revealed functional lower-extremity weakness of the hip flexors and abductors related to myopathy, possibly independent of CK level. This noninvasive approach for muscle performance testing can be an effective measure to identify and track muscle function and recovery after statin-induced myopathy.

Drugs Used Against AIDS

Patients infected with human immunodeficiency virus (HIV) are often more susceptible to myopathy because of a variety of disease- and treatment-related reasons (Kenaston et al., 2009). Zidovudine (AZT) has been used in patients with AIDS for more than three decades. The mechanism of action of AZT is inhibition of nucleoside reverse transcriptase. AZT acts as a false substrate for the mitochondrial DNA polymerase, thereby reducing mitochondrial DNA synthesis and causing mitochondrial myopathy. Although the exact mechanism of muscle toxicity is not known, patients may develop myopathy as myalgia, fatigue, muscle wasting, and diffuse weakness with a proximal predominance, along with an elevated CK. Pathological findings include muscle fiber necrosis and vacuoles with ragged-red fibers. Electron microscopy findings include changes in mitochondria, myofilaments, and tubules (Misulis et al., 2000). Unfortunately, a clear differentiation of AIDS myopathy from AZT myopathy is not always possible. Lee et al. (2012) reported skeletal muscle toxicity in HIV-infected adults treated with raltegravir. Findings revealed isolated CK elevation, myalgia without motor weakness, proximal myopathy on physical examination, and rhabdomyolysis.

Antiinflammatory Drugs

Increased levels of proinflammatory cytokines, both in the circulation and the skeletal muscle, have been attributed a key role in the pathophysiology of cachexia and muscle wasting (Fanzani et al., 2012). In this context, a more general antiinflammatory approach, as well as the use of so-called "immunomodulators," could be of interest. Thalidomide, pentoxyfylline, and statins exert antiinflammatory effects.

Antitumor and Anticancer Drugs

Several studies have attempted to identify the molecular mechanisms responsible for toxicity induced by antitumor and anticancer drugs. Doxorubicin (Dox), a potent antitumor agent used in cancer treatment, is myotoxic and results in significant reductions in skeletal muscle mass and function. It is established that Dox-induced toxicity is associated with an increased generation of ROS and oxidative damage within muscle fibers. Smuder et al. (2011) showed increased oxidative stress and activation of cellular proteases (calpain and caspase-3) in skeletal muscles of rats treated with Dox. Calpain is a Ca-dependent cysteine protease that promotes muscle atrophy by cleaving structural proteins. Increased ROS can lead to elevated levels of cytosolic Ca, which leads to calpain activation (Goll et al., 2003). In an in vitro study, Green and Leeuwenburgh (2002) observed that Dox administered to isolated mitochondria caused an increase in superoxide production, followed by increases in caspase-3 activity and cytochrome c efflux in H9C2 myocyte cells. Dox-induced cell death occurred because of mitochondrial dysfunction and apoptosis. Vincristine can cause neuropathy and myopathy, but its mechanism for myopathy is not clearly understood.

Various novel biomarkers, such as skeletal troponin I (sTnI), myosin light chain 3 (Myl3), CK M isoform (CKm), and fatty acid binding protein 3 (Fabp3) have been suggested in drug-induced skeletal muscle injury as they are more sensitive and tissue specific than conventional biomarkers, such as CK, AST, and LDH (Tonomura et al., 2012; EMA, 2015; FDA, 2015; Burch et al., 2016; Vlasakova et al., 2016; Goldstein, 2017).

DRUGS OF ABUSE

Alcohol, cocaine, opiates (heroin or pentazocine), and many other drugs of abuse are known to cause muscle damage by different mechanisms. In alcoholic binges, multiple mechanisms, including hypokalemia, hypophosphatemia, coma, or agitation, may combine to produce muscle damage. Alcohol also induces increases in ROS and RNS, thereby causing mitochondrial dysfunction. Drugs, such as ethanol, heroin, amphetamines, cocaine, and other sedatives, antidepressants, and stimulants are known to cause muscle damage by rhabdomyolysis (Richards, 2000; Chabria, 2006; Töth and Varga, 2009). The most serious sequela of rhabdomyolysis in alcoholics is renal failure. Muscle necrosis results in the release of large amounts of enzymes into the blood, such as CK, LDH, and others. Myoglobin is greatly increased in the blood and is excreted in the urine (Misulis et al., 2000). Rhabdomyolysis seen in association with heroin and barbiturate abuse is probably related to local pressure necrosis from the patient's own body while the patient is obtunded or unconscious. Rhabdomyolysis has also been associated with

phencyclidine, possibly because of muscle damage caused by the use of restraints in hyperactive—combative patients. The acute dystonic reaction induced by phencyclidine may also cause muscle damage. Amphetamine abuse has been associated with rhabdomyolysis, and hyperpyrexia and increased muscular activity seem to cause muscle damage. Cocaine-induced rhabdomyolysis could be due to the sympathetic overactivity leading to muscular hyperactivity causing microinfarctions with skeletal muscle necrosis (Lombard et al., 1988). Elevated CK activity and myoglobinuria support the finding of cocaine-induced rhabdomyolysis and can be used as biomarkers of muscle toxicity.

Intramuscular injections, particularly repeated injections of opiates, may cause muscle damage with a fibrotic reaction that can result in muscle contractures (von Kemp et al., 1989). Subcutaneous administration of barbiturates may also cause focal necrosis of the adjacent muscles.

VENOMS AND ZOOTOXINS

Envenoming by snakebite, scorpion sting, and other zootoxins constitutes a significant health problem in many parts of the world, especially in developing countries. Most venoms and poisons are mixtures of a variety of chemical compounds that often act synergistically to produce their toxic effects (Gwaltney-Brant et al., 2018). Recent studies suggest that venoms and poisons from zootoxins cause tissue damage at the site of a bite or sting, but they can affect various vital organs, such as those in the nervous, cardiovascular, and reproductive and developmental systems (Del Brutto and Del Brutto, 2012; Gwaltney-Brant, 2017; Spyres et al., 2018).

Snake Toxins

More than 5 million people are bitten by snakes every year, resulting in more than 2 million cases of envenoming and 20,000—125,000 deaths (Kasturiratne et al., 2008). Venomous snakes are found in the families of *Colubridae*, *Crotalidae*, *Elapidae*, *Hydrophidae*, *Laticaudidae*, and *Viperidae* (Gwaltney-Brant, 2017; Gwaltney-Brant et al., 2018). Snake venoms are known to contain a complex mixture of neurotoxins, myotoxins, and coagulant toxins affecting the coagulation cascade and neuromuscular transmission, as well as causing neurological complications.

Metalloproteinases, serine proteases, and C-type lentins (common in viper and colubrid venoms) have anticoagulant or procoagulant activity and may be either agonists or antagonists of platelet aggregation. As a result, ischemic or hemorrhagic strokes may occur. In contrast, the venom of elapids is rich in phospholipase A2 and three-finger proteins, which are potent neurotoxins affecting neuromuscular transmission at either presynaptic or postsynaptic levels. Presynaptic-acting neurotoxins (β-neurotoxins) inhibit the release of ACh from the presynaptic terminals. Examples of β-neurotoxins are taipoxin, paradoxin, trimucrotoxin, viperotoxin, textilotoxin, and crotoxin. On the other hand, postsynaptic-acting neurotoxins (α-neurotoxins) are three-finger protein complexes, and these cause a reversible blockage of ACh receptors by exerting a curare-like mechanism of action (Del Brutto and Del Brutto, 2012). The best-characterized α-neurotoxins are irditoxins. These neurotoxins do not cross the blood—brain barrier (BBB), but they cause muscle paralysis by affecting neuromuscular transmission at either presynaptic or postsynaptic levels (Lewis and Gutmann, 2004). Some snake venoms contain both α- and β-neurotoxins and produce a complex blockage of neuromuscular transmission.

Mamba snake venom contains a mixture of neurotoxic compounds, including postsynaptic cholinoreceptor α neurotoxins, dendrotoxins, fasciculins, and muscarinic toxins (Anadon et al., 2015). Effects at the NMJ include AChE inhibition by fasciculins (named as they produced long-lasting fasciculations in lab animals) and increased presynaptic release of ACh by dendrotoxins (polypeptides that facilitate ACh release in response to nerve stimulation). In addition, mamba venom is very rich in ACh (6—24 mg/g), which facilitates neuromuscular transmission.

Fasciculins belong to the structural family of three-fingered toxins closely related by ∼6,750 Da peptides. Fasciculins (Fasciculin 1—4) are proteinic AChE inhibitors as they bind to a peripheral regulatory anionic site of AChE in a noncompetitive and irreversible manner in mammals, especially at NMJ. Administration of fasciculin 1 and fasciculin 2 to mice at doses of 1—3 mg/kg and 0.05—2 mg/kg, ip, respectively, caused severe, generalized, and long-lasting fasciculations (5—7 h), followed by a gradual recovery to normal behavior. In vitro preincubation with fasciculins at concentrations of 0.01 μg/mL inhibited brain and muscle AChE up to 80%. Histochemical assay of AChE showed an almost complete disappearance of the black-brown precipitate at the neuromuscular endplate after in vitro incubation with fasciculins. The dendrotoxins exert toxicity by inhibiting voltage-dependent K^+ channels in motor nerve terminals, and they facilitate ACh release at the NMJ. Postsynaptic toxins present in mamba venom bind to and block nAChRs. The muscarinic toxins present in mamba venom are small (7 kDa) proteins that selectively bind to mAChRs. Recently, about 12 muscarinic toxins have been isolated and they differ in affinity for muscarinic receptor subtypes.

Snakebite envenoming has been characterized by complex pathological and pathophysiological profiles that include prominent local tissue damage, i.e., necrosis, hemorrhage, blistering and edema, and systemic alterations, such as bleeding, coagulopathy, cardiovascular shock, and renal failure (Gutiérrez et al., 2009a; b; Hernandez et al., 2011; Ranawaka et al., 2013; Da Silva et al., 2018; Teixera et al., 2018). Local tissue damage leading to necrosis of the skin and subcutaneous tissue is particularly relevant because it is frequently followed by poor tissue regeneration, with the occurrence of permanent sequelae associated with tissue loss and dysfunction. Local tissue damage in snakebite envenoming is due to the action of myotoxic phospholipase A_2 (PLA_{2s}), hemorrhagic snake venom metalloproteinases (SVMPs), and possible involvement of other components, such as hyaluronidases and nonhemorrhagic SVMPs (Gutiérrez et al., 2009a; Gutiérrez and Rucavado, 2000; Gutiérrez and Ownby, 2003; Teixera et al., 2018). The SVMPs are large multidomain proteins, which are classified as P-I, P-II, and P-III based on the presence or absence of additional nonproteinase domains (Fox and Serrano, 2005). The SVMPs are also classified as adamalysins that, alongside the matrixins, astacins and serralysins, make up the large metzincin gene superfamily (Casewell, 2012).

Cytotoxic enzymes (PLA_{2s} and metalloproteinases) activate proinflammatory mechanisms that cause edema, blister formation, and local tissue necrosis, which are a common occurrence at the site of a venomous snakebite. These enzymes also favor the release of bradykinin, prostaglandin, cytokines, and sympathomimetic amines, which are responsible for the pain experienced by the victims (Teixeira et al., 2009, 2018). Intense local pain, paresthesia, and local necrotic symptoms are more severe after viper, coral, and colubrid bites (Teixeira et al., 2009, 2018; Da Silva et al., 2018).

Chu et al. (2010) described venom ophthalmia as a syndrome characterized by ocular pain, hyperemia, blepharitis, and corneal erosions, which may occur when the venom of spitting cobras enters the eye of the victim. The myotoxins and neurotoxins can cause muscle weakness and paralysis by blocking the synaptic transmission at either presynaptic or postsynaptic levels (Lewis and Gutmann, 2004; Ranawaka et al., 2013). The first detectable signs of paralysis are palpebral ptosis and external ophthalmoplegia because ocular muscles are more susceptible to this neuromuscular blockage (Sanmuganathan, 1998). In the next few hours, facial and neck muscles become affected, followed by respiratory and limb muscles (Del Brutto and Del Brutto, 2012). The most common electromyographic (EMG) findings in these patients include prolongation of motor distal latencies and reduction in the amplitude of compound muscle action potentials (Singh et al., 1999). Lewis and Gutmann (2004) reported that generalized myokymia may occur after the bite of some rattlesnake species. The syndrome of continuous and spontaneous muscular activity resembling fasciculations and EMG finding of repetitive firing of motor union potentials was possibly due to a particular neurotoxin acting on voltage-gated K^+ channels, thus increasing nerve excitability.

Snake venom also negatively impact skeletal muscle regeneration. Skeletal muscle regeneration is a complex process, which involves the interaction of myogenic cells, resident cells, inflammatory cells, blood vessels, nerves, and extracellular matrix (Cicillot and Schiaffino, 2010). Injury to muscle fibers by snake venom leads to the activation of a population of quiescent myogenic cells, satellite cells located at the periphery of the fibers between muscle sarcolemma and the basement membrane (Cicillot and Schiaffino, 2010; Hernandez et al., 2011).

These authors and others have described two different patterns of muscle regeneration after snakebite-induced myonecrosis. When tissue is affected by venoms of toxins that cause muscle necrosis but do not affect the integrity of blood vessels, such as after injection of isolated myotoxic phospholipase A_2, regeneration proceeds successfully (Harris, 2003). When venoms affect both muscle fibers and the microvasculature, including hemorrhage, the regenerative process is impaired, with substitution of muscle tissue by fibrosis in some areas, and with the presence of regenerating fibers of reduced diameter (Gutiérrez et al., 1984; Salvini et al., 2001).

In an experimental study conducted in mice (CD1), Hernandez et al. (2011) showed that skeletal muscle regeneration is partially deficient after acute tissue damage induced by the injection of *Bothrops asper* venom by a hemorrhagic SVMP. A successful regenerative response occurs after myonecrosis induced by a myotoxin, which affects muscle fibers, but not the microvasculature nor the basement membranes of muscle fibers and nerves. Injection of the venom, at a dose that induces prominent hemorrhage, resulted in a drastic and rapid drop in the number of capillary vessels in gastrocnemius muscle, as evaluated by both the capillary/muscle fiber ratio and the number of capillaries per tissue area. These results supported the hypothesis that SVMP-induced basement membrane damage, in microvessels, muscle fibers, and nerves, is the main culprit for the poor regenerative outcome in the mouse muscle model. Fibrosis substitutes muscle tissue in some areas, and the diameter of regenerating fibers is abnormally small. Myotoxin, SVMP BaP1, and venom affected the integrity of axons in intramuscular nerves. In addition to poor muscle and microvascular regeneration, axonal regeneration is impaired. These experimental observations provided mechanistic insights and corroborated with clinical

findings of poor muscle, nerve, and vasculature-regenerative outcome.

Identification and quantification of snake venom toxins, EMG findings, and biochemical and histopathological findings can be used as biomarkers of muscle, cardiac, and renal injuries inflicted by snakebites (Teixeira et al., 2009, 2018; Hernandez et al., 2011; Casewell, 2012; Del Brutto and Del Brutto, 2012; Pycroft et al., 2012; Ranawaka et al., 2013).

Spider Venom

More than 42,700 extant species of spiders have been described, and an even greater number remain to be characterized (Klint et al., 2012). Spider venoms are complex chemical cocktails, but the major components are small, disulfide-rich peptides (Kumar et al., 2011; Peng et al., 2014; Gwaltney-Brant et al., 2018). Because single venom can contain as many as 1000 peptides, over 10 million bioactive peptides are likely to be present in the venoms of spiders (Escoubas et al., 2006). The spider-venom peptides that have been described to date are detailed in ArachnoServer, a manually created database that provides information about proteinaceous toxins from spiders (Herzig et al., 2011).

Arachnids (spiders and scorpions), such as the brown recluse, the redbacked spider, and the mouse spider, often exert more neurotoxic effects on their victims; aches and acute rhabdomyolysis along with some necrotic lesions have been described in some cases (Gala and Katelaris, 1992). Rader et al. (2012) described positive and negative examination features for brown recluse envenomation and noted that spider bites predominantly occurred during April–October.

Spider-venom peptides produce toxicity by targeting Na_v channels. The term NaScTx is employed for scorpion toxins and NaSpTx is for spider venoms, and these toxins target Na_v channels (Rodriguez de la Vega and Passani, 2005; Klint et al., 2012; Peng et al., 2014). Kumar et al. (2011) described the structure of BTK-2 toxin, which is a novel $hK_v1.1$ inhibiting scorpion toxin. There are 12 different families of spider-venom peptides that target Na_v channels. Scorpion α and β toxins interact with voltage-gated Na channels (Na_vs) at two pharmacologically distinct sites (Gurevitz, 2012). α Toxins bind at receptor site-3 and inhibit channel inactivation, whereas β toxins bind at receptor site-4 and shift the voltage-dependent activation toward more hyperpolarizing potentials. The two toxin classes are subdivided into distinct pharmacological groups according to their binding preferences and ability to compete for receptor sites at Na_v subtypes.

Black widow spiders are known to contain α latrotoxin. The toxin induces a pore in the myocytes membrane that is permeable to Na^+ and K^+, leading to membrane depolarization. Initial effects are muscle spasms, followed by depletion of ACh, and death occurs because of respiratory failure. In an electrophysiological study, Peng et al. (2014) found that black widow spiderling extract (10 μg/mL) could completely block the neuromuscular transmission in isolated mouse nerve-hemidiaphragm preparations within 21 ± 1.5 min, and 100 μg/mL extract could inhibit a certain percentage of voltage-activated Na^+, K^+, and Ca^{2+} channel currents in rat dorsal ganglion neurons. Recently, O'Connor et al. (2018) described clinical manifestations, such as pain, paresthesia, rhabdomyolysis, and cardiac abnormalities in humans after envenomation with bark scorpion (*Centruroides sculpturatus*). In an experimental study, Heidarpour et al. (2012) demonstrated that scorpion venom when injected in mice (5 mg/kg, sc) caused histopathological alterations in the heart and kidney.

BOTULINUM TOXIN

Botulinum neurotoxins (BoNTs) are produced primarily by *Clostridium botulinum* under anaerobic conditions; however, other *Clostridial* species, such as *Clostridium barati*, *Clostridium butyricum*, and *Clostridium argentinense* are also capable of producing neurotoxins. There are seven immunologically distinct serotypes of BoNT, and they are designated alphabetically, A to G (Simpson, 1981). Serotypes A, B, C1, and D have been associated with outbreaks of botulism in domestic animals, livestock, poultry, and wildlife, whereas serotypes A, B, E, and rarely F are known to cause diseases in humans (Cope, 2018). The active neurotoxin has a molecular mass of 150 kDa and exists as a polypeptide di-chain molecule. The di-chain consists of a heavy chain (HC) linked by a single disulfide bond to a light chain (LC). The 100-kDa HC is responsible for membrane targeting and cellular uptake, whereas the 50-kDa light chain mediates its intracellular action. The neurotoxin molecule can be further divided both structurally and functionally into three domains. The HC contains both a binding domain and a translocation domain, whereas the smaller LC contains a catalytically active domain. The LC of each toxin functions as a zinc-dependent endoprotease, cleaving at least one of three soluble N-ethylmaleimide–sensitive fusion (NSF) protein attachment receptor (SNARE) proteins involved in neurotransmitter release.

BoNTs selectively target peripheral cholinergic terminals because these toxins are too large to cross the BBB. Cope (2018) described that the mechanism of action of BoNT is a multistep process, which interrupts normal vesicular release of ACh from the presynaptic motor nerve terminals. The primary target site is the NMJ, where BoNTs act as potent inhibitors of synaptic

transmission in skeletal muscles. In the first stage, the toxins must bind, via their HCs, to protein receptors (and gangliosides) located on the plasma membrane of the motor nerve terminal. The second stage involves receptor-mediated uptake of the toxin into endosomes (e.g., endocytosis). The third stage occurs within the endosome, where the disulfide linkage between the toxin heavy and light chains is reduced, and a subsequent drop in endosomal pH promotes a conformational change in the toxin molecule. Following the translocation to the cytosol, the toxin light chain is free to act on the intracellular target. During the final stage, the neurotoxins enzymatically cleave one of the three specific proteins found within the presynaptic terminal. These three proteins, SNAP-25, synaptobrevin, and syntaxin, known collectively as SNARE (soluble *N*-ethylmaleimide sensitive factor attachment protein receptor) proteins, are necessary for neurotransmitter release. Proteolysis of any of the SNARE proteins by BoNT either destabilizes or prevents the formation of functional SNARE complexes, inhibiting vesicular fusion and neurotransmitter release.

The catalytic active sites of the different BoNT serotypes vary slightly, giving each serotype both substrate and cleavage site specificity. Toxin serotypes A, C, and F cleave SNAP-25; serotypes B, D, F, and G cleave synaptobrevin; and serotype C cleaves syntaxin. BoNT prevents docking of synaptic vesicles with presynaptic plasma membrane by selective proteolysis of synaptic proteins. Neurotoxin-mediated cleavage of any of these substrates disrupts the processes involved in the exocytotic release of ACh and leads to descending flaccid paralysis of the affected skeletal muscles, starting usually in the bulbar musculature to involve deficits in sight, speech, and swallowing. Paralysis eventually progresses beyond cranial nerve palsies to include generalized muscle weakness and loss of critical accessory muscles of respiration. If untreated, death is inevitable from airway obstruction secondary to paralysis of pharyngeal, diaphragm, and accessory respiratory muscles, as well as loss of the protective gag reflex.

Exposure to BoNTs can produce lethal diseases in humans and animals (Anderson and Hilmas, 2015; Pirazzini et al., 2017; Cope, 2018). BoNT is the most potent biological toxin ever encountered, with lethal doses as low as 0.03 ng/kg body wt depending on both toxin type and animal species. In humans, six different forms of botulism have been described. These include: (1) foodborne botulism, (2) infant botulism, (3) wound botulism, (4) an adult form of infant botulism, (5) inadvertent systemic botulism, and (6) inhalation botulism. Clinically, botulism is recognized as a lower motor neuron disease resulting in progressive flaccid paralysis. Although deficits in somatic neuromuscular transmission are the most prominent effects, motor deficits in cranial nerve function, as well as the autonomic nervous system, have also been described. In animals, paresis begins in the hind limbs and progresses cranially, often resulting in quadriplegia and recumbency. In both humans and animals, death may result from respiratory muscle paralysis.

The onset of symptoms in botulism depends on the amount of toxin ingested or inhaled and the related kinetics of absorption (Anderson and Hilmas, 2015; Cope, 2018). Time to onset of clinical signs can range from as soon as 2 h to as long as 8 days, although symptoms typically appear between 12 and 72 h after consumption of toxin-contaminated food. It is important to mention that regardless of the exposure route, once BoNTs reach the circulation or lymphatic system, they lead to inhibition of the release of ACh from peripheral cholinergic nerve terminals, resulting in flaccid muscle paralysis. Of course, the specific paralytic profiles associated with each of the BoNTs are typically attributed to their unique proteolytic activities within the nerve terminal. These activities are known to be mediated by the LC components of the various neurotoxins. It is noteworthy that the muscle paralytic profile may vary for different serotypes and between animal species.

The mouse bioassay model is considered the gold standard for diagnosing botulism. The mouse LD_{50} still quantitates the purity of BoNT batches and is the basis of the international standard used in serum neutralization assay of BoNT antitoxin. The mouse phrenic nerve-hemidiaphragm assay has been used to measure the effect of BoNT on skeletal muscle contraction, and the doses necessary for inhibition are well characterized. Characteristic muscle paralysis is of some value in the diagnosis of botulism. Enzyme-linked immunosorbent assay (ELISA) is widely used to identify BoNTs. Recently, LC-MS has been used for identification, confirmation, and quantification of BoNTs. Identification and confirmation of BoNTs are the best biomarkers of botulism. For details on the pharmacology, toxicology, and biomarkers of BoNT, readers are referred to Anderson and Hilmas (2015), Pirazzini et al. (2017), and Cope (2018).

MYOTOXIC PLANTS

Muscle toxicity by poisonous plants is more common in domestic animals because of their food habits. Some plant toxins directly affect the muscular system, whereas others primarily affect organs such as the liver and nervous system, with secondary effects noted in the muscles. Plant toxins are known to exert a variety of toxic effects, including muscle weakness, lameness, myodegeneration, myopathy, etc. A list of plants and

their toxins that are known to exert myotoxicity is provided in Table 20.4. Some of these plant toxins can cause minor pain or muscle weakness, whereas others can cause paralysis. In general, identification of a plant-specific toxin, elevated serum CK activity, and myoglobinuria are commonly used as biomarkers of muscle toxicity. In addition, microscopic changes in skeletal muscles are characteristic findings.

Plant-induced muscle toxicity and its biomarkers are discussed in detail in Chapter-37 of this book.

