CA-125 has demonstrated some promise as a predictive biomarker related to optimal cytoreduction. Before surgical resection of OC, levels of CA-125 have been demonstrated to indirectly reflect the degree of tumor burden. It has been shown that CA-125 levels >500 U/mL are associated with a diminished likelihood of optimal cytoreduction (Diaz-Padilla et al., 2012). Given the high response rate typically observed following the administration of chemotherapy in epithelial OC, CA-125 is not widely utilized as a predictive biomarker in this setting. The use of neoadjuvant chemotherapy is a current topic of interest in the management of OC as a means of improving the potential of optimal cytoreduction in advanced disease. It has been recently suggested in this treatment setting that initial CA-125 levels >2000 U/mL predict improved progression-free survival (Kang et al., 2011).

DIAGNOSTIC BIOMARKERS

Pancreatic Cancer

CA 19-9 is ineffective in detecting PDAC in asymptomatic patients, whereas sensitivity and specificity are elevated in symptomatic ones. Following CA 19-9, carcinoembryonic antigen (CEA) is the second most common antigen currently used but sensitivity is low and inferior to CA 19-9 (Swords et al., 2016; Viterbo et al., 2016). Combined use of CA 19-9, CA 242, and CEA has been

proposed. A metaanalysis has shown the highest sensitivity with the combination of CA 19-9 and CA 242, while the combination of CA 19-9, CA 242, and CEA provides the highest specificity (Zhang et al., 2015b).

For the early detection of PDAC, many circulating, cellular, gene, or molecular biomarkers have been studied. Attempts have been made to identify biomarkers in urine/pancreatic juice accompanied with endoscopic techniques. Studies using combination of markers, including CA 19-9, have been particularly successful in detecting early disease. Detection of circulating tumor cells in blood and peritoneal fluid using reverse transcription polymerase chain reaction has been proposed as a viable and sensitive method (Kelly et al., 2009).

An innovative approach on pathogenetic mechanisms of PDAC is the involvement of inflammation (Ahmad et al., 2014). Systemic inflammation markers such as neutrophil—lymphocyte ratio, platelet—lymphocyte ratio, and modified Glasgow Prognostic Score have been investigated (Martin et al., 2014). Neutrophil to lymphocyte ratio is calculated by dividing the neutrophil count by the lymphocyte count, with sensitivity increased at levels >5. This ratio is significantly higher in patients with PDAC (Garcea et al., 2011). Moreover, survival in advanced PDAC is strongly related to the levels of various systemic inflammation markers as they are calculated from routine blood tests. DJ-1 is a novel biomarker and when its serum levels were compared to those of CA 19-9, its area under the curve was higher (Chen et al., 2012). It has been also suggested that in 68.5% of patients with PDAC, DJ-1 correlates with tumor invasion, predicting a poor outcome. Other circulating biomarkers such as PAM4.Ic3b, REG4, serum phosphoprotein signal-regulated kinase (p-ERK1/2), and CEACAM1 need further validation before clinical use.

Several gene biomarkers have been studied in PDAC as it is known to be a genetically predisposed disease. Most commonly mutated genes are KRAS (K-Ras 2), CDKN2A/p16, TP53, and SMAD4/DPC4. PDAC has the highest amount of KRAS mutations, and >50% of patients exhibit this abnormality. Activated KRAS activates the RAF family kinase RAF1, BRAF, ARAF leading to uncontrolled cancer development. The KRAS mutation presents a critical event for PDAC for diagnosis and prognosis (Nio et al., 2001). P53 phosphoprotein is encoded by gene TP53, which is mutated in up to 50% of PDAC cases. As it is a tumor suppressor gene and activates genes due to cellular stress or DNA damage, it induces growth arrest (Moore et al., 2001). P16 is encoded by CDKN2A gene, whereas lack of P16 protein is associated with advanced disease and poor prognosis. Modification of CDKN2A causes melanoma and increased risk of PC (Duff and Clarke, 1998). DPC4/SMAD4 is a protein encoded by the SMAD4 gene located in chromosome 18. It has been found mutated in 55% of patients with PDAC (Duff and Clarke, 1998). Metastin is a gene product of the tumor suppressor gene KISS-1. PDAC expresses lower KISS-1 levels in comparison to normal pancreatic tissue; hence the presence of metastin correlates with longer survival (Masui et al., 2004). Phosphate and Tensin (PTEN) is a tumor suppressor gene encoded at chromosome 10q23.3. PTEN deletion has resulted in metaplasia leading to PDAC. In about 70% of PDAC, expression of PTEN is low or absent (Osayi et al., 2014).

Regarding molecular biomarkers, there is a high expression in all areas susceptible to PC (like liver, lymph node, and lung) of CXCL12, CXCR4 protein receptors of the CXC chemokine ligand 12. High expression of CXCR4 in resected PDAC is associated with shorter overall survival/distal metastases (Osayi et al., 2014). Cathepsin B (CTSB) is a lysosomal protease shown to degrade components of extracellular matrix and contributes to poor prognosis due to local invasion and metastasis promotion (Osayi et al., 2014). Another important factor in tumor invasion/metastases is angiogenesis. Several growth factors are implicated in promoting angiogenesis, the most important of which is the vascular endothelial growth factor (VEGF) that has been associated with PDAC metastases, especially to the liver. Epidermal growth factor receptor, a transmembrane glycoprotein, is overexpressed in 40%—70% of patient with PC (Jung et al., 2015; Yamanaka et al., 1993).

MicroRNAs (miRNAs) are noncoding molecules that aim to preserve normal cellular signals. They are involved in posttranscriptional gene regulation. Their utilization helps differentiate PDAC from chronic pancreatitis. Besides that, they appear to predict disease-free and overall survival. miRNA can act as a tumor suppressor or as an oncogene (Jamieson et al., 2012). miRs-21, miR-210, miR-155, and miR-196a are upregulated in PC tissue, representing possible novel diagnostic and prognostic factor (Ajit, 2012). miR-21 overexpression is reported as the lesion initiator in the context of pancreatic intraepithelial neoplasia causing tumor progression. The upregulation of miR-221 in PC leads to distant metastasis and unresectable tumors (Kishikawa et al., 2015).

Ovarian Cancer

Although CA-125 remains the most useful OC biomarker, numerous efforts and strategies aiming at utilizing CA-125 for screening purposes have not proven fruitful. A popular strategy has emerged within OC screening research wherein additional biomarkers are sought, which are capable of complementing the performance of CA-125 to augment sensitivity and specificity. For example, a study utilizing >2000 women

identified a four-biomarker panel consisting of CA-125, human epididymis protein (HE4), CEA (a glycoprotein biomarker associated with colorectal cancer and also loosely associated with PC), and vascular cell adhesion molecule-1 (VCAM-1; a leukocyte adhesion factor involved in extravasation of white blood cells during an inflammatory response), which could differentiate early stage OC from controls with a sensitivity/specificity of 86/98 (Yurkovetsky et al., 2010). The combination of CA-125, transthyretin (TTR), and apolipoprotein A1 (ApoA1) has also demonstrated some usefulness in the early detection of OC (Kim et al., 2012; Su et al., 2007). TTR and ApoA1 are acute phase reactants produced in the liver and released in acute inflammation state. Each of the biomarkers used individually is unlikely to offer a high specificity given that they are likely to be elevated in response to a number of inflammatory conditions. However, their use in combination with CA-125 appears to increase their efficacy. The performance of this panel has been further enhanced with the addition of other protein biomarkers (H418, transferrin). The overall performance of these panels is comparable to that of the four-biomarker panel described above. Similar levels of performance have also been reported for several larger combinations of CA-125, tumor markers, inflammatory mediators, and acute phase reactants consisting of 5–11 proteins (Amonkar et al., 2009; Edgell et al., 2010; Skates et al., 2004). In all, the use of CA-125-based biomarker combinations has produced some encouraging results; however, none of the identified panels have yet to perform reproducibly at a level that would warrant widespread implementation.

HE4 is encoded by the WFDC2 gene and is a small secretory protein that is involved in the maturation of sperm. It is overexpressed in OC and is a FDA approved peptide for monitoring epithelial OC. HE4 is expressed in epithelial OC that do not express CA-125. HE4 on its own showed the highest sensitivity for stage I disease with a specificity of 45.9% at 95% sensitivity. It has been shown that using HE4 in a multivariate panel with CA-125 yields a significantly better specificity than any of the stand-alone uses.