TABLE 20.4 Muscle Toxicity Caused by Plant Toxins

Plant	Toxin	Toxic Effects
Tansy Ragwort (*Senecio jacobea*)	Not identified	Muscle weakness and lameness
Day-Blooming Jessamine (*Cestrum diurnum*)	Similar to 1,25-dihydroxy-cholecalciferol	Calcinosis and lameness in horses
Golden Chain Tree (*Laburnum anagyroides*)	Not identified	Myodegeneration
Scotch Broom (*Cytisus scoparius*)	Quinolizidine alkaloids (sparteine, isosparteine, cytisine)	Myodegeneration
Coyotillo (*Karwinskia humboldtiana*)	Not identified	Myodegeneration
Mountain Thermopsis (*Thermopsis montana*)	Quinolizidine alkaloids (thermopsine, cytisine, *N*-methylcytisine, anagyrine)	Myodegeneration and muscle tremors
Coffee Weed/Sickle Pod Senna (*Cassia* spp.)	Not identified	Myodegeneration
Black Walnut (*Juglans nigra*)	Juglone	Laminitis
Hoary Alyssum (*Berteroa incana*)	Not identified	Laminitis and limb edema
Flatweed/Cat's Ears (*Hypochaeris radicata*)	Not identified	Lameness
Lupines (*Lupinus* spp.)	Anagyrine and ammodendrine	Muscular weakness and fasciculations
Poison Hemlock (*Conium maculatum*)	γ-Coniceine	Muscle fasciculations
Water Hemlock (*Cicuta* spp.)	Cicutoxin	Muscular tremors and myodegeneration
White Snakeroot (*Eupatorium rogosum*)	Tremetol	Muscle tremors
Rayless Goldenrod (*Haplopappus heterophyllus*)	Tremetone	Muscle tremors

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The skeletal muscles account for nearly half of mammalian body weight, and they are the targets of toxicity for many drugs of use and abuse, pesticides and biotoxins. Muscles have different fiber type compositions and are enriched with binding and reactive sites, such as receptors, neurotropic factors, neurotransmitters, enzymes, drug transporter systems, etc. Currently, drug-induced myopathy is among the most common causes of muscle disease. Muscle toxicity can range from minor pain to something as severe as paralysis. For some chemicals, such as OP pesticides and nerve agents, the mechanism of muscle toxicity is well understood, whereas for other chemicals, drugs, and biotoxins, it is poorly understood. Chemicals can cause muscle cell death due to apoptosis, necrosis or autophagy. The presence of chemicals or their metabolites can be used as biomarkers of exposure, whereas histochemical and biochemical endpoints can be used as biomarkers of muscle toxicity. Recently, many new biomarkers of muscle toxicity have been added to the list of conventional biomarkers. Future studies will unravel novel mechanisms of action and biomarkers of toxicity, which will be more sensitive and organ specific.

INTRODUCTION

The human eye serves as the receptor of light, giving rise to the sense of seeing after the cortical processing of neuronal signals originating from ocular reception. To achieve reception of light and transform it into the signal that is sent to the cortex, a combination of fine-tuned and organized tissues is utilized, tissues that combine to form the structure of the human eye. Thus, ocular histology includes all three types of tissues—muscle, nerve, and epithelial—at a very high level of organization. Light enters the eye through the cornea, which is a transparent tissue responsible for 70% of the refractive power of the eye. The cornea is composed of epithelium externally, the corneal stroma (the basic part of its structure, consisting of organized collagen fibrils and proteoglycans), and the endothelium, which maintains the corneal humidity and transparency. The cornea is the front part of the bulbar wall and the rest of it comprises the sclera, a nontransparent collagen tissue. The cornea is covered by the tear film, which is composed of three layers: the lipid layer externally, the aqueous layer, and the mucus layer internally. Each is produced by different types of glands. Behind the cornea the anterior chamber is filled with aqueous humor, which preserves the intraocular pressure. It is produced by the ciliary body and removed mainly through the trabecular meshwork in the angle of the anterior chamber. The anterior chamber is separated from the posterior by the iris and the ciliary body. The pupil is the iris diaphragm that serves to regulate the quantity of light that passes through to the crystalline lens and then to the posterior segment of the eye, where light meets the retina. The crystalline lens is responsible for 30% of the refractive power of the eye in relaxed status and adds the needed power for accommodation of near vision in pre-presbyopic individuals. Behind the crystalline lens, the eye is filled with the vitreous body. In contact with the vitreous body is the retina (Fig. 21.1). The retina contains the photoreceptors that transform light to neural signal, which, after a complex path of intraretinal transformations, travels to the visual cortex through the optic nerve and the rest of the optic pathway. This chapter describes the biomarkers of ocular diseases and toxicities.

OCULAR BIOMARKERS

A large number of diseases with an acute or chronic course and variable involvement of different ocular tissues may be present in ocular pathology. Symptoms of ocular disease vary from subjects' discomfort to deterioration of ocular refractive function or permanent visual loss due to damage in the retinal-neuronal pathway.

Recently, several new methods for the identification and quantification of molecules in biological tissues have brought about the potential to identify molecular entities that may serve as potentially useful biomarkers in ophthalmology. Biomarkers may be helpful in (1) early detection of a disease, (2) may aid in predicting severity of disease, (3) may predict the rate of disease
FIGURE 21.1   Overview of ocular anatomy.

progression, and (4) may serve as predictors of response to treatment.

Use of these molecular markers in the clinical setting appears to be a promising option. However, there are still many limitations, such as lack of common procedures for proper banking of biological tissues, as well as standardized methods and criteria in different studies. New studies are continually identifying biomarkers and seeking to standardize their values in health and disease.

In this chapter, we focus on molecular biomarkers that are involved in the diagnosis and management of several ocular pathologies and in ocular toxicity derived from agents prescribed for other systemic conditions.

Molecular Biomarkers in Ocular Surface Disease

Dry eye disease (DED) is an inflammatory disorder of the lacrimal functional unit of multifactorial origin leading to chronic ocular surface discomfort. Dry eye is a disease of the ocular surface characterized by a loss of homeostasis of the tear film that is accompanied by ocular symptoms, in which tear film instability and hyperosmolarity, ocular surface inflammation and damage, and neurosensory abnormalities play etiological roles (Craig et al., 2017). It is a significant burden for ophthalmic health care because of both its high prevalence and its capacity to affect a patients' quality of life. Because of its different origins and the variability of a patients' subjective response to clinically observed disease parameters, it is not easy to determine objective parameters for the evaluation of DED.

The pathophysiology of DED includes two distinct pathways, each with several possible initial causes that result in the same disease entity. One of the two is the aqueous deficient dry eye, where the production of tear is less than needed. The other is evaporative dry eye, where there is an increased evaporation of tears. In both conditions, there is increased osmolarity of the tear film and increased inflammation of the ocular surface, as well as patient discomfort. Proteomic analysis of the tear film of such patients has helped to identify molecular parameters that may serve as biomarkers for disease severity or predisposition to the disease.

Immune processes have been demonstrated to play a key role in dry eye. Cytokines, growth factors, and their receptors have been extensively studied in tears, corneal tissue, and conjunctival tissue. TNF-a, IL-1, and IL-6 are found to be increased in dry eye samples and are also correlated with clinical parameters. Boehm et al. (2011) have published a cytokine profile of dry eye patients' tears. They found increased tear levels of IL-1b, IL-6, IL-8, TNF-a, and IFN-g and increased expression of lipocalin, cystatin SN, and a-1 antitrypsin in dry eye patients. They also found correlations with the clinical parameters of DED. In this study, the findings were not significant in patients with evaporative dry eye, in contrast to other reports that found increased levels in such patients (Enriquez-de-Salamanca et al., 2010). These differences may be attributed to differences in methods of material collection and variations in the classification of patients and controls between studies. In a study by VanDerMeid et al. (2012), the tear levels of IL-1a, IL-1b, IL-6, IL-8, and TNF-a correlated inversely with Schirmer values; IL-1a, IL-6, and TNF-a also correlated directly with tear osmolarity. VanDerMeid et al. (2012) studied the correlations of dry eye clinical parameters (Schirmer's test, tear break up time (TBUT), tear osmolarity, and ocular surface disease index) with tear

MMP-9, MMP-1, MMP-2, MMP-7, and MMP-10 levels in a healthy volunteer group and found positive correlations of MMP levels with increasing disease severity according to each parameter. Chotikavanich et al. (2009) showed that tear MMP-9 activity was significantly higher in dry eye patients and proposed MMP-9 as a useful biomarker for dry eye. In addition, tear MMP-9 activity correlated strongly with clinical parameters, such as symptom severity score, topographic surface regularity index scores, and corneal and conjunctival fluorescein staining scores. Diurnal variation of these molecules and age should always be taken into account if these parameters are to be considered as biomarkers. Other associations with specific biomarkers have been established in recent studies of tear proteome in aqueous deficient versus evaporative dry eye patients. Such proteins include proline-rich protein 4 (which seems to be downregulated), mammaglobin B, lipophilin A, and calgranulin S100A8 that were found to be increased in these patients (Boehm et al., 2013; Perumal et al., 2016). Additionally, an association of dry eye with plasma levels of androgens has been established (Vehof et al., 2017).

Another agent that has been studied in dry eye patients is ocular mucin (MUC) levels. Recently, Corrales et al. (2011) presented differences in MUC-1, MUC-2, MUC-4, MUC-5ACn, and MUC-16 conjunctival levels in dry eye patients compared with controls. The lipid profile of dry eye patients is of high importance because of the role of the lipid layer in tear film stabilization and protection from evaporation. Changes in structure of lipids have been identified in Meibomian glands and tear film of patients with evaporative dry eye (Lam et al., 2011, 2014).

Another category of potential biomarkers for ocular surface disease is neuromediators associated with the functionality of ocular surface innervation. Corneal and ocular surface innervation is a part of the lacrimal functional unit, and this function is impaired in dry eye, as shown by studies of corneal sensitivity. Tear levels of some neuromediators have been proposed as potential useful markers of dry eye severity. Substance P, calcitonin gene-related peptide, neuropeptide Y, vasoactive intestinal peptide, and nerve growth factor tear levels have been correlated with clinical parameters of dry eye (Lambiase et al., 2011).

Molecular Biomarkers in Keratoconus

Keratoconus is a noninflammatory disorder that leads to corneal thinning, protrusion, and irregular astigmatism (corneal ectasia) (Fig. 21.2). In its end stages, corneal scarring occurs and vision is significantly impaired. It affects young individuals, mainly during puberty, and progression occurs until 30—40 years of age. Currently,
FIGURE 21.2 Slit lamp image of a patient with keratoconus.

diagnosis of the disease is done clinically with specific imaging examinations. Timely diagnosis is very important because of the possibility for stabilization treatment before the disease becomes visually impairing. In addition, diagnosis of subclinical cases or those predisposed to the disease is also very important because these patients are not suitable for refractive surgery and may develop corneal ectasia after being treated with laser surgery for their refractive error.

Although it is considered a noninflammatory disorder, a chronic low-grade inflammation may play a role in the pathophysiology of keratoconus. Recent studies indicate that certain inflammatory molecules are elevated in tears from patients with keratoconus. Lema and Duran (2005) found that levels of IL-6, TNF-a, and MMP-9 are higher in keratoconus in comparison to controls. In addition, in patients with unilateral keratoconus (clinically evident keratoconus in one eye and subclinical in the fellow eye), IL-6 and TNF-a were increased in the tears of both keratoconus eyes and fellow eyes (Lema et al., 2009). Pannebaker et al. (2010) showed that the level of MMP-1 was increased in keratoconus. Other molecules found to be expressed differently in keratoconus corneas are keratins and mammaglobin B (Pannebaker et al., 2010), zinc-a2-glycoprotein, lactoferrin and immunoglobulin kappa chain (Lema et al., 2009), and α-enolase and β-actin (Srivastava et al., 2006). A recent study of tear film of patients with keratoconus suggested gross cystic disease fluid protein-15 or prolactin-inducible protein as a biomarker for keratoconus (Priyadarsini et al., 2014).

Molecular Biomarkers in Glaucoma

Glaucoma is a vision-threatening disease affecting a large percent of the population worldwide. Glaucoma

progression leads to loss of peripheral vision (visual field) and eventually blindness. One in 40 adults over the age of 40 has glaucoma with loss of visual function, which equates to 60 million people worldwide being affected and 8.4 million being bilaterally blind. Increased intraocular pressure is the main cause of glaucoma, and this is caused mainly by obstruction in the outflow of aqueous humor. Timely diagnosis and initiation of intraocular pressure (IOP)-lowering medication is of great importance for prevention of visual loss. Follow-up of glaucoma patients is done mainly by IOP monitoring, visual fields sensitivity testing, and imaging of the optic nerve. The use of molecular biomarkers for the early diagnosis and the follow-up of patients with glaucoma is a field of great scientific interest and research. Biomarkers are identified in blood or ocular fluids such as aqueous humor and tears and show up- or downregulation in patients with glaucoma. The development of clinically useful biomarkers in glaucoma is currently an area of active investigation. Identification of such biomarkers offers insight into disease progression mechanisms. Weinstein et al. (1996) showed an association of decreased peripheral blood lymphocyte 3α-hydroxysteroid dehydrogenase (3α-HSD) activity with glaucoma. The authors concluded that the reduced levels of 3α-HSD activity in the peripheral blood lymphocytes may serve as a marker for primary open angle glaucoma (POAG) or those at risk of developing the disease.

Maruyama et al. (2002) suggested that a serum autoantibody against neuron-specific enolase (NSE) may be clinically useful for diagnosing early stages of glaucoma and monitoring glaucoma progression of normal tension glaucoma (NTG). According to the authors, the anti-NSE antibody titers were relatively higher in patients with visual field deterioration than in those without it.

Another molecule that may serve as a biomarker for early detection of glaucoma is the brain-derived neurotrophic factor (BDNF), which contributes to the building up and preserving of neurons. BDNF has been found significantly decreased in the tears of normal-tension glaucoma patients and open-angle glaucoma patients in comparison to controls (Ghaffariyeh et al., 2011).

Other studies suggest that CD44 content in ocular tissue may represent a biomarker for glaucoma (Mokbel et al., 2010). CD44 is a transmembrane protein and the principal receptor of the glycosaminoglycan, hyaluronan. In the same study, erythropoietin was also recognized as a biomarker for glaucoma.

Recent studies have revealed that the levels of homocysteine and hydroxyproline are significantly higher in the aqueous humor of patients with glaucoma than in controls (Ghanem et al., 2012).

Proteomic studies of aqueous humor and serum of glaucoma patients have found association of proteins related to inflammation and oxidative stress (Izzotti et al., 2010; Kaeslin et al., 2016; Gonzalez-Iglesias et al., 2014).

Currently, research is demonstrating several molecular biomarkers that are identified as possible indicators for the severity of glaucoma, the monitoring of the response to treatment, and also the identification of patients at high risk to develop glaucoma. Future research may provide valuable tools for clinical use in the treatment of glaucoma.

Molecular Biomarkers in Retinal Disease

Retinal pathology is one of the most intriguing parts of ophthalmology. Fundus disease may lead to irreversible visual impairment in several cases, and early diagnosis may help in the prevention or the protection of patients from disease progression. Diagnosis of retinal disorders is mainly from a clinical fundoscopic examination and specialized imaging examinations such as optical coherence tomography, fluorescent angiography, and indocyanine angiography. The most common disorders are age-related macular degeneration (ARMD) and diabetic retinopathy, which are included in the leading causes of blindness in the developed world.

Molecular Biomarkers in Age-Related Macular Degeneration

Currently research is targeted on identifying molecular agents that may contribute to the pathogenesis or the progression of ARMD. A recent study by Kim et al. (2012) discovered that in the aqueous humor of patients with ARMD, the protein composition was different from that in controls.

Recently, elevated levels of CXCL10 were reported in the sera and choroid of individuals with ARMD, and elevated intraocular CCL2 levels were observed in neovascular ARMD (Mo et al., 2010; Jonas et al., 2010). Newman et al. (2012) showed that all ARMD phenotypes in the retinal pigment epithelium (RPE)–choroid are associated with elevated expression of all, or a subset of, the following chemokines: CXCL1, CXCL2, CXCL9, CXCL10, CXCL11, CCL2, and CCL8. In addition, the upregulation of immunoglobulin genes supports an adaptive, autoimmune response in ARMD that is consistent with previous reports of immunoglobulins in drusen and drusen-associated RPE, as well as anticarboxyethylpyrrole adduct antibodies and antiretinal antigen autoantibodies in ARMD sera. Additionally,

upregulation of immune response, complement system, and protease activity has been found in vitreous humor of ARMD patients, and upregulation of inflammation and apoptosis in aqueous humor (Koss et al., 2014; Yao et al., 2013).

Molecular Biomarkers in Ocular Oncology

There are several studies that attempt to connect specific biomarkers with ocular cancers. Retinoblastoma (RB) is a malignant tumor of the retina that affects children. In the study of Beta et al. (2013), miRNAs in the serum of children with RB were compared with those in normal age-matched serum. Expression of the oncogenic miRNAs, miR-17, miR-18a, and miR-20a by qRT-PCR was significant in the serum of the RB samples exploring the potential of serum miRNAs identification as noninvasive diagnosis. Researchers concluded that the identified miRNAs and their corresponding target genes could give insights into potential biomarkers and key events involved in the RB pathway.

Uveal and conjunctival melanomas (Fig. 21.3) have also been related to potential biomarkers. The Collaborative Ocular Oncology group (Onken et al., 2012) evaluated 459 patients for the prognostic performance of a 15-gene expression profiling (GEP) assay that assigns primary posterior uveal melanomas to prognostic subgroups: class 1 (low metastatic risk) and class 2 (high metastatic risk). They assumed that the GEP assay had a high technical success rate providing a highly significant improvement in prognostic accuracy over clinical TNM classification. Zoroquiain et al. (2012) analyzed the expression of p16ink4a (p16) in conjunctival melanocytic lesions in an immunohistochemical study and concluded that it appears to be a good marker to differentiate nevi and primary acquired melanoses (PAMs) from melanomas. Errington et al. (2012) found

FIGURE 21.3   Slit lamp image of a patient with uveal melanoma.

that uveal and conjunctival melanomas consistently expressed high levels of gp100, Melan-A/MART1, and tyrosinase, which are differentiation antigens. The relation of a stem cell marker, CD133, with uveal melanoma was explored by Thill et al. (2011). Differential expression of CD133 splice variants was found in the iris, ciliary body, retina, and retinal pigment epithelium/choroid as well as in the uveal melanoma cell lines.

Noninvasive biomarkers may potentially be used for the early diagnosis of ocular tumors and follow-up treatment. More experimental studies should be carried out to isolate more biomarkers, to evaluate their functional properties, and to explore possible therapeutic approaches.

SYSTEMIC AGENTS AND OCULAR TOXICITY

Many antidepressants, antipsychotics, anti-Parkinson drugs, antihistamines, anticonvulsants, decongestants, and beta-blockers, along with hormone replacement therapy, have been shown to cause dry eye symptoms as an adverse toxic effect. Herbal products with the same effect include niacin, kava, echinacea, and anticholinergic alkaloids (Askeroglu et al., 2013). Moreover, corneal toxicity can be caused in a number of individuals by fluoroquinolones, nonsteroidal antiinflammatory eye drops, glaucoma eye drops, preservatives in eye drops, aminoglycosides, chemotherapeutic medications, topical anesthetics, cyclooxygenase-2 inhibitors, bisphosphonates, retinoids, topical steroids, topical iodine, and some herbal medications such as black mustard, chamomile, cypress spurge, goa powder, and psyllium and also by the milky latex of the plant *Asclepias tuberosa* (Fraunfelder, 2006; Mikkelsen et al., 2017). Aminoglycosides, in particular, have been shown to cause vision loss, optic atrophy, glaucoma, and pigmentary degeneration (Hancock et al., 2005). Dexamethasone, fluocinolone, and triamcinolone are well-known corticosteroids that are very toxic to the retina at high doses and can even cause cataract and glaucoma (Penha et al., 2010). Retinal toxicity may also be caused by intravitreal use of the antibiotic amikacin (Widmer and Helbig, 2006) and intracameral injection of cefuroxime (Çiftçi et al., 2014).

Hydroxychloroquine and chloroquine have been used as antimalarial agents and for the treatment of dermatological and rheumatological diseases. The administration of these drugs can lead to a wide range of toxic ocular effects such as retinal damage, pigmentary retinopathy, keratopathy, corneal deposits, cataract, photophobia, ocular muscle imbalance, and loss of peripheral and night visions (Tzekov, 2005; Tehrani et al., 2008; Tailor et al., 2012; Telek et al., 2017). Ocular quinine toxicity should also be taken into serious
consideration when treating vulnerable patient groups such as sleepwalkers, the elderly, and alcohol, and other drug abusers because of accidental overdose leading to loss of vision (Sinha and Al Husainy, 2013).

Since the 1960s, ethambutol hydrochloride has been known to cause dose- and duration-dependent ocular toxicity and, in particular, optic neuritis. The drug is used for the treatment of tuberculosis and its most common ocular adverse effect is retrobulbar neuritis (Chan and Kwok, 2006).

Low-dose fludarabine has been reported to cause hallucinations, visual changes, blurred vision, and even blindness. On the other hand, the ocular effects of high-dose fludarabine include hallucinations, blurred vision, amaurosis, bilateral papillitis, and, in some cases, cortical blindness (Ding et al., 2008).

Oral and inhaled steroids can cause cataract or glaucoma after chronic use or in individuals with high susceptibility. Oral antihistamine drugs used for the treatment of allergies can cause tear film dysfunction (dry eye syndrome) or conjunctival hyperreactivity (Bielory, 2006).

Antineoplastic agents used in chemotherapies have been proven to cause tear film changes and mucositis involving the conjunctival mucosa (Chaves et al., 2007). Cisplatin, tamoxifen, and interferons, all being chemotherapeutic agents, can cause vision loss; and cisplatin can also cause retinal neovascularization as well as blurred vision, papilledema, and optic neuritis (Kwan et al., 2006; Omoti and Omoti, 2006; Gul Baykalir et al., 2017). Moreover, zoledronic acid used in prostate cancer treatment can cause bilateral retrobulbar optic neuropathy in rare situations (Lavado et al., 2017), whereas cancer patients who undergo whole-brain radiotherapy might develop dry eye syndrome (Nanda et al., 2017). Melanoma patients treated with trametinib and dabrafenib developed reduced vision due to serous neuroretinal detachment of the fovea and should therefore be closely monitored throughout their treatment (Sarny et al., 2017).

In high concentrations, ornithine can cause retinal toxicity when administered as a supplement in patients with gyrate atrophy of the retina and choroid (Hayasaka et al., 2011). Atropine, which is used as a mydriatic in eye clinics, may cause corneal cytotoxicity and blurred vision by promoting apoptosis and cell cycle arrest (Tian et al., 2015). Topiramate toxicity was observed in two women who received the drug for the treatment of recurrent headaches and migraines. Both women are presented with macular folds associated with angle-closure glaucoma. The symptoms disappeared after discontinuation of the drug (Kumar et al., 2006).

Both macular and retinal lesions may appear after intravitreal administration of mepivacaine and adrenaline, such as in the case of local anesthesia for palpebral repair surgery (López-Herrero et al., 2017).

Deferoxamine, a chelating agent of iron and aluminum ions, can cause ocular retinal toxicity by damaging the retinal pigment epithelium. Ophthalmologic monitoring may be required when treating hematological or kidney conditions with deferoxamine (Szwarcberg et al., 1997). More recently a case of pseudovitelliform maculopathy was reported in a patient on deferoxamine treatment for 5 years. The maculopathy worsened when deferasirox, an alternative chelating agent, was administered (Bui et al., 2017).

Eye drops have been known to cause ocular toxicity after chronic use, sometimes caused by the preservatives included in the formulation. Therefore, symptoms such as cell loss; structural changes in the conjunctival epithelium and the corneal endothelium; and epithelium, fibrosis, and chronic inflammation of the subconjunctiva; and dry eye syndrome may occur (Huber-van der Velden et al., 2012). For instance, in experiments carried out in rabbits it was shown that when benzalkonium chloride, the most common preservative used in ocular drugs, was applied topically, the whole cornea was impaired and at high doses the barrier integrity of the corneal endothelium was disrupted (Chen et al., 2011).

Indocyanine green, a dye used in medical diagnostics, can cause retinal toxicity in high doses via degeneration of retinal layers and Müller cell dysfunction (Sato et al., 2002).

DED has also been reported after ciguatera fish poisoning in a 47-year-old woman. The patient had consumed Spanish mackerel that contained the ciguatera toxin (Sheck and Wilson, 2010).

Lead poisoning can also cause retinal toxicity as shown in a 35-year-old woman who suffered from loss of vision in the right eye (Gilhotra et al., 2007). Another heavy metal, iron, may play a role in retinal and macular degenerations, glaucoma, and cataract (He et al., 2007). In vitro experiments carried out in retinal pigment epithelium cells have shown that cadmium can cause disruption of the membrane integrity, alter cell morphology, and decrease the survival of the cells and could therefore play a role in age-related retinal disease in smokers (Wills et al., 2008). Cobalt toxicity following hip implant has also been reported involving degenerative alterations of the photoreceptor—retinal pigment epithelium complex with coroidal infarction and paracentral scotomas (Ng et al., 2013).

The toxic effects of crack cocaine abuse include corneal disturbances. For instance, a crack cocaine abuse case has been reported in which the patient had stromal ulceration and corneal epithelial disruption (Pilon and Scheiffle, 2006).

Mustard gas can affect the eyes, especially in cases of chronic involvement. Symptoms include dry eye, limbal

stem cell deficiency, limbal ischemia, chronic blepharitis, aberrant conjunctival vessels, meibomian gland dysfunction, corneal neovascularization, corneal irregularity, thinning and scarring, and lipid and amyloid depositions (Baradaran-Rafii et al., 2011).

Ocular toxicity of hydrogen peroxide after habitual use as an eye wash was reported in a patient who was hospitalized for inflammation and scarring of the cornea and conjunctiva (Memarzadeh et al., 1993).

Organophosphate and organochloride compounds used widely as pesticides can cause ocular toxicity. Chronic exposure to those pesticides may lead to keratectasia and corneal neovascularization, which can result in blindness (Sanyal et al., 2017). Paraquat, a common herbicide, can cause ocular surface destruction via topical exposure (Vlahos et al., 1993).

Light or electromagnetic radiation can cause retinal damage although the eye has adaptive mechanisms to avoid possible damage (Youssef et al., 2011).