Lysophosphatidic acid (LPA) is a small bioactive phospholipid that acts as an agent promoting cell proliferation, invasion smooth muscle cell contraction, cell migration, cell survival, wound healing, morphology alteration, and tissue differentiation. A metaanalysis of 19 controlled studies, including 2520 subjects, showed that plasma LPA was significantly higher for patients with OC compared with those with benign disease or healthy individuals (Li et al., 2015).

Mesothelin is a protein encoded by the MSLN gene, is present on normal mesothelial cells and is overexpressed in tumors such as OC, PDACs, and

mesotheliomas. A recent metaanalysis, indicated 94% specificity for mesothelin and 62% sensitivity for OC, suggesting that although it cannot be utilized as a stand-alone biomarker, it might be combined with CA-125 or HE4 for better outcomes (Madeira et al., 2016).

Human prostasin is a glycosylphosphatidylinositol-anchored extracellular serine protease encoded by PRSS8 and is located on chromosome 16p11.2. It is present in the seminal fluid and apical surface of epithelial tissues (the lungs, kidney, liver, bronchi, colon, and salivary glands). It acts as a proteolytic activator of epithelial sodium channels. Raised expression of prostasin is associated with various malignancies, including OC. Combined with CA-125, the sensitivity and specificity for OC is 92% and 94%, respectively. Furthermore, Tamir which induces at least an 100-fold overexpression of the PRSS8 gene in all types and all stages of OC is a promising minimally invasive biomarker of OC but should not be used to differentiate stages (Tamir et al., 2016). PRSS8's diagnostic performance is also vastly improved when combined with OVA1 (Yip et al., 2011).

Human kallikreins are low-molecular-weight proteases encoded by a family of 15 genes located on chromosome 13q13.4. Plasma kallikrein is responsible for blood pressure regulation, tissue inflammation, and plasmin formation. Tissue kallikreins play a role in smooth muscle contraction, hormonal regulation, blood pressure control, vascular cell repair, and neoangiogenesis. These proteins influence the course of various types of cancers. Their role in cancer pathogenesis and progression is due to dysregulation of growth factors, cell adhesion molecules and cell surface receptors, as well as the degradation of extracellular proteins, effect that can induce a disruption of the physiological barriers against cancer.

In OC, KLK6 and KLK10 are elevated in serum. Moreover, in advanced stages, they correlate significantly with CA-125. KLK11 is elevated notably in patients with OC compared to patients with benign disease or healthy individuals. KLK6 has a better specificity than CA-125 for early detection and is not elevated in healthy individuals. Combined use of KLK6, KLK13, and CA-125 has a greater sensitivity for early stage diagnosis (White et al., 2009). A metaanalysis of five studies, including a total of 1150 patients, reported a sensitivity of 50%, a specificity of 91% with a positive and negative likelihood ratio of 7.2 and 0.51, respectively, whereas the combined use of KLK6 and CA-125 achieved superior diagnostic efficacy for advanced OC (Yang et al., 2016).

miRNAs (noncoding RNAs secreted from cells into the circulation that regulate gene expression by altering proliferation, differentiation, and apoptosis perform their action via translational inhibition or mRNA degradation; see above) act both as tumor suppressors or promoters. Tp53 regulates miRNAs. As Tp53 mutations are

found in 96% of OC, it becomes apparent that there is dysregulation of the miRNAs. On the other hand miR-NAs downregulate BRCA1 and 2, hence they can affect the onset of the cancerous process (Leung et al., 2016). It has been shown that miRNA 21, 141, 200a, 200b, 203, and 214 could play an important role in diagnosing OC as they are overexpressed. On the other hand, miRNA 199a, 140, 145, and 125b1 were found to be downregulated (Iorio et al., 2007). miRNAs found in the exosomes of individuals with malignant disease are significantly different from the miRNA profile of healthy individuals or patients with benign disease (Taylor and Gercel-Taylor, 2008). It has been reported that a combination of CA-125 and six miRNAs (200a-3p, 766-3p, 26a-5p, 142-3p, let 7d-5p, and 328-3p) achieves a sensitivity of 98.4% and a specificity of 95.6% (Yokoi et al., 2017). It has been suggested that it is possible to overcome the difficulty of distinguishing a malignant from a benign mass without surgical intervention by applying a combination of seven miRNAs with a 86.1% sensitivity and 83.3% specificity (Yokoi et al., 2017). It also has been suggested that detection of circulating miRNAs might contribute significantly to early detection, and therefore miRNAs could be used as prognostic biomarkers because over- or under-expression of certain of these proteins is linked to poor prognosis, recurrent, or even metastatic disease (S. Zhang et al., 2015a).

At least 10% of epithelial OCs are hereditary and in ∼90% of those individuals, BRCA1 and 2 are the accountable cause, as well as RAD51D. Furthermore, Tp53 has been identified in 96% of the cases, mainly in high-grade tumors. On the other hand, KRAS and BRAF mutations are more common in low-grade sub-types. Moreover, mutations to DNA mismatch repair genes have also been found to be responsible for malignant transformation, such as hMLH 1 and 2 genes. Therefore, genetic testing for mutations might identify potentially high-risk patients before clinical presentation of the disease. Epigenetic changes such as DNA hyper- or hypomethylation that can deactivate tumor suppressor genes, also are accountable for genetic alterations, hence promotion of carcinogenesis.

Folate receptor alpha (FOLR1) is a membrane receptor that facilitates the transportation of folate into cells. Rapid mitosis and proliferation require high levels of folate to secure adequate DNA synthesis. Several studies have confirmed overexpression of FOLR1 in OC. It has been showed that FOLR1 is significantly elevated in the serum of patients with OC compared to patients with benign disease or healthy individuals (Leung et al., 2013). Furthermore, a strong synergetic effect of HE4 + FOLR1 and CA-125 + FOLR1 combinations has been demonstrated (Kurosaki et al., 2016; Leung et al., 2016).

Biomarkers in the Evaluation of a Pelvic Mass

The overall prevalence of pelvic abnormalities is estimated at 7% and it is expected that 5%–10% of American women will receive prophylactic surgery for suspected OC at some point in their lives (DiSaia and Creasman, 1997). The burden of early identification of potential OC falls predominantly on the obstetrician/gynecologist whose training in the management of cancer patients is usually limited. A series of diverse studies have demonstrated a decrease in the relative risk of reoperation, and increases in disease-free interval and overall survival for women operated on by gynecological oncologists compared with gynecologists and general surgeons (Bristow et al., 2002; Eisenkop et al., 1992; Tingulstad et al., 2003). In addition to family history, pelvic examination, ascites, and evidence of local or distant metastases, the CA-125 blood test is included in the standard criteria espoused by The Society of Gynecologic Oncology and the American College of Obstetrics and Gynecology regarding referral of a patient with a pelvic mass to a gynecological oncologist. This set of criteria has produced disappointing results in prospective studies, particularly those evaluating premenopausal women with early stage disease, providing sensitivity/specificity levels as low as 47%/77% (Dearking et al., 2007). Considerable effort has been focused on the identification of additional biomarkers capable of complementing the performance of CA-125. Several combinations have recently been approved for clinical use based on trial performance and these are discussed below. Each of the FDA approved tests is intended to aid referring physicians in choosing the most appropriate specialist for surgical intervention for patients already planning to undergo surgery.

A scoring model termed the Risk of Ovarian Malignancy Algorithm (ROMA) has been developed, which incorporates measurements of CA-125 and HE4 along with menopausal status to assign high or low risk of malignancy to a woman presenting with a pelvic mass. Based on the results of a prospective, multicenter, blinded clinical trial, ROMA was approved by the FDA for use in determining the risk of OC in pre- and postmenopausal women with a pelvic mass. The clinical impact of the ROMA test remains to be assessed as physicians independently evaluate its performance and make decisions regarding its implementation. The CA-125/HE4 combination and ROMA have received considerable attention in preclinical studies with mixed results. The superior diagnostic performance achieved through the use of the combination of both biomarkers over either biomarker used individually is widely agreed on.

However, despite the diagnostic utility of ROMA in comparison to more traditional methods of

assessment, including imaging, physical exam, and an older diagnostic model, the risk of malignancy algorithm has remained controversial (Montagnana et al., 2011, 2017).