Methanol poisoning by ingestion has led to ocular damage in three patients. Retinal and cystoid macular edema was observed with paracentral scotomas, decreased retinal sensitivity, and enlargement of one blind spot as well as bilateral multifocal retinal pigment epithelial detachment (McKellar et al., 1992; Ranjan et al., 2014).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Several molecules that may be helpful in the diagnosis of ocular disease and also several systemic agents that may cause significant damage in the ocular tissue have been identified. Research in the field of biomarkers for ocular pathology is expanding, and it is possible that soon those molecules may serve as biomarkers for early diagnosis, treatment monitoring, and patient follow-up.

INTRODUCTION

Any chemical or drug with the potential to cause toxic damage to the structures of the inner ear, including the cochlea and vestibular system (responsible for sound detection and balance, respectively), is considered ototoxic. The main chemicals associated with ototoxicity include specific classes of drugs (e.g., antimicrobials and antineoplastic agents) and industrial chemicals (organic solvents and heavy metals). Although ototoxic chemicals can cause cochleotoxicity or vestibulotoxicity, some of them can cause both, and the resultant toxicity can be transient or irreversible, depending on the compound and the length of exposure. Cochleotoxicity is manifested by hearing loss, difficulty with speech understanding in the presence of background noise, and tinnitus (ringing in the ears). In turn, vestibulotoxicity may exhibit dizziness, dysequilibrium (loss of balance) or ataxic gait, and nystagmus (involuntary abnormal eye movements). The functional and molecular biomarkers used to assess ototoxicity along with the underlying toxic mechanisms are addressed in this chapter.

STRUCTURE AND FUNCTION OF THE NORMAL AUDITORY SYSTEM

Anatomic Structure of the Human Auditory System

The auditory system consists of three components: the outer, middle, and inner ear, all of which work together to transfer sounds from the environment to the brain (Table 22.1, Fig. 22.1). The **outer ear** includes the pinna and the ear (or auditory) canal. The pinna, also called auricle, is a concave cartilaginous structure, which collects and directs sound waves into the ear canal toward the tympanic membrane (also called eardrum), thus increasing the sound pressure. The **middle ear** is composed of the eardrum and a cavity that contains the ossicular chain. This cavity is actually an extension of the nasopharynx via the eustachian tube, which acts as an air pressure equalizer for an optimum transmission of sound and also ventilates the middle ear (Fig. 22.1). The eardrum vibrates back and forth in response to air pressure changes caused by sound waves. The eardrum motion travels across the middle ear cavity via the three middle ear bones (or ossicles) called malleus (hammer), incus (anvil), and stapes (stirrup). The ossicles chain act thus as a lever, converting the lower-pressure sound vibrations of the tympanic membrane into higher-pressure sound vibrations at the oval window, a small membrane in the wall of the cochlea. This higher pressure is necessary because the structure beyond the oval window (inner ear) contains liquid rather than air as occurred at the tympanic membrane (Ervin, 2017).

The **inner ear** is composed of the sensory organ for hearing (the cochlea), as well as for balance (the vestibular system). The hearing part of the inner ear is the cochlea, a snail-shaped structure, which in cross section has three fluid-filled compartments divided by two tight junction-coupled cellular barriers, the basilar membrane and Reissner's membrane (Fig. 22.2). The two outer compartments are the scala tympani and the scala vestibule, whereas the central compartment is called scala media or cochlear duct (Ervin, 2017; Jiang et al., 2017). The vestibular apparatus is composed of three semicircular canals and the utricle and saccule, whose function is to maintain balance, regardless of head position or gravity, in conjunction with eye movement and somatosensory input (Ervin, 2017). The vestibular sensory

epithelia, which control balance and spatial orientation, possess hair cells and supporting cells arrayed in the cristae of the semicircular canals and the maculae of the utricle and saccule (Brigande, 2017).

The organ of Corti, situated on the basilar membrane of the middle compartment, consists of sensory hair cells, which are the receptors for hearing, and adjacent supporting cells coupled together by apical tight junctions. There are two types of hair cells, the sensory inner hair cells (arranged in a single row) and outer hair cells (arranged in three rows) that amplify the sound-induced mechanical vibrations of the basilar membrane. Hair cells have cilia whose

ends make contact with the tectorial membrane. Each hair cell is connected to a nerve fiber (afferent for inner hair cells and efferent for outer hair cells) that relays various impulses to the cochlear branch of the auditory nerve (Zdebik et al., 2009). Supporting cells, particularly pillar and Deiters' cells, provide a structural scaffold to enable mechanical stimulation of sensory hair cells and also play a central role in the primary repair response of hair cell loss (Wan et al., 2013). The organ of Corti transforms mechanical waves to electric signals in neurons, which are further transmitted to the brain.

The scala media is filled with endolymph whose composition is maintained by the epithelial cells of the stria vascularis in the lateral wall of the scala media, which consists of numerous capillary loops and small blood vessels (Zdebik et al., 2009). Endolymph provides metabolic support for the organ of Corti and contributes to the generation of the electrochemical (endocochlear) potential responsible for transduction of sound by sensory hair cells (Cunningham and Tucci, 2017). The endocochlear potential is generated by high K^+ concentrations in the endolymph because of $Na^+-K^+-Cl^-$ cotransporters, $Na^+-K^+-ATPases$, and rectifying potassium channels (Jiang et al., 2017).

At the base of the cochlea, the perilymph of the scala vestibuli contacts the oval window, and the perilymph of the scala tympani contacts the round window. The chemical difference between the endolymph (high concentration of K^+ and a low concentration of Na^+, similar to intracellular fluid) and perilymph (low in K^+ and high in Na^+, similar to interstitial fluid) is important for the function of the inner ear (Sprung et al., 2003).

Movement of the oval window creates motion in the cochlear fluid and along the basilar membrane. This motion excites frequency-specific areas of the organ of Corti. Although the apical portion of the basilar membrane transfers lower-frequency impulses, the basal end relays higher-frequency impulses (Ervin, 2017).

Although the ears are fully formed at birth, maturation of neuronal pathways and auditory structures continues during infancy and early childhood, making young children particularly vulnerable to the ototoxic effects of chemicals (Landier, 2016).

Hearing Mechanisms

In the human ear, a sound wave is transmitted through four separate mediums along the auditory system before a sound is perceived: the outer ear (air), middle ear (mechanical), inner ear (liquid), and the brain (neural). Air-transmitted sound waves are directed toward the delicate hearing mechanisms with the help of the outer ear, first by the pinna, which gently funnels sound waves into the ear canal that amplifies and direct sound toward the middle ear. When air movement strikes the tympanic membrane, this moves and sets the three little bones of the ossicular chain into motion. At this point, the energy generated through the sound waves is transformed into mechanical energy. This is then transmitted to the inner ear (the cochlea) via hydraulic waves that stimulate the mechanosensory hair cells of the organ of Corti. On stimulation, these cells convert sound energy into electrical activity in nerve fibers by releasing neurotransmitters that cause the neurons of the spiral ganglion to transmit the neural impulses through the VIII cranial nerve and various nuclei in the brain stem to the auditory cortex in the temporal lobe of the brain (Ervin, 2017).

Sound pressure waves entering the cochlea tonotopically vibrate the basilar membrane, deflecting the stereocilia projecting from the apices of outer hair cells into endolymph. As the stereocilia are deflected, mechanoelectrical transduction (MET) channels located at the tips of the stereocilia are opened, allowing K^+ to enter the cells. This K^+ influx opens voltage-dependent Ca^{++} channels and depolarizes outer hair cells, which change in length. This change originates motion of the basilar membrane, which in turn causes the associated inner hair cell to depolarize. This depolarization opens voltage-dependent Ca^{++} channels and initiates an electric potential that ultimately causes neurotransmitter release at the base of internal hair cell (known as ribbon synapses), eliciting an action potential in the dendrites of the spiral ganglion neurons. Since glutamate is the neurotransmitter released at the synapses between inner hair cells and spiral ganglion neurons, the postsynaptic afferent neurons represent a candidate target for excitotoxic damage (Brigande, 2017; Watson et al., 2010).

OVERVIEW ON OTOTOXICITY

Ototoxicity is a neurosensorial damage consisting of transient or definitive disturbances of auditory and/or vestibular function induced by chemicals targeting the cochlea and vestibular cells, respectively. Thus, both cochleotoxicant and vestibulotoxicant chemicals can be considered as ototoxicants (Campo et al., 2009).

Although sensory hearing loss is the result of damage to the organ of Corti or the stria vascularis, neural hearing loss is the result of loss or dysfunction of spiral ganglion neurons or of more proximal auditory structures (Cunningham and Tucci, 2017). Cochlear dysfunction spans from a slight increase of the hearing threshold, only detectable through audiometry, to complete deafness. Hearing loss can occur along with tinnitus (ringing in the ears). Clinically cochlear damage appears sooner than vestibular damage, which can even be severe before the onset of vertigo. Vestibular damages can go undetected especially if the damage development is slow and progressive and bilateral so that the actual extent of vestibular damage is hard to assess (Cianfrone et al., 2011). The main clinical features of cochlear and vestibular toxicity are shown in Table 22.2.

The first clinical manifestation of cochlear toxicity is the presence of tinnitus, usually bilateral, of sudden onset and great intensity, which may or may not evolve to hearing loss. In its initial stage the damage is limited to the acute frequencies (4000−8000 Hz), without affecting the conversational hearing, although subjects usually have a sensation of noise and auditory dullness.

TABLE 22.2   Characteristic Clinical Symptoms and Signs of Cochlear and Vestibular Toxicity

Cochlear Toxicity	Vestibular Toxicity
Tinnitus	Headache, nausea, vomiting
High-frequency hearing loss	Vertigo, loss of balance when closing the eyes
Low-frequency hearing loss	Loss of balance in ambulation
Deafness (may appear several weeks after stopping treatment)	Nystagmus

At this phase the damage is usually reversible. In its advanced stage the cochlear toxicity affects the inner hair cells of the cochlear apex affecting the most severe frequencies and conversational hearing. At this point the auditory deficit can be partially reversible or permanent. In parallel to the cochlear damage, vestibular toxicity usually develops, manifested by symptoms such as vertigo, nausea, dizziness, and nystagmus; however, these symptoms are often masked by visual compensatory and proprioceptive mechanisms, which is why the extent of this type of ototoxicity is difficult to assess, especially if it develops slowly and progressively (Casselbrant and Mandel, 2005; Cianfrone et al., 2011).

Hearing loss can be subdivided into three types: conductive, sensorineural or central hearing loss. However, sensorineural hearing loss is the most common one, usually caused by the functional impairment or loss of hair cells. These cells can be damaged by a variety of factors including genetic disorders, infectious diseases, overexposure to intense sound, and certain chemicals. However, cochlear hair cells cannot regenerate following injury because they lost their ability to proliferate during embryogenesis (Yamahara et al., 2015).

CLASSIFICATION OF CHEMICALS CAUSING OTOTOXICITY

Most ototoxic substances can be categorized as pharmaceuticals or workplace chemicals (Table 22.3). Apart from these agents, the most deleterious factor to hearing loss is occupational exposure to noise. Furthermore, the combination of chemicals and noise has been shown to be synergistic in their damaging effects to the hearing/balance mechanisms (Morata, 2007). After exposure to ototoxic chemicals there is a prolonged susceptibility period (up to 1 year) during which the ear may be more vulnerable to an increased damage.

Pharmaceuticals

The reported prevalence of ototoxicity in patients who have received potentially ototoxic therapy ranges from 4% to 90%, depending on factors such as age of patients, drug used, cumulative dose, and administration techniques. Considerable interindividual variability in the prevalence and severity of ototoxicity has been observed among patients receiving similar treatment, suggesting genetic susceptibility as a risk factor (Landier, 2016). Ototoxic chemicals may cause permanent disability because the damaged hair cells cannot regenerate or can do so to a very limited extent (Sedó-Cabezón et al., 2014).

TABLE 22.3   Chemicals Capable of Producing Ototoxicity

Group	Pharmaceuticals
Antimicrobials:	
• Aminoglucosides	Gentamicin, neomicine, streptomycin
• Glyopeptide antibiotics	Vancomicine
• Macrolides	Erythromicin
Antineoplastic	Cisplantin
	Vinca alkaloids (vincristine)
Loop diuretics	Furosemide, etacrinic acid
Analgesic—antipyretic	Salicylates (aspirin) and other nonsteroidal antiinflammatory (NSAIs)
Antipaludics	Quinines (chloroquine)
Antiepileptics	Carbamazepine, phenytoin, valproate, lamotrigine, gabapentin, vigabatrin, and oxcarbazepine

Industrial Chemicals	
Solvents	Butanol
	Carbon disulphide
	Ethanol
	Ethylbenzene
	n-heptane
	n-hexane
	Perchloroethylene
	Styrene
	Toluene
	Trichloroethylene
	Xylenes
Metals	Arsenic
	Lead
	Manganese
	Mercury
	Organotins (trimethyltin, triethyltin)
Others	Acrylonitrile
	Carbon monoxide
	Hydrogen cyanide
	Organophosphates
	Paraquat

Antibiotics

Aminoglycosides

Aminoglycosides are a group of antibiotics used to treat infections caused by Gram-negative bacteria and mycobacteria. Clinically used aminoglycosides can be primarily cochleotoxic (amikacin and kanamycin) or

primarily vestibulotoxic (gentamicin, streptomycin, and tobramycin) (Selimoglu, 2007).

Aminoglycosides enter the scala media via the Reissner's membrane and the stria vascularis and progressively accumulate in the endolymph of the inner ear from where they can enter into the cochlear hair cells via endocytosis or the MET channel pore (Karasawa and Steyger, 2015). Aminoglycosides have greater access to cochlear hair cells than to vestibular hair cells, which are tightly embedded and completely surrounded by supporting cells (Ding et al., 2016). Aminoglycosides may also decrease the number of neurons of the vestibular system, either as a result of direct toxicity or secondarily to hair cell loss (Ishiyama et al., 2005). One of the proposed mechanisms of aminoglycoside-induced ototoxicity is the excessive formation of reactive oxygen species (ROS) followed by apoptosis of sensory hair cells (Rybak and Ramkumar, 2007). Likewise, aminoglycosides can interact with transition metals such as iron and copper, which are redox active and potentiate the formation of free radicals, thus producing oxidative cell damage (Sedó-Cabezón et al., 2014).

Macrolides

Macrolide antibiotics are widely used to treat a variety of conditions because of their broad spectrum of activity, particularly in penicillin-allergic patients. However, macrolides may elicit ototoxicity as an adverse effect, which may occur at standard oral doses and through multiple mechanisms. These include inhibition of ion transport in the stria vascularis and affectation of the auditory nerve, cochlear nucleus, and superior olivary complex. Some patients may have lower thresholds for penetration of erythromycin into the inner ear or increased sensitivity to erythromycin within the inner ear fluid. Previous exposures or the presence of an underlying hearing impairment can increase the risk of developing hearing loss from macrolides (Ikeda et al., 2018).

Salicylates and Nonsteroidal Antiinflammatory Drugs

Sodium salicylate, the active component of aspirin, is widely used for its antiinflammatory, antipyretic, and analgesic effects and also for its inhibitory effect on platelet aggregation. Salicylic acid is one of the earliest known ototoxic chemicals; at high doses it produces temporary tinnitus, vertigo, and sensorineural hearing loss. Salicylate quickly enters the cochlea where the perilymph concentration is similar to that in serum. Hearing loss is typically mild to moderate and bilaterally symmetric. Recovery usually occurs 24–72 h after cessation of the drug (de Almeida-Silva et al., 2011; Sheppard et al., 2015).

The underlying ototoxic mechanisms remain unclear but appear to involve changes in cochlear blood flow and reduction of electromotility of the outer hair cells. Inhibition of cyclooxygenase results in a reduction of cochlear blood flow. Salicylate does not alter the number or distribution of hair cells, but it competitively binds and inhibits prestin, a cochlear protein expressed by the outer hair cells, which reduces the electromotility of these cells and produces hearing loss and tinnitus (Zhang et al., 2014). Salicylate also blocks the potassium channel KCNQ4 in the cochlea, leading to outer hair cell degeneration (Hoshino et al., 2010).

Inner hair cells in the cochlea are also involved in the pathological mechanism of salicylate-induced tinnitus. This mechanism involves activation of cochlear N-methyl-D-aspartate receptors, tumor necrosis factor (TNF)−α, and interleukin (IL)-1β in the cochlea hair cells. The alteration of RIBEYE expression (a specific presynaptic protein) could be one possible mechanism underlying the change in the morphology of ribbon synapses and salicylate-induced tinnitus (Zhang et al., 2014).

Long-term treatment with high doses of salicylate can exert neurotoxic degeneration and apoptosis of spiral ganglion neurons and impair auditory neural activity of the cochlea. Changes in the expression of apoptotic genes, particularly among members of the TNF family, appear to play an important role in the degeneration (Wei et al., 2010).

In addition to salicylate, nonsteroidal antiinflammatory drugs (NSAIDs) at high doses may transiently cause tinnitus and mild to moderate hearing loss. NSAIDs impair the active process of the cochlea, the mechanosensory function of the outer hair cells, and affect peripheral and central auditory neurons. However, the endocochlear potential, an indicator of the function of the stria vascularis, is not affected after NSAID treatment (Hoshino et al., 2010).

Antineoplasic Drugs

Within the group of antineoplastic drugs, cisplatin shows the highest risk of ototoxic effects, although vinca alkaloids (e.g., vincristine) have also been involved.

Cisplatin

Platinum-based drugs (cisplatin, carboplatin, and oxaliplatin) are used for the treatment of solid tumors, such as ovarian, lung, head and neck, and testicular cancer. However, dose-limiting side effects, such as ototoxicity, neurotoxicity, and nephrotoxicity, are generally shown by the majority of patients (Sheth et al., 2017). Cisplatin can enter the cochlea through various mechanisms. Copper transporter 1 (Ctr1) is a major copper influx transporter and has been shown to mediate the uptake of cisplatin, carboplatin, and oxaliplatin. The

Ctr1 transporter is expressed by hair cells, the spiral ganglion neurons, and the stria vascularis. The uptake of cisplatin into cochlear cells is also mediated by organic cation transporters (OCTs), particularly the isoform OCT2, which is expressed in the organ of Corti and stria vascularis. Cytosolic uptake of cisplatin can also be facilitated by functional MET channels and transient receptor potential vanilloid 1 (TRPV1) channels (Sheth et al., 2017; Waissbluth and Daniel, 2013).

The degree of cisplatin-induced ototoxicity has been associated with cumulative doses (usually greater than 400 mg/m^2) and dose intensity, although considerable interindividual variability exists, with hearing threshold alterations being observed in 28%−77% of patients. The ototoxicity of cisplatin has a more pronounced effect in children, where the prevalence may be greater than 60% and with more severe symptoms (Karasawa and Steyger, 2015).

Platinum-based drugs, once activated, cross-link two purine bases of DNA by reacting with nitrogens at position seven, thus interfering with cell division and transcription. The resulting DNA irreversible changes inhibit tumor cell division and activate the apoptotic process, which may be also responsible for hearing loss if cochlear hair cells are affected (Starobova and Vetter, 2017). Cisplatin can also break double-stranded DNA in strial marginal and cochlear hair cells that are transcriptionally active, disrupting cellular physiology and inducing cytotoxicity (Karasawa and Steyger, 2015).

As occurred with aminoglycosides, platinum-induced ototoxicity is characterized by the production of toxic levels of ROS within the cochlea, with destruction of hair cells and damage to the stria vascularis and spiral ganglion cells. Given the tonotopic arrangement of cochlear hair cells, the initial insult begins at the base of the cochlea, in which high-frequency sounds are processed, and further drug administration results in damage that progresses toward the cochlear apex, in which lower (speech frequency) sounds are processed. Because the destroyed cochlear sensory hair cells cannot regenerate, the sensorineural hearing loss is almost always bilateral and irreversible and also can be accompanied by tinnitus and vertigo (Landier, 2016).

Vincristine

Vincristine is commonly used in the treatment of solid tumors, hematological tumors, and nonmalignant hematologic disorders. Vincristine is thought to be uptaken by cells through a carrier-mediated transport mechanism. Similar to other vinca alkaloids, vincristine binds to the β-subunit of tubulin and inhibits microtubule formation, leading to depolymerization of the microtubule and mitotic arrest at metaphase or cell death. Peripheral sensorimotor and autonomic neuropathy represents an important dose-limiting side effect

that may occur from binding with tubulin and further disruption of microtubule assembly, axonal transport, and secretory functions, resulting in primary axonal degeneration (Kuruvilla et al., 2009). Experimental studies indicate that vinca alkaloids cause dose-related degeneration of hair cells. Although low and moderate doses of vincristine ($\leq 1.5 \text{ mg/m}^2$) do not have any significant hearing impairment, bilateral sensorineural hearing loss has been observed in adult patients receiving high doses of vincristine ($2-2.5 \text{ mg/m}^2$) (Riga et al., 2006).

Loop Diuretics

Loop diuretics are a group of drugs that inhibit renal reabsorption of Na^+, Cl^-, and K^+ in the ascending loop of Henle. They include furosemide, bumetanide, ethacrynic acid, and torasemide, which are often used to treat kidney insufficiency, hypertension, and congestive heart failure. The hearing loss induced by loop diuretics is bilateral and usually reversible that lasts only during the treatment, unless these drugs are administered to patients with severe acute or chronic renal failure or in combination with other ototoxic drugs (e.g., cisplatin or aminoglycosides). In these cases the degree of hearing loss worsens and becomes permanent (Campo et al., 2013).

Although the tight junctions in the blood−cochlea barrier prevent toxic molecules from entering cochlea, when diuretics induce a transient ischemia, the barrier is temporarily disrupted allowing the entry of toxic chemicals. Loop diuretics interfere with strial adenylate cyclase and $Na^+,K^+-ATPase$ and inhibit the $Na^+-K^+-2Cl^-$ cotransporter in the stria vascularis. Because renin is present in cochlear pericytes surrounding stria arterioles, diuretics may induce local vasoconstriction by renin secretion and angiotensin formation, resulting in a reduced blood flow of the vessels supplying the lateral wall. This mechanism parallels the effect of diuretics on kidney and ear. Ultimately, the ionic gradients between the endolymph and the perilymph are disturbed, resulting in a dose-dependent reduction of endocochlear potential, which affects sensorial transduction and produces a sudden high-frequency hearing loss (Campo et al., 2013; Ding et al., 2016).

Antimalarial Drugs

Although antimalarial medications such as quinine and chloroquine may cause sensorineural hearing loss and tinnitus after prolonged therapy in high doses, these effects are rare and usually reversible. A large dose of quinine can also lead to reversible hearing loss and tinnitus. Vertigo may appear as associated vestibular toxicity. Quinine's manifestation of ototoxicity is similar to that of salicylate, but the mechanisms of toxicity differ. These mechanisms are likely the result of an

ischemic process that affects cochlear sensory hair cells, causes atrophy of stria vascularis, and decreases neuronal population (Bortoli and Santiago, 2007).

Phosphodiesterase Type 5 Inhibitors

Phosphodiesterase type 5 (PDE-5) inhibitors are prescribed for erectile dysfunction and pulmonary arterial hypertension. Sildenafil, and to a lesser extent vardenafil and tadalafil, have been associated with sudden sensorineural hearing loss in a large population-based study (McGwin, 2010). However, results from animal studies are controversial. Sildenafil inhibits the PDE-5, the enzyme that degrades cyclic guanosine monophosphate (cGMP), leading to an increase in cGMP and enhanced vasodilation and decreased vascular resistance. However, the question of why these drugs cause hearing loss is unclear. Alterations in the nitric oxide—cyclic guanosine monophosphate (NO/cGMP) pathway, including downstream second messenger molecules, have been previously involved in the development of hearing loss, including cisplatin and aminoglycoside ototoxicity (Maddox et al., 2009).

Antiepileptic Drugs

Data from experimental, cross-sectional, and prospective studies have shown evidence for the deleterious effect of some antiepileptic drugs on the auditory and vestibular systems. Long-term treatment with some of these drugs (e.g., carbamazepine, phenytoin, valproate, lamotrigine, gabapentin, vigabatrin, and oxcarbazepine), even at therapeutic doses, may result in sensorineural hearing loss, tinnitus, dizziness, and abnormalities in brain stem auditory evoked potentials, indicating auditory and central and/or peripheral vestibular dysfunctions (Hamed, 2017).

Industrial Chemicals

Workplace chemicals with ototoxic potential include industrial solvents (e.g., toluene, styrene, and trichloroethylene) and synthetic intermediates. These compounds are toxic to both the auditory and vestibular sensory systems, with their main targets being the hair cells (Sedó-Cabezón et al., 2014). The effects of these chemicals on ear function can be aggravated by noise, which remains a well-recognized cause of hearing impairment and poses an additive risk to hearing (Campo et al., 2013).

Among industrial solvents, styrene is one of the most ototoxic agents (Gagnaire and Langlais, 2005). Styrene is used in the production of plastics, synthetic rubbers, resins, insulating materials, and protective surface coatings. Although occupational studies on styrene-associated hearing impairment have led to contradictory results, experimental studies in animals showed that styrene can induce hearing loss. However, a threshold for ototoxicity has been identified (600−700 ppm for 4 weeks of exposure) (Chen et al., 2007). In contrast to most ototoxic drugs, which initially affect the base of the cochlea, styrene and other ototoxic solvents disrupt cochlear outer hair cells starting from the middle turn, thereby leading to hearing loss in the mid-frequency range (Crofton et al., 1994). However, supporting cells (e.g., Deiters' cells) appear to be the most vulnerable target of styrene in the cochlea, with inner hair cells being relatively insensitive to styrene exposure (Chen et al., 2008). Histochemical studies on styrene-induced apoptosis indicated that both mitochondrial-dependent pathway and death receptor—dependent pathway were involved in the styrene-induced hair cell death (Chen et al., 2007).