OVA1 is another multivariate index assay for identifying high-risk OCs by using five proteins: CA-125, ApoA1, transthyretin, beta 2 microglobulin, and transferrin. It uses two different immunoassay platforms, the Roche Elecsys for CA-125 and the Siemens BNII for the four other analytes. The results are calculated with the use of an algorithm, OvaCalc. Taking into account the menopausal status of the individual, it calculates a score. Having a score of more than 5 or more than 4.4 for premenopausal and postmenopausal women, respectively, shows a higher probability for malignant disease. OVA1 has been FDA approved since 2009 as an adjunct to diagnosis of adnexal masses when radiological and clinical indetermination exists. The test is not approved for screening individuals without an adnexal mass. It should neither be utilized if conservative management is favored by clinical assessment nor if a referral to a gynecologic oncologist is necessary as it has no value for the patient's future management. The panel was evaluated in a clinical trial that utilized immunoassays targeting each of the five markers in a set of 524 women diagnosed with a pelvic mass and recommended for surgery (Ueland et al., 2011; Ware Miller et al., 2011). When the OVA1 panel was substituted for CA-125 within the American College of Obstetricians and Gynecologists OC referral guidelines, it provided not only an increase in sensitivity and negative predictive value in comparison to CA-125 but also a decrease in specificity and positive predictive value. When the OVA1 test was added to a normal physician assessment, similar trends were observed. Regarding, its performance, the presurgery assessment and OVA1 score had 96% sensitivity, 35% specificity, 40% positive predictive value, and 95% negative predictive value, whereas the physician presurgery assessment arm had 75% sensitivity, 79% specificity, 62% positive predictive value, and 88% negative predictive value. Limitations for this test include rheumatoid factor >250 IU/mL or triglyceride levels >4.5 g/L, as well as diagnosis of malignancy in the last 5 years (Nolen and Lokshin, 2013).

PROGNOSTIC BIOMARKERS

Pancreatic Cancer

Indicators of prognosis in PC could inform the development of treatment plans tailored to optimize the curative and/or palliative benefits provided to individual patients. Prognostic biomarkers would assist physicians in determining the appropriateness of surgical resection, local radiation therapy, and systemic chemotherapy. Currently, CA 19-9 offers only a limited ability to aid in these types of decisions and other biomarkers commonly used in the monitoring of PC, including CEA and CA-125, have been hampered by low levels of disease specificity. A number of additional biomarkers, including genetic markers and proteins, have received attention as potential prognostic biomarkers of PC; however, none of these have yet performed at a level warranting clinical implementation.

Gene signatures are routinely used in the management of breast cancer, and similar tools have been sought in the setting of PC. In two notable studies, a protein signature consisting of 171 genes and a much smaller 6-gene signature were both shown to stratify patients on the basis of survival (Donahue et al., 2012; Stratford et al., 2010). On an individual basis, the mutation status of the DPC4 gene, which encodes the transcription factor SMAD4, has been proposed as a means of differentiating patients likely to develop local versus distant recurrence following surgery. Such a role was supported by the results of two independent studies (Blackford et al., 2009; Iacobuzio-Donahue et al., 2009) and would suggest a method of identifying patients more likely to benefit from aggressive local therapy following surgery. However, more recent findings regarding SMAD4 expression in tissue obtained from PC patients indicated no difference between individuals demonstrating local versus distant recurrence (Winter et al., 2013), casting doubt on the usefulness of this biomarker.

A number of proteins have emerged as potential prognostic biomarkers for PC. Three such proteins, MUC1, MUC2, and mesothelin, were identified from among 13 PC-related proteins in a single study as markers capable of differentiating PC on the basis of tumor aggressiveness (Winter et al., 2012). MUC1 and MUC2 are membrane-bound proteins characterized by altered glycosylation patterns associated with a variety of malignancies. Mesothelin is a glycosylphosphatidylinositol-anchored cell surface protein that is overexpressed in mesothelioma, OC, and squamous cell carcinoma. OPN (osteopontin), another protein biomarker, which has shown promise in the early detection of PC, has also been implicated as a prognostic biomarker based on the observation that serum levels of OPN in PC patients are correlated with diminished survival (Poruk et al., 2013). Human antigen R (HuR) is an RNA binding protein involved in the regulation of gene expression in response to cellular stress. Upregulation of HuR has been linked to the development of malignancy and has also been shown to be inversely correlated with prognosis in PC (Denkert et al., 2006; Richards et al., 2010). Tissue transglutaminase (TgII) is an enzyme responsible for catalyzing calcium-

dependent transamination reactions with a diverse and expanding repertoire of intra- and extracellular functions. Demonstrated and proposed roles for TgII in cancer development and progression include cell survival, drug resistance, and cell mobility and migration. TgII is currently the focus of considerable investigation as a prognostic marker and therapeutic target in PC (Mehta, 2009).

Notch cytoplasmic signaling and HES-1 or HEY-1 expression are significantly increased in metaplastic ductal epithelium and invasive PC. Immunohistochemistry of resected specimens revealed increased Notch1 in the nerves, Notch2 and Notch 3 in vascular smooth muscle, and Notch4 in vascular endothelium. These findings implicate Notch in both invasion and angiogenesis. HEY-1 nuclear expression independently, is not a good predictive marker of overall or disease-free survival, but is associated with aggressive tumor phenotypes (Gungor et al., 2011).

Ovarian Cancer

Similarly to the approach for PC, gene signatures have been investigated in the setting of OC, which might have a prognostic value in both pre- and postoperative management. Several gene signatures have been reported to stratify patients on the basis of overall survival (Bonome et al., 2008; Spentzos et al., 2004). The identification of gene signatures offers not only potential for development of prognostic tools but may also shed light on the biological mechanisms underlying disease development through closer examinations of the molecular markers included in each signature. Several individual genetic markers have been identified that offer prognostic information in OC, including *RAB25* and *FGF1*. *RAB25* encodes a cell membrane protein involved in pseudopod extension implicated in the promotion of cell proliferation, survival, and migration, whereas *FGF1* encodes a member of the fibroblast growth factor family, a network of potent mitogens involved in numerous biological processes. Increased levels of *RAB25* mRNA are associated with decreased disease-free survival (Cheng et al., 2004), whereas *FGF1* gene amplification is significantly associated with poor survival (Birrer et al., 2007). The Cancer Genome Atlas (TCGA) project has shown that TP53 mutation is present in almost all high-grade OC and that 20% of patients with high-grade carcinoma harbor BRCA1 mutation. In patients with TP53 and BRCA1, the prognosis is poor. Women harboring only BRCA1 mutation seem to have a survival benefit. This is due to the fact that BRCA patients present at a young age and BRCA genes are involved in DNA damage recognition/homologous repair, which means that when there is a BRCA mutation there is impaired homologous repair and chemotherapy has greater potential of destroying those cells (Rzepecka et al., 2017). ING5 gene expresses a protein, characterized as a tumor suppressor protein as it inhibits cell glucose metabolism, invasion, migration, transition and induces apoptosis. Downregulated ING5 is linked to poor prognosis because it is associated with vascular invasion, lymphatic invasion, and late International Federation of Gynecology and Obstetrics (FIGO) staging (Zheng et al., 2017).

In an attempt to identify prognostic biomarkers to guide clinical practice, numerous circulating and tumor-expressed proteins have been investigated. Circulating and tumor-associated levels of osteopontin have been reported to be positively correlated with recurrent disease, bulk disease, metastasis, and poorer prognosis among patients with advanced disease (Coticchia et al., 2008; Hu et al., 2015). High serum levels of relaxin and KLK10 have also been shown to be unfavorable prognostic factors (Guo et al., 2017). On the contrary, elevated serum levels of KLK11 have been shown to be an independent favorable predictor in advanced high-grade serous OC (Geng et al., 2017). High progesterone and estrogen receptors are associated with favorable outcome in endometrioid OC. Galectins have also been reported to have various effects on disease progression. Elevated galectin 1 and 7 levels in the cytoplasm have been reported as negative prognostic factors. Multiple immune markers have a prognostic value for OC because the protective role of the immune system is well established (Labrie et al., 2017). The presence of $CD8^+$ and $CD20^+$ tumor-infiltrating lymphocytes and HLA II predicts a favorable prognosis (Santoiemma et al., 2016). Vasohibin-1, a negative feedback inhibitor of angiogenesis induced by VEGF (a prognostic biomarker for OC negatively correlating with survival) in vascular endothelial cells has been associated with poor prognosis (Sano et al., 2017). A metaanalysis, showed that cyclin E (the main regulator for transition from G1 to S phase) is overexpressed, and is a poor prognostic factor for overall survival (Farley et al., 2003). Ki67, a nuclear protein essential for cellular proliferation, is an independent prognostic factor for poor overall survival in OC patients (Liu et al., 2012). Diminished levels of E-cadherin, a glycoprotein that mediates calcium-dependent cell adhesion and interacts with actin strengthening cell−cell interaction, have been reported to manifest poor prognosis and possible late/disseminated OC due to loss of cellular contacts allowing cancer progression/dissemination (Rosso et al., 2017).