A systematic review of epidemiological studies confirmed the association between occupational exposure to diverse aromatic solvents and an increased risk of developing hearing loss, even at low concentrations (Odds ratio (OR) 2.05, 95% confidence interval (CI) 1.4−2.9). In addition, noise exacerbated the extent of hearing loss of those exposures as subjects concurrently exposed to solvents mixture and noise had an higher risk of hearing loss (OR 2.95, 95% CI 2.1−4.2) (Hormozi et al., 2017). Another study confirmed this finding and found that the combined exposure to a solvent mixture and noise increased the risk of hearing loss from 1.70 after 3 years of exposure to 8.25 after 12 years (Kaufman et al., 2005). The latency period depends on the characteristic of the exposure rather than on the type of ototoxic agent, although in the case of exposure to styrene the impairment may arise after 3 years of exposure (Johnson et al., 2006).

The cochleotoxic effects of aromatic solvents (styrene, toluene, and others) have been demonstrated in animal experiments, with longer exposures causing irreversible hearing impairments (Campo et al., 2013). Aromatic solvents can induce hearing loss by affecting hair cells of the organ of Corti, either directly after acute exposures or by the formation of chemically reactive intermediates after long-term exposures. These intermediates include ROS, which may disturb the transmembrane flux of K^+, with the accumulation of this cation into the outer channel of the organ of Corti causing outer hair cell cytotoxicity (Campo et al., 2013; Chen et al., 2007).

Exposure to high concentrations of trichloroethylene can disrupt cochlear sensory hair and spiral ganglion cells as well as the auditory nerve pathways within the cochlea. Conversely, the solvents carbon disulfide and n-hexane have been associated with retrocochlear dysfunction, as experimental studies have shown disturbances in the auditory nervous pathway beyond the cochlea (Campo et al., 2013).

Nitriles are industrial chemicals used as solvents (acetonitrile), monomers for polyacrylonitrile (acrylonitrile) and for the production of melamine resins (benzonitrile). These chemicals have shown cochleotoxic effects only in experimental animals, and hearing loss may occur with simultaneous exposure to acrylonitrile and low noise intensity (Campo et al., 2013).

Carbon monoxide and cyanides are asphyxiants that induce ototoxicity as a result of hypoxia within the cochlea. Experimental studies indicate that exposures to low concentrations of these asphyxiants impair cochlear function and induce reversible auditory effects, particularly affecting high-frequency tones. Although cyanides affect the stria vascularis, carbon monoxide induces glutamatergic excitotoxicity. Furthermore, both agents can potentiate permanent noise-induced hearing loss in both animals and humans (Campo et al., 2013).

Epidemiological and experimental studies have shown that long-term exposure to lead, mercury, and manganese, among other metal compounds, may damage different structural elements of the cochlea resulting in sensorineural hearing loss (Roth and Salvi, 2016). Workers chronically exposed to lead had impaired conduction in the auditory nerve and the auditory pathway in the lower brain system (Campo et al., 2013). Trimethyltin and triethyltin are also capable of inducing a dose-dependent hearing impairment in experimental animals as a result of increased calcium concentration in outer hair cells and spiral ganglion cells, with further disruption of the functioning of these cells (Liu and Fechter, 1996). Likewise, in vitro and in vivo studies indicate that manganese accumulates in the cochlea and that it alone may be ototoxic, although the combined exposure to manganese plus noise increases the risk of hearing loss over that caused by noise alone (Muthaiah et al., 2016).

Nonetheless, the putative hearing loss of prolonged (over)exposures to industrial chemicals may be confounded by exposure to high noise levels at work as noise by itself is known to cause hearing loss.

FACTORS MODIFYING CHEMICAL OTOTOXICITY

A number of factors contribute to an increased risk of ototoxicity of chemicals, including exposure to high concentrations of pharmaceutical or industrial agents, concurrent or consecutive exposure to several ototoxic chemicals, exposure to noise, preexisting hearing loss, genetic susceptibility, and age (Bauman, 2003). The administration of ototoxic drugs, particularly aminoglucosides, during pregnancy has been associated with impaired hearing, with a particularly sensitive phase up to approximately the fourth month of gestation (Mylonas, 2011). Young children and adults beyond 60 years are also more vulnerable to permanent hearing loss and/or balance problems. Certain predisposing diseases, such as liver or kidney failure, which cause the accumulation of certain active ingredients, may facilitate the appearance of ototoxicity. These circumstances may worsen the degree of chemical-induced ototoxicity (Bauman, 2003).

Considerable interindividual variability in the prevalence and severity of ototoxicity has been observed among patients receiving similar treatment with known ototoxic agents. Although some individuals remain unaffected at high cumulative doses, others experience severe damage at low doses. This interindividual variation can be partially accounted for by genetic susceptibility to the ototoxic effects of chemicals (Landier, 2016). Certain mitochondrial chromosome mutations can represent one of the genetic factors underlying vulnerability to aminoglycosides. The A1555G mutation (substitution of a guanine with an adenine) located on the mitochondrial RNA12S has been related to aminoglycoside ototoxicity. The fact that the mutated human form A1555G is very similar to the bacterial target for the aminoglycosides (ribosomal 16S RNA) may explain the occurrence of hearing loss even at low dosages of the drug. It has been estimated that 17% of the subjects eliciting aminoglycoside ototoxic effects harbor such mutation (Cianfrone et al., 2011).

Toxic interactions between ototoxic drugs are well known, particularly the potentiation of the ototoxic effect of aminoglycosides by loop diuretics. The mechanisms underlying this interaction can be related to the damage produced by loop diuretics on the tight cell junctions in the blood vessels of the stria vascularis, which disrupt the blood–cochlear barrier temporarily. This damage changes the positive endocochlear potential into a negative one, leading to a massive entry of the positively charged aminoglycosides into the endolymph, followed by hair cell loss and further permanent hearing loss (Ding et al., 2016; Liu et al., 2011).

On the other hand, interactions can be observed on simultaneous exposure to ototoxic chemicals and noise, such that moderate levels of noise can potentiate auditory dysfunction. Hearing loss can thus be greater than the sum of the individual effects. For instance, the lowest level of solvent exposure needed to elicit an auditory effect is reduced when individuals are co-exposed to other stressors, such as noise or carbon monoxide. This means that health-based reference values set for chemical-induced ototoxicity may not protect against hearing loss in the presence of high-level noise (Morata and Johnson, 2012).

UNDERLYING MECHANISMS OF OTOTOXICITY

Ototoxic compounds typically damage both the auditory sensory and the vestibular systems, as their main targets are the hair cells. As mentioned above, these are mechanosensory cells responsible for the transduction of either sound waves and linear and rotational movements of the head. Although sensorineural hearing loss occurs mainly as a consequence of degeneration and apoptosis of auditory hair cells, afferent dendrite terminals and the corresponding spiral ganglion neurons may also be damaged and undergo apoptosis. This damage can occur either primarily, before hair cell death, or secondarily, because of loss of trophic support after hair cell degeneration (Sedó-Cabezón et al., 2014).

After ototoxic chemicals reach the endolymph, they enter into hair cells and induce necrotic or apoptotic cell death through different mechanisms (Fig. 22.3). Nevertheless, some common features are shared between damaging mechanisms induced by these chemicals, noise and aging. For instance, the final common pathways usually involve oxidative stress and free radical–mediated damage (Niihori et al., 2015). The main toxic mechanisms include disruption of mitochondrial protein synthesis, formation of free radicals, activation of mitogen-activated protein kinases (MAPK, such as c-Jun N-terminal kinase—JNK), disruption of phosphoinositide homeostasis, mitochondrial dysfunction, and activation of caspases and nucleases (Leitner et al., 2011; Wang et al., 2007). Ultimately, activation of proapoptotic signaling pathways leads to apoptotic hair cells death (Fig. 22.3).

Chemical- or noise-induced hearing loss can be driven by the formation of free radicals, including ROS and reactive nitrogen species (RNS), within hair cells. Excessive production of these highly reactive molecules overwhelm the antioxidant defense mechanisms of the cochlea, causing a cascade of events eventually leading to apoptosis of hair cells and further sensorineural hearing loss. ROS identified in cochlear tissue are derived from hair cells mitochondria and include hydroxyl radicals, superoxide anions, and hydrogen peroxide (Falasca et al., 2017). ROS can form hydrogen peroxide (H_2O_2) or react with NO resulting in peroxynitrite formation ($ONOO^-$). Peroxynitrite can interact with proteins and form nitrotyrosine, whereas hydrogen peroxide reacts with iron to form the highly reactive hydroxyl radical (•OH). This radical then reacts with polyunsaturated fatty acids in cell membranes, produces lipid peroxidation, and generates the highly toxic aldehyde 4-hydroxynonenal (4-HNE) (Waissbluth and Daniel, 2013). Although ROS generation induces signal transduction cascades leading to apoptosis or necrosis, how ROS induces these signaling pathways remains unclear. One possibility is that increased levels of 4-HNE can induce intracellular Ca^{2+} influx, which triggers apoptosis of cochlear hair cells (Karasawa and Steyger, 2015). Ultimately, the imbalance between ROS and RNS together with reduced intrinsic antioxidant defenses represents the main elements underlying hair cell death through either apoptosis or necrosis.

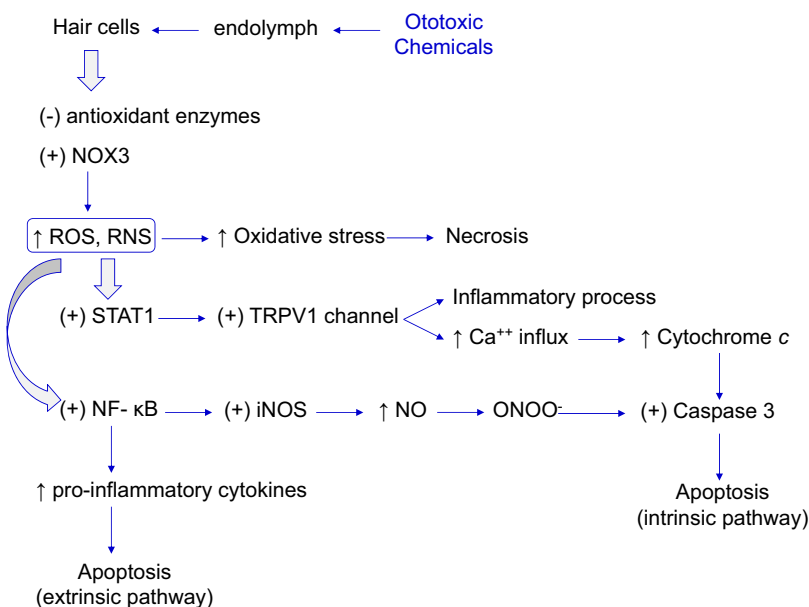
The aquated forms of cisplatin are also highly reactive, particularly with cytoplasmic thiol-containing molecules such as the antioxidant glutathione and the antioxidant enzymes glutathione S-transferase,


FIGURE 22.3 Putative mechanisms of ototoxicity (+, activation; −, inhibition).

glutathione peroxidase, and superoxide dismutase (Karasawa and Steyger, 2015; Waissbluth and Daniel, 2013). Once inhibited, these antioxidant defenses can no longer scavenge and neutralize reactive molecules, and hence the cellular redox status is shifted, leading to toxic levels of ROS and RNS and activation of the intrinsic apoptotic pathway (Fig. 22.3). Upregulation of antioxidant pathway activity, such as glutathione-*S*-transferases that are expressed in the mammalian cochlea, can protect against ototoxicity (Travis et al., 2014).

A major source of ROS in the cochlea is the NADPH oxidase 3 (NOX3), an isoform highly expressed in the organ of Corti and spiral ganglion, which is activated by cisplatin. The generation of ROS promotes activation of signal transducer and activator of transcription 1 (STAT1) leading to both inflammatory and proapoptotic actions in the cochlea. STAT1 stimulates the inflammatory process by activation of TRPV1 channels. The induction of TRPV1 also increases calcium inflow into cells, with massive cytochrome *c* release and further activation of caspase-3, thus triggering the intrinsic apoptotic pathway (Rybak et al., 2012; Sheth et al., 2017).

Another pathway leading to cochlea inflammation is activation of nuclear transcription factor-kappa B (NF-κB) through the production of ROS, as occurred with cisplatin (Chung et al., 2008). NF-κB upregulates the expression of proinflammatory cytokines such as IL-1β and TNF-α. TNF-α can, in turn, activate NF-κB resulting in a positive feedback loop that increases the inflammatory cascade (Waissbluth and Daniel, 2013). This local inflammation can activate the extrinsic signaling pathway leading to apoptosis (Fig. 22.3). NF-κB also increases the expression of inducible nitric oxide synthase (iNOS), leading to NO production that further reacts with superoxide to form peroxynitrite radical. This highly toxic molecule can activate caspase-3, which triggers apoptosis in the stria vascularis that eventually results in auditory dysfunction (Rybak et al., 2007).

The potassium channel KCNQ4, expressed in the mammalian cochlea, is another target for ototoxic chemicals. In fact, KCNQ4 mutations cause human hereditary hearing loss (O'Sullivan et al., 2017). Activation of this channel is associated with an outer hair cell potassium current (IK,n) and subsequent depolarization of outer hair cells (Hoshino et al., 2010). Salicylates cause a concentration-dependent (and reversible) reduction in IK,n (Wu et al., 2010). As the activity of KCNQ4 is linked to phosphatidylinositol 4,5-bisphosphate (PIP2) metabolism, aminoglycosides may indirectly cause KCNQ4 dysfunction by disrupting PIP2 homeostasis and in turn induce outer hair cell death (O'Sullivan et al., 2017).

The stria vascularis hosts the major blood–labyrinth barrier, a highly specialized capillary network that controls exchanges between blood and the interstitial space in the cochlea. Damage to strial cells in the cochlear lateral wall may breakdown the blood–labyrinth barrier and cause loss of the endolymphatic potential (Karasawa and Steyger, 2015; O'Sullivan et al., 2017). Some ototoxic chemicals (e.g., cisplatin) have shown to reduce the endocochlear potential in animal experiments, suggesting dysfunction of the stria vascularis. Aminoglycosides do not induce changes in endocochlear potentials during early phases but may do so after extensive treatment, leading to significant atrophy of the stria vascularis (Schacht et al., 2012).

Because hair cell synapses with the afferent spiral ganglion neurons are glutamatergic, these neurons can undergo excitotoxic damage. Excitotoxicity can be explained because under toxic stress hair cells have a limited capacity for regulating glutamate release and reuptake, and the excess of glutamate released can damage the afferent cochlear neurons as occurs with exposure to carbon monoxide (Sedó-Cabezón et al., 2014).

From the mechanistic data mentioned above it can be inferred that some molecules formed in the cochlea might be used as biomarkers of ototoxicty. These include molecular markers of oxidative stress (e.g., nitrotyrosine, a marker of NO production; or 4-HNE, a marker of cell membrane lipoperoxidation), antioxidant enzymes, cytoplasmic cytochrome *c*, iNOS and caspase-3, and inflammatory biomarkers (cytokines such as TNF-α and IL-1β). However, all these molecules are indirect biomarkers, as they lack specificity for cochlear damage.

FUNCTIONAL AND MOLECULAR BIOMARKERS FOR THE EVALUATION OF OTOTOXICITY

Early detection of ototoxic damage can improve the treatment outcome through minimizing hearing loss progression. The best way to detect ototoxicity is by assessing auditory and vestibular function directly. However, this section will address only the function of the auditory system, as this is more often assessed in clinical practice and occupational health services after exposure to ototoxic chemicals.

Functional Assessment of the Hearing Damage

Clinical evaluation of the hearing mechanisms can be performed with techniques that assess the functional integrity of the entire auditory system, from the tympanic membrane to cerebral cortex. The function of the auditory system can be assessed by using tests of mechanical sound transmission (middle ear function), neural sound transmission (cochlear function), and speech discrimination ability (central integration). In practice, the peripheral auditory pathway can be assessed by

using pure-tone audiometry (PTA), high-frequency audiometry, or speech audiometry. On the other hand, the assessment of damage to the Central Auditory Nervous System can be made through electroacoustic tests (immitanciometry, immittance decay, otoacoustic emissions), electrophysiological tests (brain stem auditory evoked potential, auditory cortical response), and central auditory processing (Hoth and Baljić, 2017).

Pure-Tone Audiometric Testing

PTA is the standard test used for assessing hearing loss and usually involves the presentation of sounds across a wide range of frequencies in a sound-attenuating test booth. This method can detect significant increases in hearing threshold, consistent with ototoxicity criteria. Besides, PTA makes distinction between sensorineural (cochlear and central auditory pathways) and conductive (outer and middle ear) type of hearing loss. PTA obtains a representation of the lowest sound intensities that can be heard across the frequency spectrum (Lustig, 2010). Threshold shifts in patients with sensorineural hearing loss typically begin in the high-frequency range (>4 kHz) and generally progress to the lower frequencies in a staggered pattern over time with continued exposure to the ototoxic agent (Landier, 2016). Most audiometric evaluations used for monitoring chemical-induced hearing loss are limited to the range of speech spectrum frequencies (0.25–8 kHz). However, such testing would fail to detect hearing loss in the ultrahigh frequencies from 10 to 20 kHz. Expanding audiometry into this range (high-frequency audiometry) would allow to detect a substantial number of cases of hearing loss that otherwise would be missed (Singh-Chauhan et al., 2011). Monitoring at the high-frequency limit of hearing provides the earliest indication of ototoxicity, consistent with the systematic progression of cochlear damage from base to apex found in animal models (Fausti et al., 1999).

Although PTA can help determine the nature and degree of the hearing loss, pure-tone thresholds do not provide qualitative information on sound perception. This is important because individuals with hearing loss can hear but cannot understand. Speech audiometry provides this additional qualitative hearing assessment. The speech reception threshold is the lowest level at which an individual can repeat a word, a measure that correlates closely with pure-tone thresholds (Lustig, 2010).

An ototoxic hearing loss can effectively be determined by comparison of audiograms from before (baseline testing) and after the administration of a drug or exposure to an ototoxic chemical (Cianfrone et al., 2011). In most scales, hearing loss is assigned a grade ranging from 0 (normal hearing, or clinically insignificant loss) to 4 (severe or profound hearing loss) (Landier, 2016).

Distortion Product Otoacoustic Emission

PTA remains the most commonly used clinical test to measure the extent of hearing loss; however, it is time-consuming and cannot discriminate between cochlear and retrocochlear hearing loss. In case of central hearing loss, a PTA can indicate normal hearing, but a person can still have difficulty understanding speech, particularly in background noise, making it difficult to hold a conversation. Thus, there is a need to use tests that evaluate the auditory system more comprehensively, from the cochlea to the higher auditory pathways. These tests may help differentiate between the individual (or the combined) effects of ototoxicants and noise on hearing. One of these complementary tests is the use of distortion product otoacoustic emission (DPOAE), a sensitive tool that can detect early ototoxic changes in the cochlea. Otoacoustic emissions are sound signals resulting from the mechanical action of outer hair cells in the organ of Corti. Because DPOAE is less time-consuming, it would allow clinical monitoring of more individuals. The inclusion of DPOAEs in a battery of tests to assess hearing would facilitate the distinction between sensory and neural hearing disorders (Campo et al., 2013; Md Daud et al., 2014).

The diagnostic value of otoacoustic emissions lies in their association with normal outer hair cell function, which is usually indicative of normal hearing. They are stable over time within individual ears and their high test–retest reliability allows them to be used as an effective monitoring examination. Moreover, otoacoustic emissions are noninvasive, non–time-consuming, easy to perform, and do not require the individual's active participation (e.g., can be used in little children) (Riga et al., 2006). DPOAE are objective, noninvasive measures that may be more sensitive to initial changes in auditory function than conventional auditory testing (Landier, 2016). Overall, the objective otoacoustic emission data largely parallel the subjective audiometric data (Gürkov et al., 2008).

Acoustic Immitance Test

This testing objectively measures the ease with which sound is transmitted through the tympanic membrane and middle ear. It consists of tympanometry and the acoustic reflex. Tympanometry measures the changes that occur in the tympanic membrane and ossicular chain as a result of a change in air pressure in the ear canal. The acoustic reflex (or stapedius muscle reflex) is measured by sensing the altered compliance of the tympanic membrane in response to a loud auditory signal (Lustig, 2010).

Acoustic Brain Stem Response Testing

Acoustic brain stem response testing (ABR), also referred to as brain stem auditory evoked responses or brain stem auditory evoked potential, is an electrical test used to measure cochlear and retrocochlear function. This test allows the retrocochlear auditory pathways to be measured, that is, those pathways between the cochlea and auditory cortex. The two main parameters analyzed are wave amplitude and latency changes. If an abnormal ABR is found, further evaluation with magnetic resonance imaging is warranted (Lustig, 2010). Because ABR is a nonbehavioral test sensitive to ototoxicity, it can be applied to little children or individuals unable to cooperate with standard behavioral testing (PTA) (Landier, 2016).

Although the audiological monitoring of individuals exposed to ototoxic chemicals is now standardized, a battery of diagnostic methods are currently available to confirm balance disorders (e.g., dynamic posturography) and to assess the labyrinthine damage, e.g., Halmagyi test, videonystagmographic record of spontaneous nystagmus, and caloric tests (Sánchez-Sellero and Soto-Varela, 2016). In addition, the video head impulse test and vestibular evoked myogenic potentials seem to be suitable procedures for objective assessment of suspected vestibulotoxic effects. The early detection of such effects has important implications for the prevention of balance disorders (Walther et al., 2015).

Molecular Biomarkers

Serum biomarkers are useful molecular indicators that can be used to assess normal or abnormal biological processes in response to pharmacological or industrial chemicals. They can also provide information on progression of disease. To be useful, biomarkers must be present in easily accessible body fluids, easily quantifiable and sensitive enough to detect the biological state, or outcome of interest, and specific enough to discern a normal from a diseased state (Naples et al., 2018).

Despite the wide array of molecular biomarkers available in clinical practice to confirm many common diseases, blood tests for detecting hearing loss and vertigo are not yet clinically available. Currently, hearing loss can only be diagnosed through hearing tests such as those mentioned in the previous section. However, there is no way to detect hearing loss at its earliest stages, with prevention and intervention options being limited at the time of diagnosis when hearing loss has developed. Recently a few blood tests have been considered to be helpful, as occurred with connexin 26/30 (proteins for contacting adjacent cells) and pendrin (an anion exchanger that elevates the endolymphatic pH), which are evaluated for genetic hearing loss. Another example is measurement of nonspecific inflammatory markers,

such as heat shock proteins, for the diagnosis of autoimmune inner ear disease. These tests generally have limited clinical applications, are not specific to the inner ear, and consequently have variable sensitivity and specificity (Liba et al., 2017).

However, there are several unique proteins specific to the inner ear with specialized functions that can be detected in minute quantities in the blood, which could be useful as otologic biomarkers. Because blood levels of these proteins correlate with inner ear disorders, they can potentially serve as biomarkers that help improve the early detection and diagnosis of hearing loss or vertigo. This is the case of otolin-1, a secreted glycoprotein expressed only in the inner ear, which increases in blood from patients with benign paroxysmal positional vertigo (Tabtabai et al., 2017). Besides, blood levels of prestin, an outer hair cell–specific protein, can be a useful biomarker for quantifying the extent of sensorineural hearing loss. In a rat model of noise-induced hearing loss, reduced hair cell counts and DPOAE levels were observed in the setting of decreased prestin levels (Parham and Dyhrfjeld-Johnsen, 2016). Prestin is likely not produced in major solid organs because its concentration in these organs does not exceed those in blood. Because prestin is released by injured outer hair cells, changes in blood prestin levels are linked to hearing loss; even before this loss it can be measured by functional tests. Nonetheless, if ototoxicity biomarkers are to be used into clinical practice, experimental validation is necessary before being translated to the clinical setting. In addition, biomarker levels should be sensitive to interventions aimed at ameliorating ototoxic damage (Liba et al., 2017; Naples et al., 2018).

Proteomic analysis of inner ear sensory epithelia has led to the identification of three major processes for normal hair cell physiology: energy metabolism, signal transduction, and cell cytoskeleton. Proteins involved in these processes can be exploited to develop new biomarkers and gain insight into pathophysiological mechanisms underlying ototoxicity (Alawieh et al., 2015).

Alternative Models

Damage to sensory hair cells in the inner ear can lead to permanent hearing or balance deficits, as regeneration of the inner ear sensory epithelia does not occur in mammals. Because zebrafish and other nonmammalian vertebrates have the ability to regenerate sensory hair cells, these models will allow for a better understanding of the molecular and cellular bases for this regenerative ability (Lush and Piotrowski, 2014).

Fish have neurosensory hair cells on their body surfaces, which can detect changes in movement and vibration from the surrounding water. These hair cells are structurally similar to those found within the human

inner ear, making zebrafish a suitable model to study inner ear dysfunction. Because of their superficial location, zebrafish hair cells can be experimentally damaged by adding exogenous toxic agents. For normal zebrafish, the induction of water flow results in a predictable "head-to-current" swimming behavior called rheotaxis (Niihori et al., 2015). The addition of aminoglycoside toxins to water has caused damage to zebrafish lateral line hair cells and negatively impacts rheotaxis behavior in a dose-dependent manner (Suli et al., 2012).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The assessment of inner ear function remains the gold standard for functional clinical diagnostics of hearing loss. At present, there are no molecular biomarkers of ototoxicity that can accurately track, precede, or reliably correlate with predicted and clinical/functional evidence of inner ear damage. This is due to a number of critical issues, such as the minute size of the inner ear, the small number of hair cells (which lost their ability to proliferate in the early postnatal period), the poor accessibility of the inner ear, the small volume of endolymph fluid that needs much more sensitive techniques to detect extremely low amounts of diverse molecules, and the complex features of cochleovestibular diseases. Identification and development of novel molecular markers of early cochlear and vestibular impairment remain a research challenge because standard functional tests lack predictivity and show abnormal results once inner ear is damaged, particularly at later stages and many times irreversibly.