PREDICTIVE BIOMARKERS

Pancreatic Cancer

The search for biomarkers predictive of therapy response in PC has been largely centered on cellular factors related to the transport and metabolism of gemcitabine, the current standard of care. Although a number of such factors have been evaluated (Brody et al., 2011), none has been deemed to be of sufficient quality for clinical use. The role of HuR in cellular handling of gemcitabine remains uncertain; however, this factor has demonstrated considerable promise as a predictive biomarker of the gemcitabine response. Although HuR overexpression is negatively correlated with overall prognosis in PC, it is positively correlated with prolonged survival following gemcitabine administration independent of tumor stage but its value remains to be validated in independent large trials (Costantino et al., 2009; Richards et al., 2010).

Mutations in several genes in terms of the Fanconi anemia DNA repair pathway have been associated with PC and may serve as predictive biomarkers for response to agents targeting DNA synthesis and repair, including poly ADP-ribose polymerase (PARP) inhibitors, platinum-based agents, or mitomycin C. Patients harboring mutations in *BRCA1*, *BRCA2*, and *PALB* have demonstrated encouraging responses to these agents (Lowery et al., 2011; Villarroel et al., 2011).

Receptor tyrosine kinase inhibitors represent a promising class of anticancer therapeutics currently in use or in clinical trials for a number of malignancies. One such agent targeting epidermal growth factor receptor, erlotinib, is currently approved for the treatment of metastatic PC in combination with gemcitabine. The introduction of erlotinib and other targeted agents in PC will require the identification of additional predictive biomarkers. Potential biomarkers may include soluble or membrane-bound receptors, or molecules which function within the signaling pathways of targeted receptors (Akt, PI3k, etc.)

The goal of the predictive biomarkers is to determine the response to a specific therapy. SPARC is a promising therapeutic biomarker in patient treated with combination nab-paclitaxel—gemcitabine chemotherapy. Patients with high-expression SPARC display increased overall survival (Von Hoff et al., 2011). Hent1 appears to play a role in the internalization of gemcitabine by PC cells and is an important factor for gemcitabine efficacy in patients with PC. Patients positive for Hent1 have longer median survival with gemcitabine therapy. Interestingly, this positive finding was not observed with other chemotherapy agents (Spratlin et al., 2004).The increased expression of some miRNAs predicts favorable response to gemcitabine treatment. They can be identified by mutational analysis on DNA or RNA and are commercially available. Some of them are miR-21, miR-200b, miR-29b, miR-221, and miR-494 (Karakatsanis et al., 2013).

Ovarian Cancer

A number of gene signatures and several protein biomarkers such as kallikrein 10 and bikunin have emerged as potential predictive biomarkers. In separate studies, elevated levels of each biomarker were found to correlate with poor response to chemotherapy (Borley et al., 2012; Costantino et al., 2009; Farley et al., 2003; Hefler et al., 2006; Liu et al., 2012; Lowery et al., 2011; Luo et al., 2001; Matsuzaki et al., 2005; Na et al., 2009; Villarroel et al., 2011). Elevated protein levels of ABCF2, a member of the ATP-binding cassette family of transmembrane transport proteins, were recently observed to correlate with chemoresistance in OC patients (Tsuda et al., 2005). miRNA let-7i has been found to have a predictive value as its levels are significantly reduced in chemotherapy-resistant patients, presaging a shorter progression-free survival (Yang et al., 2008). Another group of four miRNAs (miR-200b, miR-1274A, miR-141, and miR-200c) appears to have a predictive value as low levels of them are associated with better overall survival, with the latter able to give information regarding response to immunotherapy (Halvorsen et al., 2017). Moving to a different direction, it has been suggested that a long noncoding RNA signature held a rather high predictive accuracy of resistance to chemotherapy and was intimately associated with patients' progression-free survival (Wang et al., 2017). Another potential marker that could be implicated as an OC predictive marker and provide information about the outcome is interleukin-37, a novel antiinflammatory cytokine that is found in late-stage OC, lymph node progression, and residual disease postsurgical management and is associated with unfavorable outcome (Huo et al., 2017).

Furthermore, elevated galectin 1, 8, 9, levels are also associated with poor chemotherapy and other treatment outcomes, as well as a decline in overall survival and progression-free disease (Labrie et al., 2017). A recent study showed that three proteins, ERCC1, TUBB3 and PGP, had a significant prognostic and predictive value as they identified patients who had chemoresistance to a platinum/taxane combination (Herzog et al., 2016). Two preangiogenic factors, PDGFR-beta and VEGFR2, have been shown to have unfavorable predictive news regarding chemoresistance if elevated (Avril et al., 2017).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The diverse and unmet challenges associated with the management of patients diagnosed with PC and OC have prompted an immense amount of research into the development of clinical biomarkers as tools aimed at diagnosing, monitoring, and triaging patients more effectively. Despite this effort, only a few clinically useful biomarkers are currently available, notably, CA 19-9 for PC and CA-125 for OC. While each of these remains an important component of patient management in its respective disease setting, well-appreciated limitations are associated with each demand in the discovery and development of additional, more effective diagnostic, prognostic, and predictive biomarkers.

Research efforts aimed at the development of diagnostic biomarkers for use in screening for PC and OC are intense, diverse, innovative, and productive, resulting in numerous promising reports. Such reports have described the use of proteins, genes, miRNAs, proteomic signatures, and a variety of additional platforms. However, as alluded to by the disappointing results of the PLCO trial, population-based screening for either of these diseases does not appear to be on the horizon. Further research will be necessary to identify biomarkers capable of achieving sensitivity/specificity levels approaching 99% to overcome the challenge of disease rarity and establish a screening test that achieves acceptably low levels of false-positive results while detecting diseased individuals with high fidelity. Only then large screening trials such as the PLCO and UKC-TOCS will be warranted to establish efficacy and increase the advancement of biomarker testing into clinical implementation.

The successful clinical implementation of the ROMA and OVA1 tests represents significant achievements within the field of pelvic mass management and also within the larger field of biomarker research. The next step in the evaluation of these tests will be the so-called Phase IV trials of postmarketing efficacy. Large studies of the use of these tests by general practitioners and gynecologists will be necessary to assess the impact on OC morbidity and mortality. Comparative effectiveness research should also be undertaken to directly compare the use of the ROMA and OVA1 tests to more precisely define the indications for each and maximize the benefits.

Regarding prognostic and predictive biomarkers, many preliminary reports have been described for each; however, relatively less has been achieved in the search for predictive biomarkers. Efforts should now be made to work beyond the preliminary stage and begin to standardize analysis platforms and sampling criteria to focus on the most promising and reproducible biomarkers.

Efficacy achieved in this manner should lead to advancement into larger trials and eventual progression into clinical implementation. In conclusion, the use of biomarkers in multiple aspects of the clinical management of PC and OC has become a priority for clinicians and researchers and is likely to increase steadily in the coming years. The advancement of novel biomarker tests into the clinic should lead to significant benefits in patient care.

INTRODUCTION

Prostate cancer (PCa) represents a major health issue with an incidence mainly dependent on age. It is the second most commonly diagnosed cancer in men (1.1 million diagnoses worldwide in 2012; 15% of all cancers diagnosed) (Ferlay et al., 2015). Detection on autopsy is similar worldwide (Haas et al., 2008) with prevalence at age <30 years of 5%, increasing by an odds ratio of 1.7 per decade, to 59% by age >79 years (Bell et al., 2015). However, the incidence varies widely (highest in Australia/New Zealand, Northern America, Western and Northern Europe; largely due to prostate-specific antigen (PSA) testing use and the aging population; low in Eastern and South Central Asia, while rates in Eastern and Southern Europe, which were low, have showed a steady increase) (Ferlay et al., 2015; Haas et al., 2008). On the other hand, mortality rates vary less (generally high in populations of African descent, intermediate in the United States, and very low in Asia) (Ferlay et al., 2015). Genetic factors are associated with the risk of (aggressive) PCa, but ongoing trials are needed to define the clinical applicability of screening for genetic susceptibility. A variety of exogenous/environmental factors may have an impact on the risk of progression, but no definitive recommendation can be provided for specific preventive or dietary measures to reduce the risk of developing PCa (Mottet et al., 2017).

The therapeutic success rate for PCa can be significantly improved if the disease is diagnosed early. In most cases, this disease can be treated effectively and even eradicated when detected at a very early stage.

Thus, a successful therapy depends heavily on clinical indicators (biomarkers) for early detection and progression of the disease, as well as the prediction after the clinical intervention. However, there are a lack of reliable biomarkers to date that can specifically distinguish between those patients who should be treated adequately to stop the aggressive form of the disease and those who should avoid overtreatment of the indolent form. Current advances in molecular techniques have provided new tools to facilitate the discovery of new biomarkers for PCa. These emerging biomarkers will be critical in developing new clinically reliable indicators with high specificity for the diagnosis and prognosis of PCa. This chapter examines the current and emerging PCa biomarkers on their diagnostic and prognostic potential for prediction of disease status and response to drug- or treatment-related toxicities.

SCREENING AND EARLY DETECTION FOR PROSTATE CANCER

Population (mass) screening refers to the "systematic examination of asymptomatic men (at risk)" usually driven by health authorities, whereas early detection (opportunistic) testing refers to individualized findings driven by the individual being tested and/or his physician. Both strategies aim at the reduction of disease-specific mortality and quality of life maintenance.

PCa screening remains one of the most controversial topics in urology, but there is currently strong evidence against systematic population-based screening in all

countries, including Europe (Mottet et al., 2017). It has been recently shown from data of the European Randomized Study of Screening for Prostate Cancer (ERSPC) with follow-up of over 10 years that reduction in mortality remains unchanged with extended follow-up (Schroder et al., 2014). Screening for PCa has never been shown to be detrimental at the population level but its impact on overall quality of life remains unclear (Booth et al., 2014; Heijnsdijk et al., 2012; Vasarainen et al., 2013). An updated Cochrane review (Hayes and Barry, 2014) has showed that:

1. Screening is associated with increased diagnosis (risk ratio (RR): 1.3; 95% CI: 1.02−1.65), with detection of more localized and less advanced disease (RR: 1.79; 95% CI: 1.19−2.70; and RR: 0.80; 95% CI: 0.73−0.87, respectively).
2. Based on pooled results of four available randomized controlled trials (RCTs), no overall survival benefit has been detected (RR: 1.00; 95% CI: 0.96−1.03).
3. Based on pooled and individual results of five RCTs, randomizing >341,000 men, no PCa-specific survival benefit has been detected (RR: 1.00; 95% CI: 0.86−1.17).
4. Screening is associated with minor and major harms (overdiagnosis and overtreatment), despite the fact that biopsy is not associated with any mortality.

According to the European Association of Urology (EAU)-European Society for Radiotherapy and Oncology (ESTRO)-International Society of Geriatric Oncology (SIOG) guidelines on PCa (Mottet et al., 2017), an individualized risk-adapted strategy for early detection might be offered to a well-informed man with a good performance status and a life expectancy of at least 10−15 years. However, it is crucial to carefully detect patients likely to benefit most from individual early diagnosis, considering potential balances/harms because this approach may be associated with a substantial risk of overdiagnosis and the long-term survival/quality of life benefits of this approach needs to be proven at a population level. Men at increased risk of having PCa include those >50 years, those >45 years with positive paternal or maternal family history (Albright et al., 2015) and African Americans (Kamangar et al., 2006). Men with a serum PSA level >1 ng/mL at 40 years and >2 ng/mL at 60 years (Carlsson et al., 2014; Vickers et al., 2013) are also at increased risk of metastasis/death. Informed men requesting early diagnosis should be given a PSA test and undergo a digital rectal examination (DRE) but optimal intervals are unknown, whereas a risk-adapted strategy might be considered based on the initial PSA level (every 2 years for those initially at risk, or postponed up to 8 to 10 years in those not at risk). The age at which early diagnosis should be stopped is controversial, but men with <15 year life expectancy are unlikely to benefit (Mottet et al., 2017).

Several new biomarkers such as BRCA2 (a genetic abnormality associated with an increased risk shown prospectively (Bancroft et al., 2014; Gulati et al., 2017)), TMPRSS2-Erg fusion, PCA3 (Leyten et al., 2014; Vedder et al., 2014), or kallikreins as incorporated in the Phi or 4K score tests (Boegemann et al., 2016; Bryant et al., 2015) have been shown to add sensitivity/specificity on top of PSA, potentially avoiding unnecessary biopsies and lowering overdiagnosis. However, there is currently too limited data to base a recommendation on and further data are needed before such biological markers can be used in standard clinical practice (Mottet et al., 2017).

CONTEMPORARY CLINICAL BIOMARKERS IN PROSTATE CANCER

Prostate-Specific Antigen

PSA is a serine protease kallikrein family member, clustered in a 300-kb region encoded on chromosome 19q13.4. It is expressed both in normal and cancerous prostatic tissue. Therefore it constitutes an organ but not a cancer-specific biomarker that can be elevated in benign prostatic hyperplasia (BPH), prostatitis, and other nonmalignant conditions. Nevertheless, the use of PSA as a serum marker has revolutionized PCa diagnosis (Stamey et al., 1987). As an independent variable, it is a better predictor of PCa than DRE or transrectal ultrasonography (TRUS) of the prostate (Catalona et al., 2017). Currently, serum PSA is widely used in clinical practice for diagnostic, posttreatment prognostic, recurrence monitoring, and drug efficacy determining biomarker, but it is considered a suboptimal tool for screening, diagnosis, and prognosis due to limitations such as low specificity and its inability to identify indolent from aggressive tumors.

Two large population-based studies in Europe (ERSPC) and in the United States (Prostate, Lung, Colorectal, and Ovarian [PLCO] Cancer Screening Trial) have confirmed its modest clinical value as a screening tool for PCa (Auvinen et al., 2016; Bibbins-Domingo et al., 2017; Pinsky et al., 2017; Schroder et al., 2014). Higher serum PSA levels indicate a greater likelihood of PCa. Many men with low serum PSA levels may harbor PCa and therefore, an optimal threshold for detecting nonpalpable but clinically significant PCa is precluded (Table 48.1) (Mottet et al., 2017). Nomograms may help in predicting indolent PCa (Dong et al., 2008).

Efforts to improve the diagnostic performance of serum PSA have been extensively investigated using several modifications of PSA testing (Mottet et al., 2017). PSA density (level of serum PSA divided by the TRUS-determined prostate volume) has shown that the

TABLE 48.1 Risk of PCa in Patients With Serum PSA Levels up to 4 ng/mL

PSA (ng/mL)	PCa Gleason Score >7 (%)	PCa (%)
0.0–0.5	0.8	6.6
0.6–1.0	1.0	10.1
1.1–2.0	2.0	17.0
2.1–3.0	4.6	23.9
3.1–4.0	6.7	26.9

PCa, prostate cancer; *PSA*, prostate-specific antigen.

higher the PSA density is the more likely that PCa is clinically significant. PSA kinetics (PSA velocity; i.e., the absolute annual increase in serum PSA (ng/mL/year) and PSA doubling time; i.e., the exponential increase in serum PSA over time) may have a prognostic role in treatment but limited diagnostic value because of background noise (total prostate volume and BPH), different intervals between PSA determinations, and acceleration/deceleration of PSA velocity and PSA doubling time over time. Consequently, PSA kinetics do not provide additional information compared with PSA alone. Free/total PSA ratio stratifies the risk of PCa in men with a total serum PSA level of 4–10 ng/mL and negative DRE. The ratio is clinically useless if the total serum PSA level is >10 ng/mL or for following up PCa because it may be adversely affected by several factors (e.g., instability of free PSA at 4°C and room temperature, variable assay characteristics, and concomitant BPH in large prostates).

Additional Serum Testing

A few commercially available assays measure a panel of kallikreins in serum or plasma (Ashley et al., 2017; Saini, 2016). The most well-known and widely used are the prostate health index (PHI) test and the four kallikrein (4K) score test (Mottet et al., 2017). The former was approved by FDA in 2012. It is calculated for each patient as ([−2] proPSA isoform (p2PSA, one of the forms of free PSA)/freePSA) × $PSA^{1/2}$). The test was developed by Beckman Coulter in partnership with the NCI Early Detection Research Network and intends to distinguish cancerous and benign prostatic conditions in men aged ≥50 years with a normal DRE and total serum PSA levels of 4–10 ng/mL, thus determining the need of biopsy in such cases and, reducing unnecessary biopsies (Ashley et al., 2017; Saini, 2016). Several studies suggest that the use of PHI along with [−2] proPSA significantly improves PCa detection in cases with a Gleason score ≥7 and improves the accuracy of established PCa predictors at biopsy compared to PSA and free PSA.