Although significant efforts have been made to develop new biomarkers for other target organs, these efforts have been limited in the area of ototoxicity. Moreover, the few biomarkers available are not suitable to be appropriately used for clinical and nonclinical research applications. Attempts are currently ongoing to qualify reliable and sensitive biomarkers of cochlear and vestibular damage to be applicable for diagnostic and research use in humans and laboratory animals. One of the key new directions of novel development in ototoxicity biomarker research is the understanding of omic-based biomarkers, which would also allow pathophysiological mechanisms to be identified. Future research efforts should utilize proteomic, metabolomic, and miRNA array technologies in well-defined patient populations to identify accurate and sensitive molecular biomarkers. This approach will enable the development of reliable profiles to identify at-risk individuals and to implement personalized strategies such as the use of otoprotective agents or avoidance of ototoxic drugs in susceptible individuals to decrease the prevalence of ototoxicity and improve health-related quality of life. The maintenance of hair cell and supporting cell numbers after cochlear injury is therefore important for the treatment of sensorineural hearing loss. To achieve such treatment, protection and/or regeneration of hair cells is necessary.

Blood and Bone Marrow Toxicity Biomarkers

Sharon Gwaltney-Brant

Veterinary Information Network, Mahomet, IL, United States

INTRODUCTION

The blood and bone marrow are vital to survival, providing oxygen and nutrients to tissues, protecting the host from exogenous and endogenous invaders, providing the conduit for multisystemic communications, and preventing undue loss of bodily fluids. Because of its widespread influence within the body, toxic insults to the bone marrow or its daughter cells can result in severe consequences such as hypoxia, overwhelming infections, malignant neoplasia, or hemorrhage. The hematopoietic system contains the most mitotically active cells in the body, making it a prime target for toxicants that attack rapidly dividing cells.

The ability to quickly and effectively detect and measure toxicant-induced injury to hematopoietic or mature blood cells may allow for the institution of measures to mitigate the damage caused by the toxicant. Utilizing biomarkers as tools to predict the potential risks to the hematopoietic system posed by xenobiotics can enable us to preferentially select those compounds showing the least adverse effects on the body.

HEMATOPOIETIC SYSTEM

The hematopoietic system is composed of the bone marrow and the various cells that it produces. The production of blood cells is highly regimented and complex, involving innumerable cytokines, chemokines, neuropeptides, enzymes, and other chemical mediators. Although much has been learned about the intricate interactions among these players, there is still much that is not known about the mechanisms of hematopoietic cell proliferation, differentiation, maturation, and function.

Bone Marrow

In adults, hematopoietic marrow is concentrated in the spine, pelvis, sternum, ribs, calvarium, and proximal ends of the limb bones (Valli, 2007). Tucked away in the protective casing of cortical and cancellous bone, marrow is composed of hematopoietic cells, adipose tissue, and adjacent supportive cells and tissues. The microenvironment produced by the unique endosteal blood flow patterns, including bone−bone marrow portal capillary systems, provides the appropriate milieu for the proliferation, differentiation, and maturation of cellular components of the blood. Stromal stem cells give rise to adipocytes, osteoblasts, chondroblasts, and reticular cells that produce the structural scaffolding of the marrow and that secrete soluble mediators essential for the maintenance, differentiation, and growth of hematopoietic stem cells. In immature and young animals bone marrow is red, reflecting the high hematopoietic activity (Stockham and Scott, 2008). With age, red marrow is replaced by yellow marrow, which is composed of adipose tissue that differs from fat of other body sites in that marrow fat is more resistant to lipolysis in response to starvation (Valli, 2007). Conversion of yellow marrow back to red marrow may occur associated with pathologic states that stimulate hematopoiesis (e.g., anemia) and is most common in areas with higher blood flow such as endosteal surfaces.

Hematopoiesis

Hematopoiesis in the fetus occurs in multiple organs besides the bone marrow, including the thymic anlage, primordial lymph nodes, liver, spleen, kidney, and adrenals (Valli, 2007). At birth hematopoiesis is restricted primarily to the marrow, although occasional areas of extramedullary hematopoiesis may be found in the spleen or liver. In adults, extramedullary hematopoiesis (EMH) may occur in association with hematological disorders when bone marrow hematopoiesis is insufficient or ineffective. Typical sites of EMH include liver, spleen, lymph nodes, and paravertebral areas with the

intraspinal canal, presacral region, nasopharynx, and paranasal sinuses being less common locations for EMH (Sohawon et al., 2012). Although hematopoietic stem and progenitor cells capable of producing hematopoietic cells in vitro have been found in the stromal vascular fraction of adult adipose tissue, spontaneous EMH in adipose tissue is rare (Han et al., 2010).

Hematopoietic Cells

Hematopoiesis begins with the pluripotential stem cell, a primitive cell with almost unlimited capacity for self-renewal and the ability to differentiate into any of the blood cell lines. Growth factors and interleukins within the marrow microenvironment orchestrate the growth and differentiation of stem cells. With each level of differentiation, the commitment of the cell to a single cell type becomes more and more entrenched (See Fig. 23.1). In the event of an unusual demand for one

particular cell type (e.g., erythrocytes in an anemic patient), production of other cell lines (e.g., neutrophils) will be reduced (Valli, 2007). Ontogenic relationships can also influence the relative production of cell lines; for example, erythroid and megakaryocytic cells derive from the same precursor cell lineage, and stimuli that increase production of erythrocytes frequently result in concurrent increases in platelet numbers. As an understanding of differentiation, growth, and kinetics of the cells and soluble mediators is essential to interpretation of toxicant-induced bone marrow and blood cell injury, a brief description of the myeloid cell lines follows.

Erythrocytes

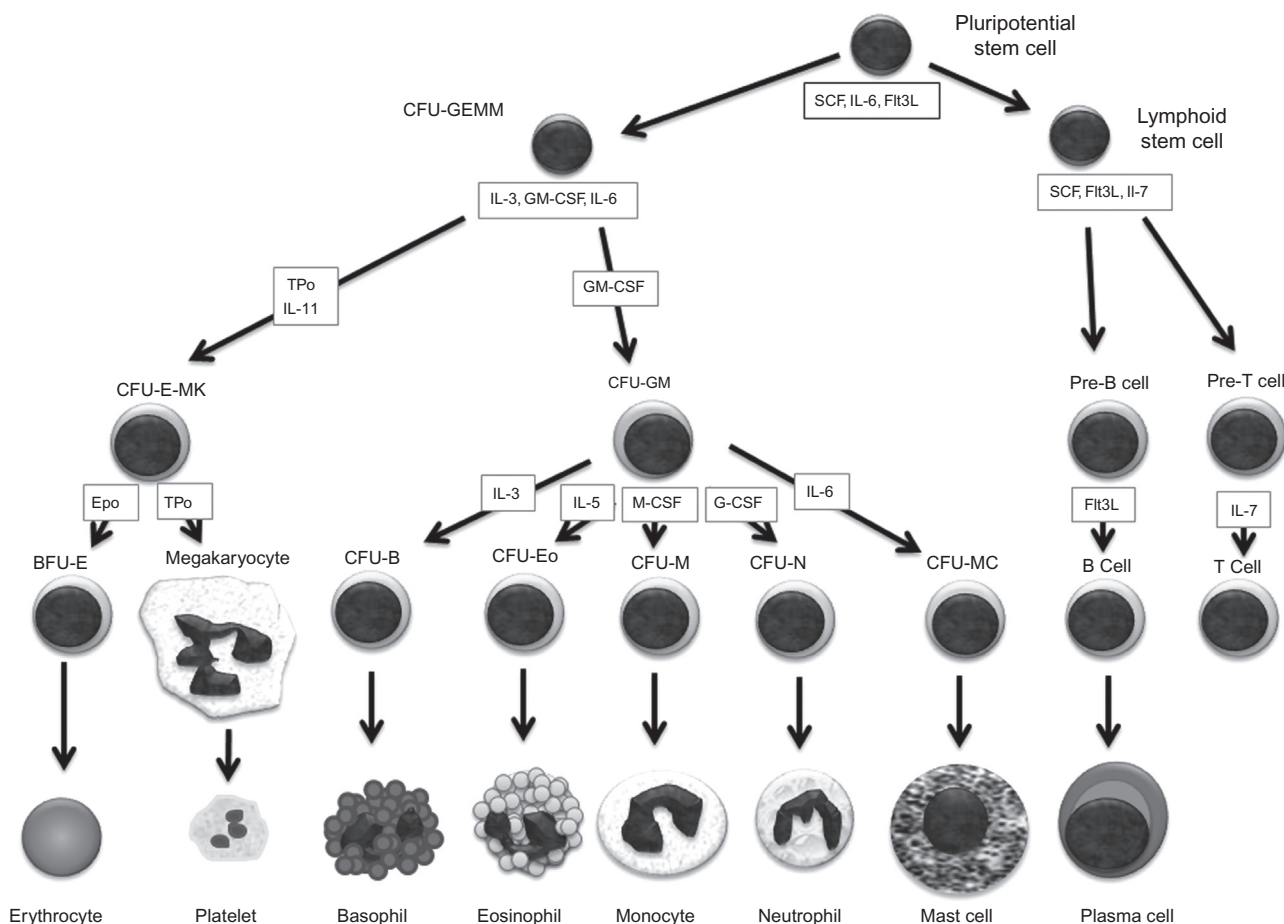
Erythrocytes comprise up to 45% of the circulating blood volume and are vital to the transport of oxygen from the lungs to the tissues, as well as the transfer of carbon dioxide from the tissues to the lungs for


FIGURE 23.1 Differentiation of mammalian hematopoietic cells. Boxes contain primary soluble mediators for each cell lineage. *BFU-E*, blast forming unit, erythrocyte; *CFU-B*, colony forming unit, basophil; *CFU-E-MK*, colony forming unit erythrocyte, megakaryocyte; *CFU-Eo*, colony forming unit, eosinophil; *CFU-GEMM*, colony forming unit granulocyte, erythrocyte, macrophage, megakaryocyte; *CFU-GM*, colony forming unit granulocyte; *CFU-M*, colony forming unit, monocyte; *CFU-MC*, colony forming unit, mast cell; *SCF*, stem cell factor; *CFU-N*, colony forming unit, neutrophil; *Epo*, erythropoietin; *Flt3L*, Flt3 ligand; *G-CSF*, granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *IL*, interleukin; *M-CSF*, monocyte/macrophage colony-stimulating factor; *TPo*, thrombopoietin.

TABLE 23.1 Species Variation in Life Spans of Erythrocytes

Species	Average RBC Life Span (days)
Cat	70[a]
Cattle	150[a]
Dog	100[a]
Horse	150[a]
Human	120[a]
Rabbit	55[b]
Rat	58[b]

[a]Stockham and Scott (2008).
[b]Rodnan et al. (1957).

exhalation (Bloom and Brandt, 2008). Erythrocytes are also important in maintaining homeostatic blood pH, clearing of immune complexes and complement fragments, and regulation of blood flow to tissues. Stimulation of the common myeloid stem cell by interleukin-3 (IL-3), IL-6, IL-11, granulocyte colony-stimulating factor, and thrombopoietin results in the differentiation of the myeloid stem cell into the erythroid/megakaryocytic precursor cell (Aster, 2005). In the presence of erythropoietin, which is produced in the fetal liver and adult kidney, further differentiation into an erythrocyte colony forming unit (CFU) occurs, resulting in the development of erythroblast, which synthesizes and accumulates hemoglobin and eventually extrudes the nucleus, forming a reticulocyte. Reticulocytes retain stainable RNA and ribosomes which give the cells their name; as the RNA and ribosomes are lost, the reticulocytes become mature erythrocytes and are released into the circulation. Erythropoiesis requires approximately 4 days to complete. Toxicants that interfere with cell differentiation, proliferation, or growth can alter erythrocyte production, resulting in anemia or polycythemia. Toxicants that alter hemoglobin synthesis (e.g., lead) result in erythrocytes with reduced oxygen-carrying capacity and increased membrane fragility (Thompson, 2018).

Erythrocyte life spans vary with species (Table 23.1) and are related to the level of oxygen-derived radicals formed and the efficiency of the intrinsic erythrocyte antioxidant systems for each species (Kurata et al., 1993). Toxicants that deplete or damage erythrocyte antioxidant systems or increase free radical formation can shorten the erythrocyte life span.

Platelets

Platelets function in the formation of the hemostatic plug to mitigate hemorrhage from vascular damage. Platelets also play roles in wound healing and inflammation, primarily through communication with inflammatory cells via soluble mediators. Platelets are not cells, but rather cytoplasmic fragments derived from megakaryocytes. Megakaryocytes are formed from the erythroid/megakaryocytic precursor cell under the continued influence of thrombopoietin. It takes about 4 days for platelets to be produced and, once released into the blood, platelets have a life span of 5–10 days (Valli, 2007).

Monocytes

Monocytes account for ∼5% of the total circulating leukocyte population and they are the precursors to tissue macrophages (Tizard, 2013). As part of the innate immune system macrophages function as phagocytes, removing pathogens and necrotic debris from sites of inflammation. Acting as antigen-presenting cells, macrophages also function in the acquired (adaptive) immune response. Under stimulation by IL-3, IL-6, granulocyte-macrophage colony-stimulating factor, and finally macrophage colony-stimulating factor, the myeloid stem cell gives rise to the monocyte precursor and ultimately differentiates into the monocyte. Once released into the bloodstream, monocytes circulate for approximately 3 days before entering tissues where they can replicate or differentiate into macrophages (Tizard, 2013). Tissue macrophages have extremely variable life spans, but generally are considered long-lived cells.

Neutrophils

The neutrophil is the most abundant leukocyte in circulation, comprising up to 75% of circulating white blood cells; up to two-thirds of the hematopoietic output of the bone marrow is composed of neutrophils (Tizard, 2013). Neutrophils are the first line of defense in innate immunity as they act as phagocytes and also have direct killing capabilities. Neutrophils share a common precursor cell with monocytes and differentiate under the influence of granulocyte stimulating factor. Neutrophils take approximately 6 days to be produced and have a relatively short life span of less than 12 h after entering the blood.

Eosinophils

Eosinophils have phagocytic and bactericidal capabilities, play a role in immune defense against parasites, and inactivate mediators released from mast cells (Stockham and Scott, 2008). Eosinophil precursors differentiate from myeloid precursor cells stimulated by IL-3, IL-5, IL-6, and granulocyte-macrophage colony-stimulating factor; further IL-5 exposure

stimulates their differentiation into eosinophiloblasts which then mature into eosinophils. After minutes to hours in the blood, eosinophils migrate into tissues where they may persist for up to a few weeks.

Basophils

Basophils are the least abundant granulocyte population as they account for less than 1% of circulating leukocytes. Basophils play a role in immediate hypersensitivity disorders, as well as atopy, allergic contact dermatitis, and possibly autoimmune diseases such as systemic lupus erythematosus (Siracusa et al., 2011). Basophils can act as antigen-presenting cells, and they have antiparasitic functions similar to eosinophils. Basophils differentiate from myeloid stem cells under the influence primarily of IL-3 and other, as yet unidentified cytokines. Once mature, basophils have an estimated life span of 60−70 h (Siracusa et al., 2011).

Lymphocytes

Circulating lymphocytes account for 20%−35% of the leukocyte population. Lymphocytes differentiate from the common lymphoid precursor cell under the influence of IL-7, Flt3 ligand, and stem cell factor; further exposure to IL-7 stimulates maturation of T cells within the thymus, whereas Flt3 ligand stimulates B cell maturation in the bone marrow. Refer to Chapter 24, "Immunotoxicity Biomarkers," in this book for more detailed descriptions of lymphoid cells.

Soluble Mediators

A large number of soluble mediators have been identified that exert tremendous influence in the proliferation, differentiation, growth, maturation, and function of cells of the bone marrow and blood (Fig. 23.1). These include growth factors, colony-stimulating factors, interleukins, chemokines, and neuropeptides. Stem cell factor, an activator of the receptor tyrosin kinase c-Kit, is crucial for the initiation of normal hematopoiesis and, along with IL-6 and Flt3 ligand, mediates the commitment of pluripotential cells to lymphoid or myeloid lineages (Lennartsson and Ronnstrand, 2012). Flt3 ligand is another hematopoietic cytokine that interacts with tyrosine kinase III receptors essential for the initiation, expansion, and maintenance of hematopoiesis (Wodnar-Filipowicz, 2003). Expression of Flt3 receptors is limited to hematopoietic cells lacking lineage-specific markers, so they are found on the most primitive (i.e., least differentiated) hematopoietic cells. Stem cell factor and Flt3 ligand act synergistically with a wide range of specific colony-stimulating factors, growth

factors, and interleukins (especially IL-3, IL-5, IL-6, IL-7, IL-11, and IL-15) to stimulate proliferation and mediate the commitment of cells to their respective lineages (Lyman, 1995).

MECHANISMS OF HEMATOTOXICITY

With so many cells, mediators, and enzymes involved in the production and maintenance of the bone marrow and blood, there are countless potential mechanisms by which toxicants can exert their adverse effects. Within the hematopoietic stem cell population only a fraction of cells is undergoing replication, with the majority of cells in a resting phase that protects them from toxic insult from external forces that target rapidly dividing cells (e.g., ionizing radiation, chemotherapeutic agents). Some toxicants such as lindane are directly cytotoxic to hematopoietic progenitor cells regardless of the phase of cell cycle, causing necrosis of cells with subsequent myelosuppression (Parent-Massin et al., 1994).

Direct damage to mature cells by toxicants can lead to hemolytic anemia, thrombocytopathy, or depressed immune function due to depletion of erythrocytes, platelets, or leukocytes, respectively. (Rebar, 1993) Indirect injury to blood or bone marrow cells can occur through a variety of means, including stimulation of immune responses against cell membranes or other structures, interference with cell surface receptors preventing normal cell function, and interference with cytokines or other soluble mediators necessary for hematopoietic cell proliferation, differentiation, maturation, or maintenance. For instance, the antineoplastic paclitaxel has been shown to alter the bone marrow microenvironment, which decreases the sensitivity of late erythroid progenitors to erythropoietin, resulting in depletion of erythroid precursors during late erythropoiesis (Juanisti et al., 2001). Toxicants may interfere with enzyme systems essential for normal cell function by inhibition of enzymes or interference with cofactors, such as occurs with interference with folate or cyanocobalamin by ethanol (Bloom and Brandt, 2008), and with decreased erythrocyte δ-aminolevulinic acid dehydrogenase activity in lead toxicosis (Jangid et al., 2012; Feska et al., 2012). Toxicant-induced alteration of enzymes involved in hemoglobin synthesis can result in mature erythrocytes with reduced oxygen-carrying capacity due to deficient hemoglobin levels. Platelet function can be permanently disabled by inhibitors of cyclooxygenase such as aspirin (Hall and Mazer, 2011). Inhibition of vitamin K epoxide reductase by coumadin-based anticoagulants (e.g., warfarin) results in depletion of vitamin K-dependent clotting factors II, VI, IX, and X, resulting in coagulopathy. Mature erythrocytes with normal hemoglobin levels can have their oxygen-carrying capacity

altered by toxicants such as carbon monoxide or methemoglobin-inducing agents (e.g., nitrites).

BIOMARKERS OF HEMATOTOXICITY

A variety of assays are used clinically and nonclinically to evaluate the status of the bone marrow and blood (Table 23.2). Although newer technologies such as flow cytometry and automated cell counters have improved the speed and efficiency of some of the benchmark assays, microscopic examination of these tissues is still necessary for full evaluation of bone marrow and blood cell status. Biomarkers of leukocyte toxicity are discussed in Chapter 22, "Immunotoxicity Biomarkers."

MARKERS OF HEMATOPOIETIC/ HEMATOLOGIC TOXICITY

Complete Blood Count

The complete blood count (CBC) is the easiest, quickest, and most cost-effective method to get a rapid snapshot of the status of the blood and bone marrow, making it the most efficient means of screening the blood for evidence of toxicant-related injury (Adewoyin and Nwogoh, 2014). At a minimum, the CBC should include the following parameters: hematocrit (also called packed cell volume; Hct or PCV), mean cell volume (MCV), mean cell hemoglobin concentration (MCHC), total white blood cell count (WBC), differential white blood cell count, platelet count, and evaluation of stained blood smears.

Although modern blood analyzers can perform the cell counts, manual evaluation of the stained blood smear is necessary to verify accuracy of the counts when pathologic conditions are present. For example, nucleated red blood cells present in the circulation of lead poisoning cases may be read out by the machine as white blood cells. Similarly, morphologic aberrations due to toxicants, such as the presence of Heinz bodies in oxidant-induced hemolytic anemias or basophilic stippling in lead toxicosis, will need to be evaluated visually (Table 23.3). Platelet clumping may result in falsely lowered manual and automated platelet counts, again emphasizing the need for light microscopic confirmation. Abnormalities in hematocrit can include polycythemia, such as is seen with cobalt (Simonsen et al., 2012). Anemia is the more common hematocrit abnormality and may be the result of increased erythrocyte loss, such as in hemolytic anemia induced by oxidants, or decreased production due to bone marrow suppression. Mean cell volume is a measure of the size of erythrocytes and may be decreased in chronic lead

toxicosis, as may the MCHC, resulting in a microcytic, hypochromic anemia.

Markers of Erythrocyte Toxicity

Biomarkers of erythrocyte toxicity include quantitative and qualitative evaluation of erythrocytes for abnormalities in number and/or morphology and evaluation for presence of abnormal compounds. Packed cell volume, or hematocrit (PCV, Hct), is the value representing the percentage of erythrocytes in the blood. Increases in PCV can occur following exposure to bone marrow stimulants such as erythropoietin or with exposure to toxicants that increase erythropoietin levels (e.g., cobalt) (Simonsen et al., 2012). Decreased PCV can occur following exposure that causes damage to mature erythrocytes or that damages or inhibits replication of erythrocyte progenitors within the bone marrow. Erythrocytic toxicants may cause identifiable alteration in erythrocyte morphology, which can give clues as to the type of toxicant that caused the damage (Table 23.3). For instance, lead toxicosis is sometimes associated with the presence of relatively large numbers of nucleated red blood cells or with basophilic stippling of erythrocytes, and echinocytosis is a prominent feature in many envenomations (Flachsenberger et al., 1995). Similarly, the presence of methemoglobin and/or Heinz bodies in erythrocytes is suggestive of injury due to oxidative compounds such as nitrites, chlorates, and phenols. In addition to reduced erythrocyte numbers and morphologic alterations, oxidative erythrocyte injury resulting in hemolysis will cause elevations in total serum bilirubin secondary to hemolysis.

Some toxicants cause no visible morphological change to red blood cells, but instead alter oxygen-carrying capacity to such a degree as to cause life-threatening hypoxia to the patient. Carbon monoxide binds to hemoglobin with high affinity, shifting the oxygen dissociation curve to the left, preventing oxygen delivery to tissues, and leaving no apparent morphological change in the erythrocyte, although grossly visible cherry red mucous membranes and blood are clues to the presence of hyperoxygenated blood (Guzman, 2012). Carboxyhemoglobin levels can be quickly measured in most hospital settings; levels over 20% are generally associated with signs of toxicosis, including shortness of breath, headache, and dizziness, whereas levels over 50% can be lethal.

Lead poisoning is a significant concern in many parts of the world because of past and/or current use of lead-based paints and gasoline (Liu et al., 2008). Lead alters erythrocyte function through interference with heme synthesis. Inhibition of δ-aminolevulinic acid dehydratase and ferrochetolase interferes with the insertion of lead into the protoporphyrin ring during heme

TABLE 23.2 Biomarkers of Hematotoxicity (See Also Table 22.1 for Additional Leukocytes Biomarkers)

Assay	Matrix	Endpoint	Example Toxicant
BIOMARKERS OF TOXIC EFFECTS ON BONE MARROW			
Bone marrow evaluation	Bone marrow	Altered M:E[a]	Alkylating agents (↑), azathioprine (↑), phenols (↓)
		Cellularity ↓	Busulfan
		Cellularity ↑	Cobalt
Morphologic alterations	Methotrexate (Megaloblastosis)		
Progenitor cell colony formation	Bone marrow, blood	Colony formation ↓	Clopidogrel, lindane
Metabonomics profiles	Urine	Altered metabolite profiles	Benzene (biomarker of exposure)
Proteomic profiles	Serum, blood	Altered protein profiles	Benzene
Toxicogenomic assays	Blood cells, bone marrow	Altered gene expression	Benzene, cisplatin, carboplatin
Glycophorin A gene loss mutation assay	Erythrocytes	Increased	Benzene
BIOMARKERS OF TOXIC EFFECTS ON HEMOGLOBIN			
δ-Aminolevulinic acid levels	Urine	Increased levels	Lead
δ-Aminolevulinic acid dehydratase activity	Blood	Decreased activity	Lead
Mean cell hemoglobin concentration (MCHC)	Blood	Decreased levels	Lead
Coproporphyrin	Urine	Increased levels	Lead
Zinc protoporphyrin	Blood	Increased levels	Lead
BIOMARKERS OF TOXIC EFFECTS ON ERYTHROCYTES			
Hematocrit/Packed cell volume	Blood	Increased Hct	Cobalt
	Decreased Hct	Oxidants, lindane	
Mean cell volume (MCV)	Blood	Decreased MCV	Lead
Reticulocyte count	Blood	Increased	Oxidants causing hemolysis (e.g., arsine)
Carboxyhemoglobin level	Blood	Increased	Carbon monoxide
Methemoglobin level	Blood	Increased	Oxidants (e.g., methylene blue)
Heinz body preparation	Blood	Increased	Oxidants (e.g., nitrites)
BIOMARKERS OF TOXIC EFFECTS ON THROMBOCYTES			
Bleeding time (BT)	In vivo assay	Prolonged	Aspirin
Platelet count	Blood	Decreased	Heparin
Direct platelet assays	Blood	Decreased activity	Aspirin
BIOMARKERS OF TOXIC EFFECTS ON LEUKOCYTES			
Leukocyte count	Blood	Increased neutrophils	Corticosteroids
		Decreased neutrophils	Phenothiazine
		Increased eosinophils	L-tryptophan
		Decreased eosinophils	Corticosteroids
		Increased monocytes	Corticosteroids
		Increased basophils	Allergens

TABLE 23.3 Toxicant-Induced Erythrocyte Abnormalities

Erythrocyte Abnormality	Description	Significance	Example Toxicant
Basophilic stippling	Dark blue to purple dots or specks	Represents aggregated ribosomes	Lead-induced inhibition of pyrimidine 5′-nucleotidase results in decreased RNA degradation
Eccentrocyte	Eccentric dense staining hemoglobin with adjacent clear crescent or edge	Represents fusion of membranes damaged by oxidants	Nitrites
Echinocyte	Sharp, spiny membrane projections	Represents alterations to lipid membrane	Crotalid venom
Heinz body	Pale, rounded protruding defect in membrane; dark blue with new methylene blue stain	Represents precipitated hemoglobin due to oxidative injury	Nitrites, methylene blue
Nucleated erythrocyte	Presence of dark nucleus in red blood cell; basophilic tint to cytoplasm	Represents accelerated erythropoiesis and early release from bone marrow	Lead
Reticulocyte	Aggregated or punctated basophilic staining of cytoplasm	Represents residual RNA; accelerated erythropoiesis	Oxidant-induced hemolytic anemia
Siderotic granules	Fine granular basophilic inclusions	Represents iron accumulation in damaged mitochondria	Lead
Spherocyte	Decreased central pallor, decreased diameter	Represents membrane loss	Snake envenomations

formation (Sakai, 1995). Biomarkers of lead toxicosis include elevations in urinary δ-aminolevulinic acid and coproporphyrin levels, increased zinc protoporphyrin levels in the blood, decreased δ-aminolevulinic acid dehydratase activity, and decreased levels of erythrocyte hemoglobin (Jangid et al., 2012).