The four kallikrein (4K) score test, offered by OPKO Health Inc., is available as a Clinical Laboratory Improvement Amendments—based laboratory developed test, i.e., commercially developed for PCa but not yet approved by the FDA (Ashley et al., 2017; Saini, 2016). It measures the blood plasma levels of a panel of four prostate-derived kallikrein proteins, i.e., total PSA, free PSA, intact PSA, and human kallikrein 2 (hK2), another kallikrein with 80% PSA homology. These biomarkers are combined with other parameters such as age, DRE status, and prior biopsy status to calculate the risk of pathologically insignificant versus aggressive PCa. The test assists to identify patients eligible for biopsy based on the probability of having aggressive PCa, and helps to avoid unnecessary biopsies in low-risk patients.

A few prospective multicenter studies have shown that both tests described above outperform the free/total PSA ratio for PCa detection, with an improved prediction of clinically significant PCa in cases with a serum PSA level between 2 and 10 ng/mL, whereas in a head-to-head comparison both tests perform equally (Mottet et al., 2017). PHI remains to be tested as a population-based screening tool for showing clinically meaningful benefit for screening that will lead to reduction of PCa mortality. The predictive ability of the 4K test appears to increase the diagnostic accuracy of detecting PCa using a subcohort of the ERSPC study, but a head-to-head comparison in large cohorts with serum PSA alone has not yet been studied. Nevertheless, according to the EAU-ESTRO-SIOG guidelines on PCa, before performing a prostate biopsy, a further risk assessment for asymptomatic men with a PSA level between 2 and 10 ng/mL, an additional serum or urine-based test (e.g., PHI, 4K score or Prostate cancer gene 3 [PCA3]; see below) among other tools, such as risk calculators or multiparametric magnetic resonance imaging (mpMRI), is recommended to avoid unnecessary biopsies (Mottet et al., 2017).

mpMRI is mainly recommended if clinical suspicion persists in spite of previous negative biopsy for deciding on a repeat systematic prostate biopsy with extra targeting of any lesions seen. On the other hand, despite the fact that additional information may be gained by additional serum-based, urine-based, or even tissue-based epigenetic tests (e.g., PHI, 4K score; PCA3 or ConfirmMDx [see below], respectively) the role of such tests in deciding whether to take a repeat biopsy in men with previous negative biopsy is uncertain and probably not cost-effective (Mottet et al., 2017).

Prostate Cancer Antigen 3

PCA3 or DD3 is a prostate-specific, noncoding mRNA biomarker with unknown function that is

detectable in urine sediments obtained after three strokes of prostatic massage during DRE. It is encoded on chromosome 9q21−22; it is not expressed in normal prostate tissue and has very low expression in hyperplastic prostate but is highly expressed in PCa (Ashley et al., 2017; Saini, 2016). The commercially available Progensa urine test (Hologic, Marlborough, MA) is superior to total and percent-free PSA for detection of PCa in men with elevated PSA as it shows significant increases in the area under the receiver-operator characteristic curve for positive biopsies (Mottet et al., 2017). An optimal cutoff for urinary PCA3 levels have yet to be established for maximizing the tradeoff between clinical benefit versus overdiagnosis (Saini, 2016). Currently, the main indication for the Progensa test is to determine whether repeat biopsy is needed after an initially negative biopsy (Mottet et al., 2017), but its clinical effectiveness and cost-effectiveness is uncertain (Nicholson et al., 2015).

CANDIDATE BIOMARKERS FOR PROSTATE CANCER

Current advancements in proteomics, tissue microarray, DNA microarray, immunohistochemical staining, microRNA, single nucleotide polymorphism analysis for genetic variations, and other biotechnologies have paved the way and significantly increased the pace at which novel biomarkers are being discovered and developed. Using these methodologies, researchers have reported a number of biomarkers with great potential: These biomarkers are currently undergoing further investigation for validation. A few of the recently identified candidates that have generated some excitement for their potential as PCa biomarkers are discussed below.

ConfirmMDx Test

The ConfirmMDx (MDx Health Inc.) test, is a non-FDA approved test that detects an epigenetic field effect or "halo" associated with a cancerization process at the DNA methylation level in cells adjacent to cancer foci (Hammarsten et al., 2016; Saini, 2016). The concept is that benign prostatic tissue near a PCa focus shows distinct epigenetic alterations. Core specimens collected during a 12-core biopsy are used (minimum requirement of eight cores; from apex, mid- and left/right base, and two additional locations of the prostate). If PCa is missed at biopsy, demonstration of epigenetic changes in the adjacent benign tissue indicates the presence of carcinoma. The test quantifies the methylation level of the promoter regions of three genes (RASSF1, GSTP1, and APC) in benign prostatic tissue. A multicenter study concluded that repeat biopsy could be avoided in men with a negative test, namely

methylation absent in all three markers (negative predictive value of 88%) (Partin et al., 2014). Because of limited available data, no recommendation can be made regarding its routine application (Mottet et al., 2017).

Cell Cycle Progression Signature Test

The CCP signature test (Prolaris; Myriad Genetics Inc.) is a genomic test for predicting PCa aggressiveness in conjunction with clinical parameters such as Gleason score and PSA. The test quantifies a patient's risk of disease progression and PCa-specific mortality using a gene-expression-based cell cycle progression (CCP) score. In biopsy-derived PCa tissue, the expression of a set of 31 cell cycle progression−associated genes and 15 housekeeping genes is measured to predict disease progression (Mottet et al., 2017; Saini, 2016). Expression of the cell cycle−related genes is correlated with PCa proliferation, serving as a risk stratification tool that enables a better treatment/monitoring strategy for patients at diagnosis. Low expression of these genes is associated with low risk of progression and those men may be candidates for active surveillance, whereas high expression is associated with higher risk of disease progression in men who may be treated. Potential utility of the CCP test has been evaluated in a US-based clinical setting (Shore et al., 2014). It was concluded that the CCP score adds meaningful new information to the risk assessment for localized PCa patients and that real-world use of the test is likely to lead to a change in treatment in a significant portion of tested patients, particularly by shifting patients toward more conservative management, which could reduce overtreatment of patients with less aggressive disease. Results of prospective multicenter studies are awaited before recommendation in routine application (Mottet et al., 2017).

Oncotype DX Test

Similarly, the Oncotype Dx (Genomic Health, Redwood City, CA) test is a multigene expression assay developed for formalin-fixed paraffin-embedded diagnostic prostate needle biopsies containing as little as 1 mm of PCa (Ashley et al., 2017; Saini, 2016). This RNA-based test reveals the underlying biology of the tumor to determine aggressiveness by assessing the activity of a set of 12 cancer-related genes involved in four different biological pathways (androgen pathway (AZGP1, KLK2, SRD5A2, RAM13C), proliferation (TPX2), cellular organization (FLNC, GSN, TPM2, GSTM2), and stromal response (BGN, COL1A1 and SFRP4)). Five reference genes are included to normalize data and control for variability. These measurements are algorithmically combined to calculate a Genomic Prostate Score. The assay has been validated as a predictor

of aggressive PCa (Knezevic et al., 2013). Results of prospective multicenter studies are awaited before a recommendation can be made regarding their routine application (Mottet et al., 2017).

Transmembrane Protease Serine 2-Erythroblast Transformation Specific—Related Gene Fusion Rearrangement

Transmembrane protease serine 2, also known as TMPRSS2, is an androgen-regulated, type II transmembrane-bound serine protease that is locally expressed in the prostate and overexpressed in neoplastic prostate epithelium. TMPRSS2 was thought to play a role in PCa metastasis through the activation of protease-activated receptor-2 (PAR-2). An extensive study focusing on gene fusion transcripts in PCa identified the fusion between TMPRSS2 (located at 21q22.3) with the transcription factor genes ERG (erythrocyte transformation specific—related gene) (21q22.2) and ETV1 (7p21.1), both ETS family members. One TMPRSS2 allele loses its promoter, and one of the ERG alleles gains it, resulting in an over expression of ETS family members in the cancer cells (Mwamukonda et al., 2010). The gene fusion rearrangements between TMPRSS2 and ERG or ETV1 have been reported in several cancers, particularly in hematological malignancies. TMPRSS2-ERG is the most frequent oncogenic gene fusion rearrangement in PCa. It has been observed in almost half of PCa patients and detected in about one-quarter of patients with prostatic intraepithelial neoplasia. This TMPRSS2-ERG fusion is usually found in PCa tissue from men undergoing prostatectomy, and especially among men in North America with PCa on biopsy: However, it is not present in benign prostate biopsy. Another multicenter study showed that the TMPRSS2-ERG urine test could be used to select men with clinically significant PCa (Leyten et al., 2014). The TMPRSS2-ERG fusion can be detected in the urine after DRE with 37% sensitivity and 93% specificity. The addition of TMPRSS2-ERG detection also increased the sensitivity of the urine PCA3 test from 62% to 73% (Mosquera et al., 2009) and resulted in a greater prediction of positive tumors with a higher Gleason score. The results suggest that the combination of TMPRSS2-ERG detection with PCA3 can be very useful in accurately predicting PCa development during screening. TMPRSS2—ERG could be an useful tool for managing and stratifying patients with newly diagnosed PCa as those with fusion-negative TMPRSS2—ERG have worst outcomes (Stone, 2017).

Glutathione S-transferase P1

Glutathione S-transferase P1 (GSTP1) is a ubiquitous family of multifunctional enzymes that conjugate reactive substrates with reduced glutathione and is involved in cellular detoxification. Their role in protecting the cells from oxidative attack, and consequently being upregulated in the presence of free radicals, makes them a prime candidate for consideration as a cancer biomarker. Hypermethylation of the GSTP1 gene was detected in plasma samples from patients with PCa. Genomic DNA was analyzed using methylation-specific polymerase chain reaction technique. Analyzing the GSTP1 gene could discriminate between PCa and BPH patients (Dumache et al., 2014). With the help of polymerase chain reaction (PCR), the methylated GSTP1 gene can be detected in the urine of men who have undergone prostate biopsy (Gonzalgo et al., 2003). This implies the possible additional use of this biomarker in risk stratification of men undergoing prostate biopsy. GSTP1 displays several good characteristics that make it a viable biomarker. For instance, it is highly prevalent in the disease condition, and clinicians are able to measure quantitatively the methylation status of the gene in biopsy/prostatectomy tissues and in cells isolated from serum, urine, and seminal plasma. Furthermore, GSTP1 inactivation by hypermethylation leads to a cell's reduced ability to detoxify electrophilic compounds (such as carcinogens and cytotoxic drugs) by glutathione conjugation, a mechanism that accounts for increased cell vulnerability to carcinogenesis. Therefore, hypermethylation of the GSTP1 gene in prostate cells could also serve as a potential toxicity biomarker for carcinogens and response to cytotoxic anticancer drug treatment. If it is successfully validated, GSTP1 methylation testing of cells derived from samples of serum and urine may possess a significant clinical potential for early detection of PCa and post-treatment monitoring of the disease.

α-Methylacyl Coenzyme A Racemase

α-Methylacyl coenzyme A racemase (AMACR) is an enzyme localized to peroxisomes, is involved in fat metabolism and has been identified to function as a growth promoter, independent of androgens, in PCa. The AMACR gene is overexpressed in PCa tissue and is currently used as a highly specific tissue biomarker to aid in the pathological diagnosis of PCa (Rubin et al., 2002). The potential use of analyzing the levels of AMACR from urine and needle biopsy for PCa detection has been tested (Rogers et al., 2004). Considerably more enhanced sensitivity and specificity in PCa patients with mid-range PSA levels have been observed with AMACR antibodies in comparison to PSA testing alone. This demonstrates that AMACR can be useful in distinguishing control subjects from those with PCa. Some of the limitations of AMACR as a biomarker include the possibility of humoral response and production of endogenous AMACR antibody as a result of

certain cancers other than prostate in patients suffering from autoimmune diseases. In addition, AMACR levels are commonly increased in patients with other urological disorders such as BPH. In spite of these restraints, the diagnostic capability for characterizing organ-confined and metastatic PCa is increased with the addition of the AMACR test to serum PSA testing. A promising new noninvasive screening test for PCa is to use quantitative reverse transcriptase PCR (RT-PCR) to identify the ratio of AMACR-to-PSA transcript (Zha et al., 2003). Furthermore, AMACR could be a potential therapeutic target. Use of AMACR inhibitors may be complimentary to androgen therapy (Carnell et al., 2013). Further testing is in progress to assess and possibly validate the prospective use of this serum biomarker.

Chromogranin A

Chromogranin A (GRN-A, also known as secretory protein I), part of the granin family of proteins, is an acidic protein that has been identified in all neuroendocrine cell types and is produced in larger amounts than other secreted proteins by those cells. The growth of prostate cells has been found to be regulated by peptides derived from GRN-A (Lee et al., 1994). Because it is produced and secreted by prostate cells, GRN-A has been examined for its diagnostic and prognostic values as a biomarker for PCa. Based on prior studies, one can use GRN-A to monitor the success of cancer treatment and to predict the outcome of diseases that are androgen-independent. These predictions would precede any indication of PSA progression and reveal that increased levels of GRN-A correlated with disease progression and diminished overall survival (Berruti et al., 2005). In addition, GRN-A levels could be a potential prognostic biomarker in castration-resistant PCa (CRPC) treated with enzalutamide or abiraterone and other new hormonal therapies (Burgio et al., 2014; Conteduca et al., 2014). Therefore, GRN-A may be very useful as a prognostic factor in patients with advanced PCa. However, limitations do exist. One noted weakness of using GRN-A as a biomarker is the fact that neuroendocrine cells do not reside in all prostate tumors. Another disadvantage is its inability to detect the disease at a very early stage. In spite of these shortcomings, GRN-A may possess clinical potential as a biomarker for progressive and recurrent PCa. More research is necessary to clearly determine the clinical value of GRN-A as a serum and tumor marker for PCa.

Prostate-Specific Membrane Antigen

Prostate-specific membrane antigen (PSMA) is a cell surface membrane protein that exhibits some enzymatic activity, although its biological role remains unclear. PSMA has been detected in prostate tissues, PCa cells, and serum. Higher levels of PSMA appear to correspond with poorer clinical outcomes. PSMA levels are higher in primary PCa and metastatic disease, with over 90% of the protein prevalent in diseased tissues. The serum levels of PSMA increase with age and are considerably higher in men above 50 years of age. Although levels of PSMA found in PCa patients are considerably higher than levels found in healthy men or those with BPH, and PSMA appears to be upregulated in patients following hormone deprivation therapy, concrete evidence has yet to validate that a relationship exists between high levels of serum PSMA and the aggressive disposition of the disease. In fact, some studies have observed a decrease in serum PSMA in advanced cases of the disease (Xiao et al., 2001). One of the shortcomings of using PSMA as a serum biomarker is that high PSMA levels have been noticed in the serum of breast cancer patients. This could make it difficult, in some cases, to accurately diagnose men with PCa. Another limitation previously alluded to is the fact that levels of serum PSMA tend to naturally increase with age, potentially complicating diagnoses sought in elder years. PSMA could be a therapeutic target for monoclonal antibodies in patients with PCa (Muthumani et al., 2017). PSMA also has a role in biochemically recurrent PCa (BCR). In fact the superiority of 68Ga-PSMA-PET/CT compared to other imaging techniques seems to be most marked at low PSA levels (Udovicich et al., 2017). More data are required to validate whether this biomarker is clinically acceptable for use in PCa detection, monitoring of treatment, or as an actual means of treatment.

Prostate Stem Cell Antigen

Prostate stem cell antigen (PSCA) is a membrane glycoprotein predominantly expressed in the prostate. Although the expression of PSCA has been shown to be upregulated in the majority of PCa, its biological role in PCa is tentative. Studies have implied that PSCA may be involved in various processes, including androgen-independent progression, metastasis, or signal transduction. In most PCa, a positive correlation was detected between increased levels of PSCA expression and higher Gleason grades, indicative of more an advanced tumor stage and poor overall survival (Li et al., 2017; Reiter et al., 1998). PSCA expression is also associated with seminal vesicle invasion and capsular invasion in PCa; these findings suggest that PSCA has potential as a therapeutic target. In addition, elevated PSCA could be a prognostic indicator for BCR after radical prostatectomy (RP) in patients with clinically localized prostatic cancer (Kim et al., 2017). Using human xenografts grown in SCID mice, researchers found

that anti-PSCA monoclonal antibodies inhibited prostate tumor growth and metastasis formation (Ross et al., 2002), providing evidence for PSCA immunotherapy targeting as a potential treatment for PCa. Although PSCA displayed inferior sensitivity and considerable inability to distinguish between malignant and benign disease when juxtaposed against PSA and PSMA, the circulating prostate biomarker possesses the highest disease specificity and independent predictive value (Hara et al., 2002). Despite the research revelations about PSCA and its potential, no definitive conclusions have been reached in regard to it being a serum biomarker. Factors that militate against PSCA as a candidate for further development include an inadequate number of published studies supporting PSCA as a valuable clinical biomarker and the lack of better measuring techniques. Hence, the value of PSCA as a therapeutic target and its effectiveness as a clinical PCa marker must await more supportive evidence.