Markers of Platelet Toxicity

Toxic effects on platelets can be reflected by decreased platelet numbers and/or decreased platelet function, both of which can lead to increased incidence of bleeding due to loss of a critical hemostatic "plug" in the face of vascular injury. Decreased platelet numbers are readily identified during routine CBC analysis, although spurious thrombocytopenia can occur due to platelet clumping within the blood sample (Stockham and Scott, 2008). Bone marrow analysis may be helpful in determining if decreased platelet numbers are due to increased consumption or decreased megakaryocyte production. Decreased platelet function, such as occurs with cyclooxygenase inhibitors such as aspirin, can be measured using direct assays of platelet function. Bleeding time is a quick and rudimentary test of platelet

function, which is often done as a prescreening test to determine if further platelet and/or coagulation assays are indicated. A small cut is made in the skin with a lancet or needle and the amount of time that it takes for the bleeding to cease is measured.

MARKERS OF BONE MARROW TOXICITY

Bone Marrow Evaluation

Evaluation of bone marrow can be done using histopathology, cytology, or flow cytometry. Histopathological evaluation of hematoxylin and eosin-stained (H&E) sections of bone marrow tissue may be used as an initial screening tool but has some limitations, so it is prudent to prepare bone marrow smears at the time of autopsy or biopsy for cytological examination in case further evaluation is needed (Elmore, 2006). Histopathology can provide estimates of cellular density, myeloid/erythroid (M:E) ratios, amount of hemosiderin present, and abnormalities in the numbers of megakaryocytes, adipocytes, and bone marrow stromal cells. Additionally, abnormalities such as necrosis, hemorrhage, fibrosis, granulomas, neoplasia, or alterations in endosteum, bone, and vasculature can be detected (Reagan et al., 2011). Because many of the mononuclear cells in bone marrow "all look alike" under H&E, differentiating the lymphoid lineage cells from early myeloid precursors can be difficult.

Cytological examination of Romanowsky-stained bone marrow smears may be more rewarding in cases where there is a need to differentiate early hematopoietic precursors, to correlate changes in peripheral cell numbers with bone marrow hyper- or hypocellularity, to investigate suspected abnormal erythropoiesis, to differentiate lymphoid from erythroid precursors, or to determine maturation indices of one or more cell lines (Elmore, 2006). Flow cytometry may be used in addition to or instead of cytology to further characterize alterations in bone marrow cells. However, although flow cytometry can readily classify cells into the major cell lineages and produce rapid counts of large numbers of cells, it does not evaluate cellular morphology; for this reason, flow cytometric methods are generally used in addition to either cytology or histopathology (Reagan et al., 2011).

Bone marrow evaluation generally starts with estimation of the relative cellularity and the M:E ratio, which compares the relative proportions of myeloid cells to erythrocytic cells (Table 23.4). Generalized hypocellularity of bone marrow can occur due to infection, irradiation, or exposure to various drugs or toxicants such as benzene, cephalosporins, chloramphenicol, or phenylbutazone (Bloom and Brandt, 2008; Bloom et al., 1987). Because immature hematopoietic cells are difficult to differentiate, the M:E ratio obtained by visual inspection is a relatively subjective estimation (Stockham and Scott, 2008). In most healthy mammals, the M:E ratio trends toward slightly >1, i.e., a somewhat greater proportion of myeloid cells (Elmore, 2006). Increases in M:E ratio can be due to increases in myeloid cells or decreases in erythrocytic cells, which can be determined by estimating the overall cellularity of the marrow. Hypercellular marrow with increased M:E ratio suggests myeloid hyperplasia, whereas hypocellularity of hematopoietic cells and increased M:E ratio suggests erythroid hypoplasia. The most common cause of myeloid hyperplasia is increased demand during times of acute or chronic inflammation, which oftentimes will also be reflected in the results of a CBC. Erythroid hypoplasia can occur in response to drugs such as isoniazid or azathioprine (Thompson and Gales, 1996).

Decreases in M:E ratio can occur during times of erythroid hyperplasia, such as occurs in response to acute hemorrhagic anemias or cobalt exposure, or to myeloid hypoplasia, such as may occur with carbamazepine or clozapine (Simonsen et al., 2012; Bloom and Brandt, 2008).

TABLE 23.4 Bone Marrow Evaluation, Assessments, and Potential Causative Agents

M:E Ratio	Cellularity	Assessment	Example Causes
Decreased	Hypercellular	Erythroid hyperplasia	Erythropoietin therapy or excess Hemorrhagic anemia Hemolytic anemia: e.g., acetanilide, nitrofurantoin, phenol, sulfonamides Cobalt
Decreased	Hypocellular	Granulocytic hypoplasia	Alkylating agents, benzene, carbamazepine, cisplatin, clozapine, isoniazid, lindane, methimazole, nitrosourea
Normal	Hypocellular	Bone marrow hypoplasia	Alkylating agents, benzene, chloramphenicol, chlorinated hydrocarbons, diclofenac, mycotoxins, sulfonamide
Increased	Hypercellular	Granulocytic hyperplasia	Inflammation leukomogenic response: e.g., alkylating agents, azathioprine, benzene (chronic), bleomycin, high-dose ionizing radiation, procarbazine
Increased	Hypocellular	Erythroid hypoplasia	Chronic renal disease (decreased erythropoietin) azathioprine, estrogen, isoniazid, phenytoin

Bone marrow examination should include evaluation of all of the major cellular components for anomalies in morphology. Toxicants such as ethanol, lead, or isoniazid can cause defects in synthesis of the porphyrin ring, resulting in failure of iron to incorporate into heme and leading to precipitation of iron within erythrocyte mitochondria, resulting in sideroblastic anemia (Bloom and Brandt, 2008). Megaloblastic anemia develops when folate or vitamin B_{12} deficiencies occur either due to nutritional deficiency or due to effects of toxicants such as phenytoin, phenobarbital, and sulfasalazine. In megaloblastic anemia, asynchronous development of nucleus and cytoplasm in erythroid precursors results in cells with abundant cytoplasm and immature, enlarged nuclei displaying exaggerated chromatin patterns (Stockham and Scott, 2008).

Progenitor Cell Colony Formation

Evaluation of hematopoietic cells in early differentiation stages is difficult by means of light microscopy and flow cytometry due to lack of distinctive cell markers. Bone marrow and blood cells cultured in a semisolid methylcellulose—based medium containing appropriate growth factors will proliferate and differentiate into colonies of maturing hematopoietic cells (Wognum et al., 2013; Masenini et al., 2012). Classification and enumeration of the colonies is performed by light microscopy or flow cytometry and allows for the quantification of erythroid, myeloid, lymphoid, and megakaryocytic cell lineages to detect toxicant-induced increases or decreases in specific hematopoietic cell lines.

MARKERS OF HEMOSTATIC TOXICITY

Prevention of excessive loss of blood is essential to maintain the integrity of the hematologic system; an elaborate and overlapping coagulation system, involving platelets and clotting factors, has evolved to ensure prompt repair of vascular leakage. Hemostasis involves sequential activation of serine proteases, culminating in the formation of fibrin clots to seal defects in the vasculature (Fig. 23.2).

Although hypercoagulable states can occur secondary to exposure to some chemotherapeutic agents (e.g., tamoxifen), most alterations in hemostatic ability are due to deficiencies in one or more components of the coagulation cascade resulting in ineffective coagulation and predisposing to uncontrolled hemorrhage. Decreases in coagulation factors can occur due to reduced synthesis or increased clearance. Perhaps the most common cause of decreased coagulation factor synthesis is due to vitamin K deficiency induced by anticoagulants

such as warfarin and related compounds such as diphacinone and brodifacoum. These anticoagulants inhibit vitamin K epoxide reductase, a vital enzyme in the regeneration of vitamin K, resulting in an inability to generate vitamin K-dependent coagulation factors II, VII, IX, and X (Stafford, 2005). As these coagulation factors are depleted, coagulation becomes impaired and incomplete coagulation proteins are released into the circulation. Defects in coagulation can be measured using several assays, including activated partial thromboplastin time (APTT), prothrombin time (PT), proteins induced by vitamin K antagonism or absence (PIVKA), and measurement of individual coagulation factors. The APTT, PT, and PIVKA assays are the most frequently used for detecting early anticoagulant-induced coagulopathy (Stockham and Scott, 2008). The APTT and PT assays are performed by incubating test plasma with partial thromboplastin (APTT) or thromboplastin (PT) along with other intermediates and measuring the time until clot formation occurs. The PIVKA assay used in human diagnostic laboratories directly measures the incompletely carboxylated coagulation factors, whereas the PIVKA assay used in veterinary medicine (Owren's thrombotest) is essentially a modified PT assay (Stockham and Scott, 2008). Individual coagulation factors can be measured, and although these assays are more commonly used for suspected inherited coagulation factor deficiencies (e.g., hemophilia), certain xenobiotics can result in deficiencies of individual coagulation factors; for instance, ciprofloxacin
FIGURE 23.2 Schematic diagram of the coagulation cascade. Coagulation initiates with activation of intrinsic factor XII to XIIa and/or activation of the combined factors VII and III to VIIaIIIa. XIIa initiates a series of factor activations culminating in production of activated factor VIII. Factors VIIaIIIa and/or VIIa then activate factor X, triggering activation of factor V, which triggers the conversion of prothrombin to thrombin. Thrombin acts on fibrinogen to form fibrin. Enzymatic action by activated factor XIII in presence of ionized calcium results in cross-linkage of fibrin strands. *indicates vitamin K-dependent factors.

has been associated with transient acquired von Willebrand syndrome due to increased proteolysis of von Willebrand factor (Michiels et al., 2011).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Our understanding of the intricate connections responsible for the normal functioning of the blood and bone marrow has expanded tremendously over the last few decades. With this expanding knowledge has come the realization that this delicately balanced system is highly susceptible to injury induced by xenobiotics such as pharmaceuticals and environmental toxicants. Toxicant-induced bone marrow injury can have serious repercussions throughout the body and can put the host at risk of infection, hypoxic injury, or uncontrolled hemorrhage. This ripple effect underscores the need to determine that new and existing pharmaceuticals and environmental compounds pose minimal risk to blood or bone marrow components. Future research to further our knowledge of the mechanisms of toxicity of hematopoietic tissues will enable the development of pharmaceuticals, pesticides, and other compounds that pose less of a risk to humans, other animals, and the environment. Newer technologies in research such as toxicogenomics, proteomics, and metabonomics will allow further progress in mechanistic investigation and risk assessment.

Toxicogenomic profiles have been proposed as potentially useful biomarkers for exposure to various toxicants. For instance, circulating reticulocyte expression of the hemoglobin beta chain complex, aminolevulinic acid synthase 2, and cell division cycle 25 homolog B genes was altered following exposure of rats to myelosuppressive agents such as linezolid, cisplatin, and carboplatin, suggesting that this pattern of gene expression may pose a useful biomarker for myelosuppressive anemia in rats (Uehara et al., 2011). Microarray evaluation of the hepatic expression of six genes (Alas2, beta-glo, Eraf, Hmox1, Lgals3, and Rhced) showed high negative correlation with red blood cell counts and high positive correlation with total serum bilirubin levels in rats with drug-induced hemolysis, suggesting that these genes may be useful biomarkers for hemolytic anemia (Rokushima et al., 2007). Further validation of these and other toxicogenomic profiles will be required to determine if similar changes in gene expression are shared among other mammalian species. Benzene is a potent myelotoxic compound associated with aplastic anemia, acute myeloid leukemia, and other blood disorders in humans (Zhang et al., 2010). In humans, increased levels of gene duplication mutations in glycophorin A have been proposed as a potential biomarker for cumulative exposure to benzene, although sensitivity issues have been raised (Rothman et al., 1995; Smith and Rothman, 2000).

Proteomics is the branch of toxicogenomics that studies alterations in protein levels and posttranslational protein modifications that result from altered gene expression caused by exposure to toxicants (Joo et al., 2003). Two proteins, platelet factor 4 and connective tissue activating peptide III, have been found to be consistently downregulated in patients exposed to benzene when compared with control individuals and are being investigated as potential biomarkers for the early biologic effects of benzene (Zhang et al., 2010). Similarly, downregulation of platelet basic protein and apolipoprotein B100 has been detected in humans with hematotoxicity due to exposure to benzene (Huang et al., 2012). Plasma haptoglobin levels in the plasma of pancreatic cancer patients have been shown to be correlated to risk of hematologic adverse events from the chemotherapeutic agent gemcitabine (Matsubara et al., 2009) Further work is needed to determine if these potential biomarkers will prove to be reliable in determining risks of benzene exposure.

Metabonomics is a means of metabolic profiling to determine biological markers for mechanistic and diagnostic study in toxicology, pharmacology, and biomedicine. Benzene and its metabolites have been found in breath, blood, and urine, and levels in these matrices have been used as biomarkers for exposure and risk assessment in humans (Weisel, 2010). In mice, metabonomic profiles of benzene metabolites in urine have been further utilized as a sensitive tool to detect benzene-induced toxicity (Sun et al., 2012).

Immunotoxicity Biomarkers

Sharon Gwaltney-Brant

Veterinary Information Network, Mahomet, IL, United States

INTRODUCTION

Employing a variety of cell types (e.g., granulocytes, macrophages, lymphocytes) and soluble mediators (e.g., interleukins, interferons, tumor necrosis factors), the immune system identifies, processes, and destroys foreign invaders (e.g., bacteria, viruses, fungi) and endogenous neoplasms. The immune system can distinguish between nonself (foreign) and selfantigens, effectively defending the body against foreign and domestic invaders that would threaten the homeostatic stability of the host. Immune responses result in the destruction and/or sequestration of nonself invaders to limit their ability to injure the host.

The complex interplay between the various components of the immune system achieve, under normal conditions, a delicate balance of physiological reactions that maintain the integrity and health of the host. Disruption of this delicate balance can result in a system-wide malfunction that can have deleterious effects on the host. A wide variety of toxicants can act to alter the immune system in such a way that the normal immune response is attenuated, intensified, or directed against the body's own tissues. Immunosuppression may result in more frequent and/or more severe infections, infections by organisms with normally low pathogenicity (opportunistic infections), or increased incidence of neoplasia (Descotes et al., 1995). Immunostimulation may result in increased incidence of allergic responses or autoimmunity.

THE IMMUNE SYSTEM

Innate immunity is the first line of defense against nonself invaders, and it includes physical and biochemical barriers such as skin and mucosal barriers, mucosal cilia and secretions, physiological alterations (e.g., fever), and cellular interactions. Innate immune responses are tasked with preventing pathogens (e.g., microbes, neoplastic cells)

from gaining a foothold in the body, or, failing that, to hold off the pathogenic assault until reinforcements, in the form of cells of the adaptive immune response, can be recruited to assist in eliminating the threat. Adaptive (acquired) immunity encompasses the production of an immune response against nonself and utilizes specialized populations of cells to identify, isolate, and process antigens and initiate the appropriate agonistic response. Acquired immunity requires memory of previous exposure to trigger a response against a specific invader. At the heart of the immune system is a complex mixture of lymphoid organs, specialized cell types, and soluble mediators that interact in a complex and highly regulated fashion to generate appropriate responses to exogenous and endogenous threats to the integrity of the body.

LYMPHOID ORGANS AND TISSUES

Lymphoid organs form the stationary framework in which the migratory immune cells are generated, mature, and interact with antigens (Kaminski et al., 2008). Immune cells arise from the differentiation of self-renewing pluripotent stem cells within the bone marrow (Fig. 24.1). During differentiation, cells become committed to three distinct cell lineages—null cells, lymphoid precursors or myeloid precursors—from which the various immune cells arise. Lymphoid precursors further commit to either B or T cell differentiation, whereupon T cell precursors migrate to the thymus where they are programmed to distinguish between self and nonself.

Because of their roles in the production of B and T cells, the thymus and bone marrow are considered primary lymphoid organs. Secondary lymphoid organs include lymph nodes and spleen, which filter lymph and blood, respectively, and where naïve B and T cells are introduced to antigens. Tertiary lymphoid tissues/organs include Peyer's patches and surface-associated
FIGURE 24.1 Ontogeny of the mammalian immune system. Blackwell Publishing, Ames, IA; Tizard (2013).*

lymphoid aggregates, such as bronchial-associated lymphoid tissue and gut-associated lymphoid tissue. Tertiary lymphoid tissues are the sites where memory and effector cells perform immunoregulatory, as well as immunologic, functions.

CELLS OF THE IMMUNE SYSTEM

Leukocytes, or white blood cells, are the cells involved in mediating immune reactions within the body. Whether producing antibodies, phagocytosing foreign invaders such as bacteria, presenting antigens for stimulation of humoral or cell-mediated immunity, or directly attacking neoplastic or virally infected cells, leukocytes are the workhorses of the immune system. Although independent cells, leukocytes are intimately linked via a chemical network of cytokines and chemokines that regulate the movement and activity of immune and inflammatory cells within the body.

B Cell Lymphocytes

B cells are produced and mature in the bone marrow. The role of the B cell lineage in adaptive immunity is to produce and secrete antibodies in response to binding of soluble antigen to receptors on the B cell membrane surface (Dean et al., 2008). Following antigenic stimulation, interaction between B cells and T helper cells triggers the differentiation of B cells into antibody-secreting plasma cells or into memory B cells, which provide for a rapid antibody response on re-exposure to those antigens at some future time. Five classes of antibody (immunoglobulin, Ig) are produced by plasma cells: IgA, IgD, Ig E, IgG, and IgM. Each antibody class has distinct biological functions in immune responses. Immunoglobulin M secretion predominates in the early stages of an initial immune response, while IgG is primarily secreted during secondary immune responses. Immunoglobulin D functions as a lymphocyte receptor, while IgA is the primary antibody associated with seromucous

secretions and IgE mediates allergic reactions. Antibodies bind specific antigens on invading organisms, resulting in direct neutralization or in opsonization that facilitates phagocytosis. Antibodies may also coat target cells, triggering cytotoxic responses from Fc receptor–bearing natural killer cells. Complement fixation by IgG and IgM triggers cytotoxicity and phagocytosis of foreign invaders.

T Cell Lymphocytes

T cells are produced in the bone marrow and migrate to the thymus, where they mature. In the thymus, T cells are programmed to distinguish between antigens belonging to the host ("self") and those foreign to the host ("nonself") (Kaminski et al., 2008). T cells differentiate into either cytotoxic T cells or helper T cells, and, like B cells, T cells develop into memory cells that recognize specific antigens. However, unlike B cells, which can be activated by binding directly to soluble antigen, T cells require the intervention of antigen-presenting cells (APCs) such as macrophages or dendritic cells to become activated.

T helper (Th) cells function in a primarily regulatory role, facilitating the activities of B cells and other T cells through interactions between surface receptors and secretion of immunoregulatory cytokines (Dean et al., 2008). Several subtypes of Th cells have been identified based on differences in cytokine production and cell types impacted. Th1 cells are produced in response to interleukin (IL) 12, secrete interferon-γ, and are instrumental in the generation and maturation of cytotoxic T cells. Th2 cells develop in response to IL-4 and are major producers of IL-4, IL-5, and IL-13. These cells are essential in humoral responses and defense against parasites, and are also involved in allergic responses and asthma. Alterations in Th ratios have been identified with exposure to several toxicants; for example, lead (Pb) alters the balance of Th1 and Th2 cells, resulting in decreased Th1 (cell-mediated) response (DeWitt et al., 2011). Th3 cells are members of a group of regulatory T cells (Tregs) that suppress responses to self-antigens, as well as attenuating responses mediated by Th1 and Th2 cells (Corsini et al., 2011). Th17 cells develop in response to IL-6 and IL-13 and produce IL-17 and IL-21 (Mishra and Sopori, 2012). Th17 cells are important in recruitment of neutrophils and macrophages to areas of infection, and they have been implicated as principal cells involved in autoimmune and inflammatory diseases.

Cytotoxic T cells are effector cells that release specialized proteins that result in death and lysis of the target cell (Janeway et al., 2001). Recognition of specific antigens on target cells results in the release of granules from cytotoxic T cells. Within the granules are polymers of the protein perforin and proteases collectively referred to as granzymes. Polymerization of perforin forms a cylindrical structure that is inserted into the target cell membrane, allowing water, solutes, and granzymes to enter the cell. Within the cell, granzymes initiate an enzyme cascade leading to activation of nucleases and subsequent programmed cell death. Cytotoxic T cells also have a regulatory role by mediating suppression of B and T cell activity (Dean et al., 2008).

Neutrophils

Neutrophils (polymorphonuclear neutrophils, PMNs) derive from the granulocyte lineage of the bone marrow and are the most abundant leukocyte type in mammals. Abundant in the blood, neutrophils are the first cell type to arrive at an area of acute inflammation caused by infection or injury. Cytokines released by neutrophils at the inflammatory site recruit further immune cells, amplifying the inflammatory response. Toll-like receptors (TLRs), type I transmembrane proteins, within the neutrophil membrane are responsible for recognition of microbial-associated molecular patterns (MAMPs) such as bacterial lipoproteins, lipopolysaccharide, and peptidoglycan (Mishra and Sopori, 2012). Binding of TLRs to these MAMP ligands triggers the production of immunostimulatory and proinflammatory mediators. Neutrophils have phagocytic activity and can directly kill or induce apoptosis in target cells through the release of reactive oxygen species (Kaminski et al., 2008). Extracellular killing of foreign pathogens by neutrophils is accomplished by the ejection of cytoplasmic contents, nuclear histones, and chromatin in the form of a mesh that ensnares microbes which are subsequently killed by proteins and histones within the matrix of the neutrophil extracellular trap, as this mechanism has been termed (Gray et al., 2013). Recruitment of other immune cells such as Th1 cells and B cells to sites of inflammation is mediated by release of cytokines from activated neutrophils.

Macrophages

Derived from circulating blood monocytes, macrophages are phagocytic cells that reside in a variety of tissues, including liver (Kupffer cells), lung (pulmonary alveolar macrophages or PAMs, pulmonary interstitial macrophages or PIMs), skin (Langerhans cells), and brain (microglia) (Dean et al., 2008). Like neutrophils, macrophages possess TLRs that aid in recognition of microbes, and they function in both innate and adaptive immunity. Besides phagocytosis of pathogens, macrophages can act as APCs to T cells, secrete proinflammatory cytokines, and remove necrotic debris from

inflammatory sites. Macrophages facilitate muscle regeneration through the secretion of substances that stimulate muscle proliferation, repair, and regeneration. In addition to their beneficial actions, macrophages can at times contribute to the progression and/or severity of certain disease conditions. Phagocytosis of pathogens or particles resistant to degradation can lead to chronic granulomatous diseases such as tuberculosis and asbestosis (Dean et al., 2008; Mishra and Sopori, 2012). Macrophages have also been implicated in enhancing the growth of certain tumors by establishing tumor promoting microenvironments, promoting angiogenesis, promoting metastasis, and suppressing antitumor immune response.

Natural Killer Cells

Natural killer cells (NK) are non-B, non-T lymphocytes that do not require specific antigenic activation to detect and kill pathogens, making NK a component of innate immunity. NK are important factors in destroying virus-infected cells and limiting the progression and spread of tumors. NK cells are located predominantly in the blood, lymphoid organs, liver, and lung. NK exert their cytolytic effects using perforin and granzymes in a manner similar to cytotoxic T cells (Kaminski et al., 2008). Although NK are considered important components of innate immunity, they are also involved in the initiation and regulation of acquired immunity through their response to and secretion of immunoregulatory cytokines (Dean et al., 2008).

Mast Cells

Mast cells originate in the bone marrow and are released into the blood as promastocytes, which then enter surface tissues with frequent exposure to potential pathogens or allergens such as the skin, respiratory tract, and alimentary tract (Galli et al., 2008). Once in their resident tissues, the promastocytes further differentiate and mature into recognizable mast cells. Mast cells play important roles in both innate and acquired immune responses. Mast cells can be activated by a variety of stimuli, including IgE, specific antigens, physical injury, chemical injury, or activated complement proteins (Prussin and Metcalfe, 2003). Mast cells function to destroy pathogens, increase vascular permeability, stimulate bronchial smooth muscle contraction, and degrade toxic endogenous peptides or exogenous venom components (Galli et al., 2008). Immunoregulatory functions of mast cells include recruitment of other immune cells, enhancement of antigen presentation to T cells, promotion of B cell IgE production, promotion of Th2 cell responses, and promotion of production of chemokines and cytokines of airway smooth muscle. Mast cells also serve to suppress sensitization for contact hypersensitivity, suppress cytokine production by T cells and monocytes, suppress proinflammatory cytokine and chemokine production by keratinocytes, and enhance the ability of dendritic cells to reduce T cell proliferation and cytokine production.

SOLUBLE MEDIATORS OF IMMUNITY

Cytokines

Cytokines are glycoproteins that play crucial roles in the regulation of both innate and acquired immune responses. Cytokines mediate cell-to-cell interactions and are important regulators of immune cell proliferation, differentiation, maturation, activation, migration, inhibition, and effector functions (Kaminski et al., 2008). Unlike hormones that act on cells of distant organs, cytokines are produced and act locally and they are rapidly cleared by the circulation; these factors play important roles in restricting their activity to the immediate environment. Th cells produce a large proportion of cytokines, but many other cells, both immune and nonimmune, are also capable of producing cytokines. A plethora of cytokines have been identified, and they can be roughly placed (with overlap in many cases) into five major classes based on function: interleukins, colony-stimulating factors, interferons, tumor necrosis factors, and hematopoietins (Dean et al., 2008). Interleukins are predominantly immunoregulatory compounds that act in stimulatory or inhibitory fashion on immune cells. Colony-stimulating factors are involved in the proliferation and differentiation of leukocyte progenitors. Interferons are primarily involved in regulating antiviral activity of immune cells. Tumor necrosis factors have antitumor activity and are involved in triggering apoptosis in target cells. Hematopoietins are involved in regulating bone marrow and production of hematopoietic cells. In addition to these major classes, there are many other cytokines with varied functions in immunoregulation that do not fit into these classes.

Chemokines

Chemokines are small peptide molecules that are produced by most cells of the body and that have a variety of vital biological functions both within and outside the immune system. Immunoregulatory functions of chemokines include mediation of allergic inflammation, leukocyte function, and Th1:Th2 ratios. Chemokines play important roles in autoimmunity and hypersensitivity disorders.

Other Soluble Mediators

Acute phase proteins include C-reactive protein, serum amyloid A, and serum amyloid P, which contribute to acute response to infection by binding pathogens such as bacteria and facilitating complement activation (Kaminski et al., 2008). The complement cascade is a system of globulins that ultimately forms a membrane attack complex capable of cytolytic action on membranes bound by antibodies. Reactive oxygen species released from neutrophils and macrophages as part of the killing response to microbes contribute to the inflammatory process. The cytolytic effects of granzyme and perforin have been previously discussed. Lymphoid cells possess receptors for various hormones, neuropeptides, and neurotransmitters, indicating that the immune system is able to respond to a variety of endocrine and paracrine signals from the endocrine and nervous systems that can attenuate or enhance the immune response. This neuroendocrine communication works both ways, as some immune cells are capable of secreting hormones and neurotransmitters that directly influence endocrine and nervous system functions.

MECHANISMS OF IMMUNOTOXICITY

It is apparent from the previous section that the immune response is not, as once thought, analogous to scattered bands of soldiers (immune cells) that patrol the body, burning and pillaging with abandon all in sight when they happen on foreign invaders (pathogens). Instead, in the healthy host, immune responses act like a highly disciplined army that uses sophisticated communication and tracking systems (soluble mediators, neuroendocrine input) to focus its efforts on removing foreign invaders in as specific and coordinated a manner as possible so as to minimize collateral damage to the host. Given the large number of players and tight regulatory requirements in the immune system arena, it should not be surprising that there are many opportunities for derangements in the system to develop because of interference of any one player by external forces such as toxicants. Additionally, because of the intricate connections between the immune system and other organ systems, toxicant-induced damage to nonimmune organs may result in altered immune responses both locally and throughout the body. Alterations in immune function may result in immunosuppression or excessive immunostimulation, either of which is detrimental to the overall health of the host.

The means by which toxicants may alter immune integrity are many and varied and can include direct and indirect mechanisms (Mishra and Sopori, 2012).

Toxicant-induced damage to any single immune cell lineage can reduce the number and viability of that type of immune cell; because of the intricate intercellular communication, loss of one cell type will adversely affect other cells as well (e.g., loss of APCs can decrease T cell responses). Toxicants may inhibit protein synthesis by altering the structure or function of DNA, RNA, or synthetic enzymes, resulting in decreased immune cell proliferation and maturation, decreased antibody production, and decreased production of soluble mediators; the net result will be immunosuppression. Some toxicants inhibit enzymes or enzyme systems, interfering with normal cellular function; for example, organophosphate insecticides are thought to induce lymphocyte membrane dysfunction through inhibition of membrane esterases (Galloway and Handy, 2003). Compounds that alter immune cell membrane and receptor structures can interfere with signal transduction, cell-to-cell communication, degranulation, response to cytokines, and antibody secretion. Toxicants may bind to immune cell membrane receptors, resulting in aberrant cell signaling that can over- or understimulate cell responses. Toxicants may indirectly alter immune function through the triggering of stress responses that stimulate cortisol release, which can result in glucocorticoid-induced apoptosis of lymphocytes (Lill-Elghanian et al., 2002). Interaction of toxicants with cellular macromolecules can result in hapten formation, triggering hypersensitivity reactions. Similarly, toxicant-induced tissue damage can alter body proteins, leading to the development of autoantibodies and autoimmune disease.

BIOMARKERS

The field of immunotoxicology has undergone tremendous growth over the last 25 years as knowledge of the immune system, and its susceptibility to exogenous forces, has expanded (House and Selgrade, 2010). Identification of immune-mediated disorders within the human population has been continuously rising over the last several decades, and immune-mediated disease is a significant public health concern (Hochstenbach et al., 2010). With the realization that many pharmaceuticals and environmental toxicants have the potential to trigger immune-mediated diseases and with the rapid growth in development of immunomodulating drugs to treat conditions such as rheumatoid arthritis, there is increasing need for development of biomarkers that can identify exposure to, and injury by, xenobiotics that can have deleterious effects on the immune system. The ideal biomarker should show clinical relevance, reflect the molecular or biochemical basis of the disease process, show sensitivity and specificity, be reliable and minimally invasive, and have simplicity in use and

application (Duramad and Holland, 2011). Unfortunately, an ideal biomarker panel that would reliably predict immunotoxicity of various compounds is yet to be developed. The paucity of adequate immunotoxicity tests has been recognized as a serious deficiency in the development of pharmaceuticals, evaluation of environmental toxicants, formulation of risk assessments for individuals and populations, and diagnosis of immune-mediated disorders (Duramad et al., 2007; Piccotti et al., 2009; Hochstenbach et al., 2010; Kawabata and Evans, 2012; Luebke, 2012).

The general strategy in evaluation of immunotoxicity is to apply a tiered approach, generally beginning with screening tests (tier 1) and following through with more comprehensive testing (tier 2) to confirm the nature of the immune defect (Dean et al., 2008). This approach is appropriate for both clinical and nonclinical evaluation for immunotoxicity, although the lack of validation of some tests can limit their use in clinical practice. Table 24.1 lists some biomarkers used in the assessment of immunotoxicology.

BIOMARKERS OF IMMUNE STATUS

Cell Counts

The standard hemogram, composed of a complete blood cell count with differential leukocyte count, is the most basic, rapid, and least expensive means of screening for adverse effects on the immune system. Elevations in total white blood cell counts can be indicative of inflammatory or neoplastic disorders; physiologic leukocytosis can occur as a result of acute or chronic stress. Elevations in neutrophils can occur following exposure to exogenous glucocorticoids and lithium and in early estrogen toxicosis (dogs) (Stockham and Scott, 2008; Petrini and Azzara, 2012). Toxicant-induced decreases in total leukocytes or neutrophils may be seen with bone marrow suppressants such as chemotherapeutic drugs, chloramphenicol, and sulfonamides, as well as compounds that cause destruction of mature granulocytes such as phenothiazines (Aster, 2005). Lymphocytosis may occur because of chronic infection or allergic reactions. Lymphopenia, as defined as absolute lymphocyte count $<1500/mm^3$, may occur because of severe stress, malnutrition, autoimmune disease, and hematopoietic malignancy (Dean et al., 2008). Monocytosis may occur secondary to stress or exogenous corticosteroid administration. Peripheral blood eosinophilia occurs with parasitism and hypothyroidism, and it is a significant feature of the eosinophilia—myalgia syndrome that has been associated with ingestion of the nutritional supplement L-tryptophan (Fenstrom, 2012).

Organ Weight

Determination of lymphoid organ weight has been a standard component of immunotoxicity testing during preclinical safety testing of pharmaceuticals and safety assessments of pesticides, industrial chemicals, and environmental contaminants. For obvious reasons, this type of immunologic screening is only suited to research studies.

Histopathology

Histomorphological examination of lymphoid organs is useful in assessing immunotoxicity of a xenobiotic. Microscopic determination of differences in cell density among the various lymphoid organs and immunohistochemical staining to differentiate various lymphoid cells can help identify which immune cell lineages are most severely affected. Accuracy of histomorphological scoring of immunotoxicity depends on a consistent and stringent scoring system to maximize specificity. Enhanced histopathological methods should be utilized to maximize accuracy, which includes identifying the separate compartments that support specific immune functions within each lymphoid organ, evaluating each compartment individually, and using semiquantitative descriptive (rather than interpretative) terminology to characterize any changes (Elmore, 2012). Within the spleen, five endpoints are evaluated: number of germinal centers, cellularity of periarteriolar lymphatic sheaths, lymphoid follicles, marginal zone, and red pulp. Lymph nodes have four endpoints that must be evaluated: cellularity of follicles, paracortical areas, medullary cords, and sinuses, while the thymus has three endpoints: corticomedullary ratio and cellularity of cortex and medulla. Although most commonly utilized for preclinical/premarketing safety assessments, histopathological evaluation of bone marrow and lymphoid tissue is also used clinically as part of the evaluation of the immune status of individual patients.

Antibody Assays

Serum levels of immunoglobulins have been used frequently in epidemiological studies and a variety of assay methods are readily available, including radioimmunoassay, enzyme immunoelectrodiffusion, enzyme-linked immunosorbent assay, single radial diffusion, double diffusion in agar gel, laser nephelometry, and immunoturbidimetric assay (Dean et al., 2008; Mali et al., 2009). The use of appropriate reference ("normal") ranges is vital because serum immunoglobulin levels can vary due to a variety of factors, including sex, age, ethnicity, nutritional status, geographical location, gender, and environment.

TABLE 24.1 Biomarkers Used in the Assessment of Immunotoxicology

Assay	Matrix	Endpoint	Example Toxicants
Biomarkers of Immune Status			
Leukocyte count	Blood	Total Leukocytes ↑	Cortisol, Lithium
		Total Leukocytes ↓	Chloramphenicol, Chemotherapeutics
		Neutrophils ↑	Cortisol, Estrogen (dogs, early), Lithium
		Neutrophils ↓	Phenothiazine
		Lymphocytes ↑	Allergens
		Lymphocytes ↓	Lithium
		Monocyte ↑	Cortisol
		Eosinophil ↑	L-Tryptophan
Organ Weight	Spleen, Thymus, Lymph Node	Organ Weight ↑	Immunostimulants
		Organ Weight ↓	Immunolytics
Enhanced histopathology	Tissues	Compartment cellularity ↑	Immunostimulants
		Compartment cellularity ↓, Apoptosis ↑	Immunosuppressants, Immunolytics
Antibody Assays	Serum, Secretions, Exudates	IgA, IgD, IgG, IgE, IgM ↓	B cell depressants
T-Dependent Antibody Response	Sensitized Spleen Cells	Plaque formation ↓	Dibenzo[def,p]chrysene, PAH[a], Indomethacin (rats)
Delayed-Type Hypersensitivity Response	*In vivo* (skin)	Induration	PPD tuberculin, *Toxicodendron*
Lymphocyte Phenotyping	Blood	Altered CD ratios	Lead, Beryllium
Natural Killer Cell Activity	Isolated lymphocytes	Cytolytic activity ↓	
Phagocytosis, chemotaxis, killing	Peritoneal Macrophages, Blood Neutrophils	Decreased adherence, chemotaxis, and/or phagocytosis	Aluminum trichloride, Deoxynivalenol
Proliferation Tests	Isolated lymphocytes	↓ T cell proliferation	Arsenic trioxide, Tributyltin
		↑ T cell proliferation	Beryllium
		↓ B cell proliferation	Prostaglandin
		↑ B cell proliferation	Lipopolysaccharide
Cytokine Profiling	Serum, Cell Supernatant, Saliva, Sputum	Measured levels	Cigarette smoke, VOC[b]
Urinary Leukotriene E(4)	Urine	Measured levels	Tobacco Smoke, Air Pollution
Biomarkers of Hypersensitivity			
Local Lymph Node Assay	Lymph Node	Radioactivity counts	Contact allergens
Human Repeat-Insult Patch Test	*In vivo* (Skin)	Erythema, irritation	Contact allergens
IgE Levels	Serum	Binding to antigen	Various allergens

Continued

TABLE 24.1   Biomarkers Used in the Assessment of Immunotoxicology—cont'd

Assay	Matrix	Endpoint	Example Toxicants
Biomarkers of Autoimmunity			
Autoantibodies	Serum, Inflammatory exudate	Measured levels	Mercury[c]
Proteomics	Plasma, Serum, Saliva, Sputum, Urine, Local Fluids, Tissues	Protein expression profile	N/A

[a]*PAH = polycyclic aromatic hydrocarbons*
[b]*VOC = volatile organic compounds*
[c]*Gardner RM, Nyland JF, Silva IA, Ventura AM, de Souza JM, Silbergeld EK (2009) Mercury exposure, serum antinuclear/antinucleolar antibodies and serum cytokine levels in mining populations in Amazonian Brazil: a cross-sectional study.* Envron Res **110(4):**345-354.

In experimental animal studies, humoral responses to sheep erythrocytes have been used to evaluate compounds for immunotoxicity—following exposure to the compound in question, test animals are inoculated with sheep erythrocytes, which generally trigger robust innate and adaptive immune responses (Van Loveren et al., 2001). Rhesus monkeys exposed to polychlorinated biphenyls (PCBs) had reduced antibody responses to sheep erythrocytes, suggesting a depressant effect of the PCBs on the monkeys' immune systems.

Although antibody levels have been used for population studies in humans, generally to estimate exposure to infectious agents, results of studies attempting to document altered responses to vaccination (and thus altered immune function) in humans exposed to putative toxicants have been equivocal. For instance, cigarette smokers had suboptimal immune responses to vaccination with hepatitis B vaccine (Roome et al., 1993), yet had increased levels of antibodies to influenza following vaccination (Mancini et al., 1998). Furthermore, immunoglobulin levels do not necessarily correlate with protective antibody responses following vaccination. Exposure to immunotoxicants may result in decreased levels of one or more class of immunoglobulin. However, it is unlikely that measurements of serum immunoglobulin levels provide the level of sensitivity needed to detect mild to moderate toxicant-induced alterations in immune function within a population (Luster et al., 2005).

T-dependent Antibody Response

The T-dependent antibody response (TDAR) assay evaluates the ability to produce IgM antibodies following exposure to potentially immunotoxic compounds (White et al., 2010). Following exposure to the test compound, spleen cells are isolated from the test animal and incubated in a matrix of agar, sheep erythrocytes, and Guinea pig serum. Lysis of erythrocytes around IgM secreting antigen-specific plasma cells results in formation of clear plaques in the agar, which are then counted. The TDAR is a sensitive assay for measuring the effects of xenobiotics on the humoral immune system. Feeding pregnant rats indomethacin in late gestation can result in offspring that have suppressed TDAR because of alteration in release of Th2 cytokines (Kushima et al., 2009). Dibenzo[def,p] chrysene is a polycyclic aromatic hydrocarbon that is a potent carcinogen and that has been associated with persistent suppression of TDARs (Lauer et al., 2013).

Delayed-type Hypersensitivity Response

The delayed-type hypersensitivity (DTH) assay measures cell-mediated immunity, including ability of memory T cells to recognize foreign antigen, proliferate, migrate to the site of antigen, and secrete cytokines and chemokines, as well as ability of monocytes to migrate to the area (Kaminski et al., 2008). A classic example of the DTH assay is the PPD tuberculin test to detect individuals sensitized by *Mycobacterium* spp (Rosenstreich, 1993). The sensitized host has antigen inoculated intradermally, and the inoculated site is evaluated at 48 and 72 h for erythema, swelling, and edema.

Lymphocyte Phenotyping

Study of cell-surface markers (CDs) on immune cells using flow cytometry has greatly enhanced the ability to study lymphocyte development, activation, and function (Lappin and Black, 2003; Shipkova and Wiedland, 2012). In humans, B cells are identified by CD19 and T cells possess CD3. Using multiple fluorochromes to stain immune cells has resulted in the identification of a variety of cell subtypes and allows the study of the

responses of the various subtypes to xenobiotics. Flow cytometry also allows for the study of numerous cytokines simultaneously, giving a better picture of the interactions between immune cells and soluble mediators. Using flow cytometry, changes in numbers of subpopulations of immune cells in response to a xenobiotic can be detected as can alterations in the amounts and types of cytokines elaborated in response to an immunotoxicant. For example, individuals occupationally exposed to lead had decreases in $CD3^+$ cells (i.e., B cells) and a decreased $CD4^+$ to $CD8^+$ cell ratio (Garcia-Leston et al., 2012). Evaluation of the number of beryllium-responsive $CD4^+$ in the blood has been proposed as a biomarker to distinguish patients with chronic beryllium disease from those who have been sensitized to beryllium but have not developed the pulmonary form of beryllium-induced disease (Martin et al., 2011).

Natural Killer Cell Activity

NK activity is measured by culturing lymphoid cells with radiolabeled tumor cells known to be susceptible to NK-mediated cytolysis. Quantitation of radioactivity in the supernatant indicates the degree of NK activity as the lysed tumor cells release their radiolabel. A technique using flow cytometry has been developed to quantitate NK activity and has the advantage of avoiding the use of radioactive isotopes (Kim et al., 2007).

Phagocytosis and Chemotaxis

Measurement of chemotaxis by immune cells generally involves incubating the cells in question in a diffusion chamber or on a porous substrate with a chemoattractant gradient used to direct chemotaxis. Soluble mediators elaborated by the cells may be measured and adhesion and chemotaxis evaluated. Failure of cells to adhere, migrate appropriately, or elaborate appropriate soluble mediators suggests impairment in immune function. Phagocytic activity of macrophages and neutrophils is measured in vitro by isolating peritoneal macrophages or peripheral blood neutrophils and incubating them with foreign antigen (usually radiolabeled) and then examining them for the presence of the marker antigen. A similar in vivo test involves injecting the antigen into the animal, which is subsequently killed and tissues examined for the presence of the marker antigen within phagocytes. Toxicant-induced deficiencies in phagocytosis ± adhesion can be evaluated. Defects in adherence, chemotaxis, and phagocytosis have been documented in macrophages exposed to aluminum and neutrophils exposed to deoxynivalenol (Hu et al., 2011; Gauthier et al., 2013).

Proliferation Tests

Proliferation tests measure the ability of B or T cells to proliferate in response to stimulation by antigen. B cells are stimulated by anti-CD19 antibody in the presence of IL-4 or with lipopolysaccharide, a B cell mitogen. T cells are incubated with anti-CD3 antibody in the presence of IL-2 or with either concanavalin A or phytohemagglutinin, T cell mitogens. Response is measured by the uptake of ^{3}H-thymidine into DNA of the cultured cells. Little to no response of the lymphocytes following antigenic stimulation suggests that the immune response has been suppressed. Arsenic and tributyltin have been shown to cause decreased T cell proliferation, while prostaglandin E has been associated with depressed B cell proliferation (Kurland et al., 1977; Frouin et al., 2008; Morzadec et al., 2012). Increased T cell proliferation occurs in beryllium disease, and microbial lipopolysaccharide is associated with increased B cell proliferation (Mond and Brunswick, 2003; Martin et al., 2011).

Cytokine Profiling

As previously mentioned, cytokines are crucial molecules in facilitating the proliferation, maturation, and function of immune cells, especially T cells. Cytokine levels can be measured by ELISA or flow cytometry in serum, plasma, bronchioalveolar fluid, or in supernatant from cultured cells. Cytokine profiling entails measuring the levels of a battery of cytokines simultaneously to provide insight into how immunotoxicants exert their effects on immune function. Through study of cytokine profiles, it has been determined that Th1 cytokines (IL-2, IFN-γ, TNF-β) are associated with contact sensitization, whereas Th2 cytokines (IL-4, IL-5, IL-6, IL-10) are associated with respiratory sensitization (Kaminski et al., 2008). Neonatal humans have predominantly Th2 cytokine profiles that gradually progress toward a balanced Th1/Th2 ratio (Luster et al., 2005). Exposure to toxicants that delay or prevent this balance from being achieved can predispose to immune dysfunction; for instance, sustained Th2 cytokine profiles increase the risk for allergic disease. Examples of environmental toxicants that can increase T2 cytokine production include maternal cigarette smoking and indoor volatile organic compounds. Cytokine profiling has been proposed for detecting immunotoxicity induced by nanoparticles used for therapeutic or diagnostic purposes (Elsabahy and Wooley, 2013).

Cytokine profiling does have some limitations as an immunotoxicology biomarker. Baseline data may not

exist for a particular population (e.g., healthy children), and there are multiple genetic, physiological, and environmental factors that can contribute to significant individual variability in response (Luster et al., 2005). Lack of standardization of methods can make it difficult to make direct comparisons between studies if, for instance, one study used ELISA supernatant from in vitro stimulated peripheral blood cells, while the other used flow cytometric evaluation of intracellular cytokines while a third study used polymerase chain reaction to measure cytokine RNA rather than the proteins themselves. Finally, due to the transient nature of cytokines, a single profile is no more than a snapshot in time that may or may not reflect the response that is occurring in the target organ.

Other Soluble Mediators

Numerous endogenous compounds are being investigated as potential markers for immune disorders. Eosinophil-derived neurotoxin, an eosinophil degranulation product, has been proposed as a novel marker to diagnose, treat, and monitor allergic disease (Kim, 2013). Urinary leukotriene E(4) is being investigated as a biomarker of environmental exposure to tobacco smoke and air pollution, as well as a predictor of risk for asthma exacerbations related to tobacco smoke (Rabinovitch, 2012). Neuropteron, produced by monocytes and macrophages on activation, has been used as a measure of activation of the cell-mediated immune response (Garcia-Leston et al., 2012).

BIOMARKERS OF HYPERSENSITIVITY

Local Lymph Node Assay

The murine local lymph node assay (LLNA) has become the standard nonclinical test for testing the potential for chemical sensitization by xenobiotics (Anderson et al., 2011; Peiser et al., 2012). The LLNA has largely replaced the Guinea pig–based tests (i.e., Guinea pig maximization assay and Buehler assay) that had been used historically to test for chemical sensitization. The candidate substance is applied topically to mice once daily for three consecutive days, and on day 6 the mice are injected intravenously with ^{3}H-thymidine. Hours later, the mice are sacrificed and lymph nodes draining the site of chemical application are evaluated for radioactivity, which will correlate with degree of lymphocyte proliferation. Because lymphocyte proliferation has been shown to be related to chemical sensitization and the measured degree of response to the LLNA can be correlated to an objective measure of relative allergenic potency of a compound,

the LLNA has been investigated as a potential tool to use in human quantitative risk assessment.

Limiting factors that need to be considered when using the LLNA include the fact that the assay measures reactions following acute (3-day duration) exposures without providing information on any differences in response with long-term or intermittent exposure. Additionally, interspecies differences need to be considered, as rodents have increased skin penetration of chemicals compared with humans. False positives in the LLNA may occur when nonspecific skin irritation, rather than chemical sensitization, occurs; tools used to attempt to filter out this complicating factor have been developed for use in research but they have not been validated for the purpose of risk assessment.

Human Repeat-Insult Patch Test

The human repeat-insult patch test is a test of skin sensitization that is primarily intended to confirm safety of topically applied compounds rather than identify skin sensitization (as with the Guinea pig and murine tests) (Kimber et al., 2001). Ethical issues with the use of human subjects prohibit or restrict the use of this method in many countries. An occlusive patch containing test material is applied to the upper arm or back of a human volunteer and maintained in place for 24 h after which the patch is removed and the skin evaluated for erythema and edema (Hayes et al., 2008). After a 24-h rest, a second patch is applied to the same site (Voss-Griffith test) or a new site (Draize test); the process is completed until a total of 9 (Voss-Griffith) or 10 patches (Draize) have been applied. Ten to fourteen - days after removal of the last patch, a challenge patch is applied for 24 h and the sites examined at 0, 48, and 96 h for evidence of reaction.

Immunoglobulin E Levels

Measurement of total serum IgE antibody levels can be used as a core screen for allergic disease, although tests for IgE response against a battery of allergens in a multiallergen screen are considered the core biomarker that allows characterization of allergic status of the individual (Szefler et al., 2012). A variety of assays have been developed in which serum from the patient is placed on the test substrate containing allergens and a colorimetric change occurs when IgE in the serum binds the allergen, indicating sensitization of the patient to the allergen. In vivo measurement of allergen-specific IgE is also available as "skin testing." Allergens are introduced to the skin via skin prick or intradermal injection and the resulting wheal and flare reaction identifies those allergens to which IgE is present.

BIOMARKERS OF AUTOIMMUNITY

Loss of "self" recognition by the immune system can lead to the development of antibodies against normal body components such as basement membranes or individual cell types (e.g., erythrocytes, keratinocytes). Toxicants can initiate this loss of self-recognition through tissue damage that alters cellular proteins, thereby triggering an autoimmune response (Mishra and Sopori, 2012). Autoimmunity can develop against a huge range of cellular and extracellular components, so it is not surprising that a single test for autoimmunity does not exist. Instead, diagnosis of autoimmunity generally relies on the detection of specific autoantibodies, and oftentimes an array of tests is required before the correct autoantigen is recognized (Lemmark, 2001). An ideal autoimmune biomarker would be measurable from serum or plasma and would reflect the real-time severity of the disease as it fluctuates during disease progression and therapy.

Currently, biomarker discovery efforts are focused on proteins that reflect the autoimmune process, namely degradation products arising from destruction of affected tissues, enzymes that are involved in tissue degradation, and cytokines or other proteins associated with immune activation (Prince, 2005). Many of these proteins are restricted to the anatomical site of production (e.g., synovial cavities in cases of autoimmune arthritis), which can make obtaining samples problematic. Proteomic platforms utilizing mass spectrometry or gel electrophoresis coupled with liquid chromatography have been investigated to identify and quantify proteins thought to contribute to autoimmune disease (Gibson et al., 2010). Although unique, single-protein biomarkers are unlikely to be found for most autoimmune diseases, characterization of the patterns of multiple proteins expressed during different autoimmune processes may provide unique profiles that aid in the diagnosis, prognostication, and monitoring of various autoimmune disorders (Ademowo et al., 2013). An advantage with using the proteomic methods is the ability to develop profiles for a variety of matrices, including plasma, serum, saliva, sputum, urine, local fluids (e.g., synovial fluid, cerebrospinal fluid), and tissues.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The field of immunotoxicology has expanded greatly in the past three decades with the growing understanding of the many functions and vulnerabilities of the immune system. No longer merely a "bug killer," the immune system is now known to be a complex, highly regulated, and delicate entity tasked with preserving the integrity of the host against outside forces. Increased understanding of how xenobiotics can impact the function of the immune system has led to development of assays to identify the effects of immunotoxicants and to study the mechanisms of immunotoxicity and develop rational risk assessments for the wide range of xenobiotics to which we are exposed on a daily basis. Immunotoxicology can be seen to be in its infancy, and future discoveries will undoubtedly further advance our knowledge and ability to predict, prevent, and treat immune-mediated disorders.

The development of in vitro or in silico (computer model) alternatives to the use of live animal research is an area of study that is receiving a great deal of attention within the scientific community (Corsini and Roggen, 2009). Although currently available methods fall short of being able to totally replace live animals for some vital parameters (e.g., carcinogenicity, reproductive toxicity), some progress is being made in the development of in vitro assays and in silico models as first-line screening tools for contact sensitizers. The myeloid U973 skin sensitization test and human cell line activation test (h-CLAT) have been accepted for prevalidation as alternatives to the LLNA for measuring skin sensitization (Anderson et al., 2011).

Immunotoxicogenomics is an emerging field of study that explores the potential to use analysis of gene expression in both the study of immunotoxicants and the assessment of relative risks of toxicants to the immune system (Luebke et al., 2006). Microarray analysis is already being used to investigate pathway-level changes that lead to altered immune responses, and the use of microarray analysis of genomes to screen for potential toxic effects, determine mechanisms of toxicant action, and provide data germane to the risk assessment process is already under investigation in other areas of toxicology; application to immunotoxicology is in progress. Using whole genome gene expression in human peripheral blood mononuclear cells, Hochstenbach et al.(2010) were able to identify a set of 48 genes that could distinguish a group of immunotoxic compounds from nonimmunotoxic compounds. Many barriers (e.g., cross-species extrapolation, correlating genotypic pattern with phenotypic expression, etc.) must be overcome before the marriage of immunotoxicology and genomics can be expected to produce reliable and useful means of evaluating compounds for immunotoxic potential, determining hazard assessments, and contributing to our understanding of immune function, but the field of immunotoxicogenomics holds much promise.

Bisphenol A Biomarkers and Biomonitoring

P. Cohn[1], A.M. Fan[2]

[1]New Jersey Department of Health (retired), Trenton, NJ, United States; [2]California Environmental Protection Agency (retired), Oakland/Sacramento, CA, United States

INTRODUCTION

Bisphenol A (BPA), 2,2-bis (4-hydroxy-phenyl) propane, has been receiving increasing attention because of evidence on its reproductive toxicity and endocrine disruption effects in laboratory studies, the growing literature correlating environmental BPA exposure to adverse effects in humans, its high production volume, its widespread human exposure, and the potential diverse types of human health effects in addition to reproductive toxicity and endocrine disruption (Fan et al., 2017).

The widespread use of BPA in the production of polycarbonate plastics and epoxy resins used in many consumer products, including packaged foods, has led to its extensive distribution and contamination in the environment and nearly universal exposure to humans in developed countries. Due to the instability of the polymers, BPA leaches out because of heating or the acidity/alkalinity of the food. Importantly, maternal exposure to BPA results in embryos and newborns receiving BPA via placental transfer and breast milk.

The evidence available from laboratory animal studies is that unconjugated BPA (uBPA) has estrogenic activities of concern at levels found in human environmental exposure (Richter et al., 2007; Vandenberg et al., 2013), whereas BPA conjugated with glucuronide or sulfate is inactive. Most of the conjugation activity occurs in the liver, and blood flow from the intestinal tract goes first to the liver. Dermal absorption and direct absorption in the mouth do not pass first through the liver. The concern about individual variation in the level of uBPA informs one of the key biomarker issues in the next section.

Although the European Food Safety Authority (EFSA) based its temporary tolerable daily intake of 4 µg/kg body wt/day on increased kidney weight in male mice (EFSA, 2015), mammary gland, liver, various endocrine functions, and metabolism have also been shown to be affected (Vandenberg et al., 2013). As part of an update on BPA toxicology, the US National Toxicology Program (NTP) recently announced the peer review of the Draft NTP Research Report on the Consortium Linking Academic and Regulatory Insights on BPA Toxicity (CLARITY-BPA) Core Study (NTP, 2018). The draft report is on perinatal and chronic extended-dose-range study of BPA in rats. This study is part of the CLARITY-BPA, a research program between the NIEHS, NTP, and the National Center for Toxicological Research (NCTR) of the US Food and Drug Administration (FDA). CLARITY-BPA was developed to bridge guideline-compliant research conducted at the FDA with hypothesis-based research investigations conducted by academia on the toxicity of BPA. The final conclusions are expected in 2019, which will be based on the integration of the Core Study and Grantee Study findings.

In considering the toxicity and adverse health effects of BPA exposure, a particular concern is the possibility of low-dose effect and that nonmonotonicity of BPA would occur at doses lower than those used in regulatory toxicity studies, as demonstrated in nonmonotonic dose−response curves (NMDRC). The NMDRC is characterized by a change in the sign of the slope, and the function can take on the shape of a U, the shape of an inverted U, or another shape that has more than one inflection point. There are uncertainties requiring additional research on effects on mammary gland, and reproductive, neurobehavioral, immune, and metabolic systems at low levels. The causes of the U-shaped curve can include the inhibition/activation of different subsets of cellular receptors, one or more enzymes, and nuclear transcription factors and proteasomes as the dosage is changed from low to high.

The environmental and human health concerns have led to bans or restrictions in use in different countries. The preponderance of international regulatory bodies evaluated and determined that there is no health risk in the general population from average BPA exposure, and that existing exposures are below the health guidance value of 4 µg/kg body wt/day established by the EFSA (2015). However, other opinions have expressed concerns about its potential human health hazard and uncertainties relating to the toxicity and exposure of BPA. These aspects in toxicology and risk assessment of BPA have been described in an earlier discussion (Fan et al., 2017), which should be read as a supplementary compendium to this chapter to serve as a background to the present discussion on biomarkers with a focus on urinary BPA biomarkers. Readers are also referred to the discussion in an earlier chapter on biomarkers in toxicology, risk assessment, and chemical regulations for a discussion of the different types of biomarkers (i.e., biomarkers of exposure, biomarkers of effect, biomarkers of susceptibility) and some of the chemical samples presented (Fan, 2014).

The present discussion will focus on review of recent reports (last 10 years or relevant as appropriate) on the following: (1) studies that investigate the prevalence of BPA exposure in humans, using urinary BPA as biomarker, including several major population studies (e.g., biomonitoring studies such as the United States [US] National Health and Nutrition Examination Surveys [NHANES], Canadian Health Measures Survey [CHMS], Generation R study in the Netherlands, Norwegian Mother and Child Cohort Study [MoBa] for the general and certain specific populations); and (2) selected studies on findings on urinary BPA in pregnant women, children, and mother–child pairs, along with observations of neurobehavioral effects in some of the studies. Children are more susceptible to the effects of environmental toxicants under certain conditions especially in the early months of life (Marty, 2015). They have immature metabolic pathways and differences in ability to metabolize, detoxify, and eliminate toxins compared to adults. These led to a particular interest in BPA, which has been shown to have endocrine activities, reproductive toxicity, and adverse effects on the young.

BISPHENOL A BIOMARKER ISSUES IN BIOMONITORING

Environmental chemicals that have entered the human body may leave markers reflecting the exposure. The marker may be the chemical itself or a derivative of the chemical, measured in the biological matrix, but it may also be some change in the body resulting from the agent or its breakdown product(s). Biomonitoring programs provide an important source of human exposure data to environmental chemicals, including BPA.

BPA has been measured as total BPA, uBPA, BPA glucuronide, and BPA sulfate in human urines. In humans and other primates, orally administered BPA is rapidly absorbed and transformed to BPA glucuronide during first pass metabolism in the gut wall and the liver and a small amount of BPA is converted to a sulfate conjugate (WHO, 2009). More than 80% of orally administered BPA is cleared from the body in 5 h. The conjugated forms of BPA are devoid of estrogenic activity. BPA metabolism is influenced by age, gender, route of exposure, and physiological state (e.g., pregnant vs. nonpregnant). There are variations in metabolism due to genetic polymorphisms. There are also mechanisms to deconjugate BPA (Ginsberg and Rice, 2009), and these could be affected by polymorphisms in individuals. Some of these could affect only certain tissues, but not be obvious by measuring urinary BPA.

Urinary BPA has been the preferred biomarker in BPA studies because of its practicality. Calafat et al. (2015) discussed considerations that are essential when evaluating exposure to nonpersistent, semivolatile environmental chemicals such as phthalates and phenols (e.g., BPA) and concluded that the biological and technical factors strongly support urine as the optimal matrix for measuring nonpersistent, semivolatile, hydrophilic environmental agents. The factors include representativeness of usual personal exposures and not recent extraneous exposures; minimization of contamination arising from collection, sampling, or analysis procedures; pharmacokinetics (e.g., fast metabolism and urine is the compartment with the highest concentrations of metabolites); and knowledge of intraindividual reliability over the biologic window of interest. Potential external contamination sources include sampling containers, preservatives, air, or dust (the latter reported by Longnecker et al. (2013)).

There are various approaches to correct for urine dilution to avoid overestimation with highly concentrated urine samples and underestimation with dilute samples. Creatinine adjustment is widely used for urinary chemical testing and has been shown to vary by factors such as age, gender, and race/ethnicity. The easiest calculation is by reporting a chemical by µg/g of creatinine, but inclusion of creatinine in multivariate statistical regression is also used. The other method is to directly adjust for urine dilution/concentration by the specific gravity (SG) of the urine sample.

Vandenberg et al. (2010a,b) examined more than 80 published human biomonitoring studies that measured BPA concentrations in human tissues, urine, blood,

and other fluids, along with two toxicokinetic studies of human BPA metabolism. The biomonitoring studies examined included measurements in thousands of individuals from many developed and some developing countries, and these studies overwhelmingly detected BPA in individual adults, adolescents, and children. uBPA or free BPA was routinely detected in blood in the ng/mL range, and conjugated BPA was routinely detected in the vast majority of urine samples (also in the ng/mL range). These data indicate that the general population is exposed to BPA and is at risk from internal exposure to uBPA. The studies provide data that account for all sources and routes of exposures. Although oral exposure has been thought to be the major source, not all sources for BPA have been identified. The authors found that (1) the large number of biomonitoring studies are highly consistent and therefore reliable; (2) the detection rates and concentrations of BPA in urine and blood of environmentally exposed individuals are remarkably similar in studies performed in many laboratories using a variety of techniques, including highly accurate and sensitive methods as used in the US Centers for Disease Control and Prevention's (CDC) national biomonitoring programs (Calafat et al., 2005; Calafat and Needham, 2008); and (3) there is no evidence to suggest that these studies have poor quality control (e.g., contamination from collection materials, breakdown of conjugates during storage, inadequate blanks). Overall, the reproducibility of these results showed that internal doses in humans for uBPA have a central measure of the distribution in the 0.5–3 ng/mL (equivalent to µg/L) range, but as much as 10 ng/mL.

Vandenberg et al. (2010a,b) also evaluated two toxicokinetic studies conducted in 15 adults administered BPA (Volkel et al., 2002, 2005) that suggested human uBPA exposure is negligible, and determined that the studies had significant deficiencies and are directly contradicted by environmental exposure studies. Other studies described in this chapter have provided additional extensive evidence of exposure.

The level of systemic BPA exposure, as represented by serum or plasma, may differ from exposure as represented by urinary BPA (Ginsberg and Rice, 2009; Vandenberg et al., 2014b; vom Saal and Welshons, 2014; Stahlhut et al., 2016), particularly in infants because of low activity of metabolic enzymes (Ginsberg and Rice, 2009). A remaining issue is the practicality of blood sampling in epidemiology. It is possible to reliably measure the various forms of BPA in blood (Vandenberg et al., 2014a), but there remains a debate about practicality (Calafat et al., 2015, 2016). Veiga-Lopez et al. (2015) conducted a fetal growth study based on maternal and cord plasma (see below in the Mother-Infant/Child Pairs

section) following the round robin laboratory methods discussed by Vandenberg et al. (2014a). The observed median uBPA in first and third trimester BPA was 0.66 and 3.0 µg/L plasma, respectively, whereas the umbilical cord plasma median was 0.19 µg/L. The respective 75th percentile levels were 1.5, 16.6, and 2.8 µg/L, and the respective 95th percentile levels were 32, 59, and 14.8 µg/L. The total BPA levels were only moderately higher, by factors of 5%–20%, because of the low level of glucuronidation. The limit of detection for both uBPA and glucuronidated BPA was 0.02 µg/L.

Gerona et al. (2016) noted that most biomonitoring studies to date have estimated prenatal exposure to total BPA indirectly, using enzyme hydrolysis to cleave glucuronide and sulfate bonds with BPA, then quantifying uBPA. They used the direct analytical method, LC-MS/MS, to avoid the possibility of incomplete enzyme hydrolysis at higher BPA levels in a study of predominately low-income pregnant women (n = 112) in their second trimester. They found universal and high exposure to uBPA and its metabolites: median concentrations were 0.25, 2.6, and 0.31 µg/g for uBPA, BPA glucuronide, and BPA sulfate, respectively. Median total BPA, 4.0 µg/g, was roughly twice that measured in US pregnant women in other studies. The 75th percentile level in this study was 13.9 µg/g. On average, total BPA consisted of 71% BPA in glucuronide form, 15% BPA in sulfate form, and 14% in uBPA.

As BPA has a short average half-life of less than 6 h, a single measurement would be useful only if the environmental exposure is relatively constant over weeks or months, and issues of representativeness of longer-term exposures, temporal reliability, and stability after storage need to be considered. Nepomnaschy et al. (2009) evaluated the stability of BPA in urinary specimens after 22–24 years of storage and measured within-person temporal variability in urinary BPA. They concluded that the similar levels found in later sampling (see Section NHANES, below) provide indirect evidence that BPA is relatively stable during long-term freezer storage. These findings suggest that developmental effects of BPA exposure could be investigated with measurements from stored urine. Jusko et al. (2014) noted that exposure to BPA is episodic, varying in dose and duration. Because of its short half-life, an estimate of exposure based on a spot urine specimen is likely to misclassify individuals with regard to their average long-term exposure, for example, over 9 months of pregnancy. They evaluated the reproducibility of BPA concentration in serial urine specimens taken during pregnancy and noted that results indicate a high degree of within-person variability, which presents challenges for designing well-powered epidemiologic studies.

EXPOSURE AND SELECTED OUTCOME STUDIES

Analysis of health effects is an important use of surveys such as NHANES, although in general the epidemiological design is cross-sectional (exposure and outcome are measured at the same time) and, therefore, cannot be easily used for determining causality. Although questionnaire data on past use of tobacco and alcohol are valid retrospective data, chemicals that are quickly excreted, such as BPA, represent only a moment in time. Prospective studies on pregnant women and their children are presented in this chapter (in the subsections on Mother-Infant/Child Pairs and on Children, below). Urinary BPA in gestational samples taken during regular clinical visits have been compared to later outcomes, such as fetal growth, thyroid, neurodevelopment, and respiratory outcomes, which represent the largest number of studies, summarized in Tables 25.2–25.5. Other studies have also been published on other endocrine effects, metabolism, liver function, immune function, oxidative/nitrosative effects, and epigenetics, but are not discussed in this chapter.

LARGE GENERAL POPULATION BIOMONITORING PROGRAMS

The following presents a brief description of some of the large biomonitoring programs that measured BPA in human fluids. The review is not meant to be comprehensive. Studies usually included other potential endocrine disruptors, such as phthalates, but the focus was placed on BPA. Summary of BPA levels are shown in Table 25.1.

National Health and Nutrition Examination Survey, United States

In the United States, the Division of Laboratory Sciences of the CDC operates the National Biomonitoring Program (NBP), which also assesses the nutrition status of the US population (CDC, 2018a). Biomonitoring data are used to determine the presence and concentrations of chemicals in human blood, urine, breast milk, and saliva and to track exposure trends and impacts of public health programs.

The NBP measures more than 300 environmental chemicals and nutritional indicators. The data and biomonitoring research are used to develop various studies and publications, including two key reports: (1) the National Report on Human Exposure to Environmental Chemicals, which is a series of ongoing assessments of the US population's exposure to environmental chemicals; and (2) the National Report on Biochemical Indicators of Diet and Nutrition in the US population, which is a series of publications that provide ongoing assessment of the U.S. population's nutrition status. The NHANES is a program conducted by the National Center for Health Statistics of studies designed to assess the health and nutritional status of the noninstitutionalized civilian resident population of the United States (CDC, 2018b). The survey combines interviews and physical examinations. This information is used to estimate the prevalence of various diseases and conditions and to provide information for use in planning health policy. Urine BPA has been measured by NHANES in each 2-year cycle since 2003.

In 2005, Calafat et al. (2005) provided the first reference range of human internal dose levels of BPA in a demographically diverse human population. BPA was measured in archived urine samples from a reference population of 394 adults in the United States selected from the Third NHANES (NHANES III, 1988–94) callback cohort, a nonrepresentative subset of NHANES III composed of approximately 1000 adults. The urine samples were all spot samples, collected at different times throughout the day.

The concentration ranges of BPA were similar to those observed in other human populations. BPA was detected in 95% of the samples examined at concentrations ≥ 0.1 μg/L urine; the geometric mean (GM) and median concentrations were 1.33 μg/L (1.36 μg/g creatinine in urine, abbreviated below as μg/g) and 1.28 μg/L (1.32 μg/g), respectively; the 95th percentile concentration was 5.18 μg/L (7.95 μg/g). Gender and age group (<50 or ≥ 50 years of age) were not statistically significant predictors, but rural versus urban residence was. The adjusted GM of BPA for an urban resident (1.21 μg/L) was significantly lower than that for a rural resident (1.56 μg/L).

Since 1999, NHANES has been conducted continuously with approximately 10,000 respondents from 30 locations in each 2-year data cycle. BPA is measured in 1/3 of the samples (Parker et al., 2018). This study is limited to adults aged 20 and over with complete data on BPA, creatinine, race/ethnicity, gender, age, poverty status, urbanization, education, and cigarette smoking (6608). Summary results for 2003–12 NHANES showed that the estimated median of BPA (μg/L) by gender and race/Hispanic origin, for adults, are as follows: male—non-Hispanic white, 2.00; Mexican American, 2.00; non-Hispanic black, 2.70; females—non-Hispanic white, 1.6; Mexican American, 1.9; non-Hispanic black, 2.8.

In a second study, Calafat and Needham (2008) assessed exposure to BPA in the US general population. Total (free plus conjugated) urinary concentrations of BPA were measured in 2517 participants ≥ 6 years of age in the 2003–04 NHANES study. Urine

concentrations of total BPA differed by race/ethnicity, age, gender, and household income. BPA was detected in 92.6% and 57.4% of the persons, respectively. Least square geometric mean (LSGM) concentrations of BPA were significantly lower in Mexican Americans than in non-Hispanic blacks and non-Hispanic whites. LSGM concentrations for non-Hispanic blacks and non-Hispanic whites were not statistically different. Females had statistically significantly higher BPA LSGM (2.8 µg/L) concentrations than males (2.4 µg/L). Children (6–11 years old) had higher concentrations (4.3 µg/L) than adolescents (2.8 µg/L), who in turn had higher concentrations than adults (2.4 µg/L). LSGM concentrations were lowest for participants in the high household income category (>$45,000/year).

Lakind and Naiman (2011) also estimated BPA daily intakes in the United States based on the 2005–06 NHANES urinary data on BPA and its metabolites. Excretion of ingested BPA into urine, mainly as the glucuronide conjugate, is essentially complete in 24 hr. Therefore, total urinary BPA in a 24-hr urine sample approximates the BPA intake from the previous 24 hr. Associations between urinary BPA levels and items from the NHANES questionnaire and examination data that specifically related to packaged food/drink consumption, smoking, and specific medical procedures were evaluated. The median daily BPA intake was approximately 34-ng/kg body wt/day for the overall population, and 54-ng/kg body wt/day for 6–11-year-olds, the youngest group. Intakes for men were statistically significantly higher than for women, and there was a significant decrease in daily BPA intake with increasing age. Estimates of daily BPA intake have decreased compared with those from the 2003–04 NHANES. Consumption of soda, school lunches, and meals prepared outside the home—but not bottled water or canned tuna—were associated with higher urinary BPA.

More recently, Lakind and Naiman (2015) compared the 2003–04 to 2011–12 NHANES to examine temporal trends and assess the resiliency of the previous reported associations. The median daily intake for the overall population was approximately 25 ng/kg day, which represents a gradual decrease in exposure.

Three approaches were assessed for their effect on trends and associations: (1) use of generic literature-based 24-h urine excretion volumes, (2) use of creatinine adjustments, and (3) use of individual urine flow rate data from NHANES. Estimates of associations between lifestyle/demographic/dietary factors and BPA exposure revealed inconsistencies related to both NHANES survey year and the three approaches listed above. The authors noted that these results demonstrate the difficulties in interpreting urinary BPA data, despite efforts to account for urine dilution. Stahlhut et al. (2009) investigated the relationship between urine BPA concentration and fasting time in 1469 adult participants in the 2003–04 NHANES. Because food is the predominant BPA exposure source, and BPA appears to be rapidly excreted, BPA levels in fasting individuals should decrease with increased fasting time. They estimated the BPA half-life for fasting times of <4.5 h, 4.5–8.5 h, and >8.5 h. Results showed that the overall half-life for the 0- to 24-hr interval was 43 h (95% confidence interval [CI], 26–119 h). Among those reporting fasting times of 4.5–8.5 h (n = 441), BPA declined significantly with fasting time, with a half-life of 4.1 h (95% CI, 2.6–10.6 h). However, within the fasting time intervals of 0–4.5 h (n = 129) and 8.5–24 h (n = 899), no appreciable decline was seen. Fasting time did not significantly predict highest (>12 ng/mL) or lowest (below limit of detection) BPA levels. Overall, BPA levels did not decline rapidly with fasting time in this sample. The authors noted that this suggests substantial nonfood exposure, accumulation in body tissues such as fat, or both. Of course, delayed uptake from the gut (due to fat content and differences in gut motility) and diurnal patterns of kidney function are also likely factors, even after exclusion of subjects using laxatives and antidiarrheal medications or drinking coffee, tea, or carbonated beverages or using mints or lozenges during the fasting period.

Nelson et al. (2012) analyzed data from the 2003–06 NHANES using multivariable linear regression to examine the association between urinary concentrations of BPA and multiple socioeconomic measures and race/ethnicity. BPA was inversely associated with family income, higher in people who reported very low food security and received emergency food assistance. This association was particularly strong in children: 6–11-year-olds whose families received emergency food had BPA levels 54% higher (95% CI, 13%–112%) than children of families who did not. Smaller and less consistent associations with education and occupation were observed. Mexican Americans had the lowest BPA concentrations of any racial/ethnic group. Income, education, occupation, and food security appear to capture different aspects of SEP that may be related to exposure to BPA and are not necessarily interchangeable as measures of SEP in environmental epidemiology studies. Differences by race/ethnicity were independent of SEP.

Silver et al. (2011) noted that previous studies using data from the NHANES showed an inconsistent association between prevalence of self-reported type-2 diabetes mellitus (T2DM) and urinary BPA. The authors also used hemoglobinA1c (HbA1c) as a surrogate for T2DM with a larger subset of NHANES. They analyzed data from 4389 adult from three NHANES cycles (2003–08). T2DM was defined as having a HbA1c ≥ 6.5% or use of diabetes medication. Multivariate analysis of the total sample revealed that a twofold increase