Early Prostate Cancer Antigen

Early PCa antigen (EPCA) is a nuclear matrix protein linked with nuclear transformations that occur in early PCa development. EPCA was found in PCa precursor lesions, specifically in prostatic intraepithelial neoplasia and proliferative inflammatory atrophy, as well as in PCa tissue. Also, the protein has been identified in men with a preliminary negative biopsy, but who later developed cancer (Dhir et al., 2004). EPCA cannot be linked with early carcinogenesis as no relationship could be found between EPCA and the disease stage or Gleason score after RP (Uetsuki et al., 2005). However, EPCA-2 could differentiate BPH from cancer in PCa suspects (Pourmand et al., 2016). Furthermore, studies have verified the potential diagnostic value of serum EPCA by demonstrating the ability of EPCA antibodies to recognize PCa. Although EPCA appears not to be present in patients devoid of PCa, it has been detected in surroundings free of, but adjacent to, the cancer (Dhir et al., 2004). More studies are needed to further characterize the protein as a suitable biomarker to diagnose PCa.

B7-H3

B7-H3 is the first immune molecule that possibly participates in the development of PCa and in predicting the recurrence and progression of cancer. B7-H3 is a member of the B7 family, a group of proteins that are important ligands interacting with known and unknown receptors to regulate the activation and function of T lymphocytes. The B7-H family proteins, including B7-H3, can both arrest cancer growth and shield cancers from the immune system by paralyzing immune cells, thereby exhibiting both an immune stimulatory and inhibitory role in cancer growth (Luo et al., 2004). More research is warranted, however, to understand how the immune system is affected by B7-H3. This information is critical and will help to establish the effectiveness of B7-H3 as a clinical biomarker of disease and target for therapy. In contrast to PSA, B7-H3 remains bound to the surface of normal prostate cells and the surfaces of premalignant and cancerous prostate cells that show no apparent indication of migration (metastatic ability); this attribute, in particular, makes B7-H3 an attractive therapeutic target and biomarker (Roth et al., 2007). One study revealed a link between a rising level of B7-H3 in PCa and adverse pathologic features of the disease. In a large cohort, B7-H3 expression is presented in most of the localized PCa cases. Increased levels of B7-H3 were associated with tumor aggressiveness and extent (Benzon et al., 2017). If the connection holds, B7-H3 may have the potential to independently predict PCa progression, making it useful as a diagnostic and prognostic biomarker to evaluate disease status and immunotherapeutic responses.

Sarcosine

Sarcosine, a N-methyl derivative of glycine, is a natural amino acid found in muscles and other body tissues. It is classified under the group collectively known as metabolites. Sarcosine was found to stimulate malignant growth of benign PCa cells has been suggested as a potential indicator of malignancy of PCa cells when detected in the urine (Sreekumar et al., 2009). Following screening of urine, blood, and tissues and profiling more than 1126 metabolites related to PCa, researchers were able to differentiate between benign prostate, clinically localized PCa, and metastatic disease based on the levels of sarcosine. Higher level of sarcosine were observed in invasive PCa cell lines compared with benign prostate epithelial cells (Sreekumar et al., 2009). Furthermore, it was reported that PCa invasion weakened when glycine-N-methyltransferase, the enzyme that catalyzes the production of sarcosine from glycine, was knocked down. In contrast, knocking down the enzyme responsible for sarcosine degradation or adding exogenous sarcosine stimulated an invasive phenotype in BPH cells. Together, these results suggest that sarcosine may be a vital metabolic intermediary propelling PCa cells toward invasion and aggressiveness (Couzin, 2009). The ultimate goal of diagnosis is to detect aggressive-type PCas at their premature stage. At the center of the contradicting scientific viewpoint regarding whether sarcosine is a better diagnostic biomarker or not than PSA at detecting aggressive PCa is the concern raised by the fact that several scientists, with personal investment

interests in sarcosine use, have criticized for their possible motives. Another study reported that sarcosine in urine samples of patients with PCa was not a significant biomarker for cancer diagnosis (Gkotsos et al., 2017). Another potential role for sarcosine would be to study its usefulness in the diagnosis of PCa. If proven successful with further human use, this radiotracer containing c11-sarcosine might exemplify a new concept for PET imaging of cancer (Piert et al., 2017). Subsequently, further investigations must be performed on the metabolites with patient outcomes monitored long term to truly substantiate any correlation of sarcosine with patients who developed different forms of PCa.

Caveolin-1

Caveolin-1 (Cav-1), an integral membrane protein expressed in two isoforms (Cav-1α and Cav-1β), is a major component of caveolae membranes in vivo. It has been implicated in regulating several signaling pathways and mediating intracellular processes, specifically as a negative regulator in several mitogenic pathways and in oncogenesis. Cav-1 seems to function as a tumor suppressor protein at early stages of cancer progression. Studies of prostate tissue from men with only localized PCa indicate a significant decrease in levels of Cav-1. It was also discovered that the protein was absent in tumor tissue from men with metastatic PCa, and the reduced levels of Cav-1 were associated with a high Gleason score (Thompson et al., 2010). However, Cav-1 is also found to be upregulated in several metastatic and multidrug-resistant cancer cell lines and in some human tumor specimens (Shatz and Liscovitch, 2008). Cav-1 is secreted by PCa cells. Other studies have shown that this secreted protein can promote cell survival and angiogenic activities. Cav-1 has been reported to overexpress in PCa cells and is associated with the progression of the disease. Research conducted on stromal Cav-1 expression in patients with BPH, primary PCas, and PCa metastases revealed that almost all BPH samples showed an abundant stromal Cav-1 immunostaining, while a subset of samples with primary PCa had significantly decreased levels of stromal Cav-1. All metastatic tumors (either from lymph node or bone) lacked stromal Cav-1 staining (Di Vizio et al., 2009). The concentration of preoperative serum Cav-1 showed prognostic potential in patients undergoing radical prostatectomy (Thompson et al., 2010). Recent clinical studies have shown the possible role of Caveolin-1 as a biomarker for cancer prognosis during RT (Mahmood et al., 2016). Also Cav-1 could be a useful tool in management for patients in active surveillance or watchful waiting (Basourakos et al., 2018; Hammarsten et al., 2016). These findings suggest Cav-1 expression may be a useful prognostic marker for PCa.

Serum Calcium

PCa cells express calcium-sensing, G-protein-coupled receptors, which can be activated by extracellular calcium. These cells also express calcium-dependent potassium channels that regulate their proliferation by controlling the entry of calcium into the cells. High levels of total calcium in serum have been linked with greater risk of fatal PCa through growth and metastasis (Lallet-Daher et al., 2009). Independent investigations by separate groups confirmed the association between increased serum calcium and terminal PCa, suggesting that serum calcium is a promising prospective biomarker for the screening of fatal PCa (Schwartz, 2009).

Hypermethylation of PDZ, LIM Domain Protein 4 Gene, and PDLIM5

Hypermethylation of the PDLIM4 gene has been shown to be a sensitive molecular tool in detecting prostate tumorigenesis (Vanaja et al., 2006). PDLIM4 mRNA and protein levels were found to decrease in various PCa cell lines. PDLIM4 may function as a tumor suppressor by associating with actin in PCa cells, thereby controlling cell proliferation (Vanaja et al., 2009). PDLIM5 (PDZ and LIM domain 5) is a cytoplasmatic protein, which may be involved in oncogenesis of many types of cancer such as the lungs, thyroid, breast, and gastric (Edlund et al., 2012; Eeckhoute et al., 2006; Heiliger et al., 2012; Li et al., 2015b). Recent study showed that PDLIM5 was upregulated in PCa tissues (compared with normal prostate tissue). PDLIM5 could be an oncogene in PCa cells associated with progression, metastasis, and recurrence of cancer (Liu et al., 2017). These findings support the potential use of hypermethylated PDLIM4 and PDLIM5 as a biomarker of PCa.

Exosomes

Exosomes are nanometer-sized vesicles secreted by a broad range of normal and neoplastic cell types. They contain both functional mRNA and microRNA, called exosomal shuttle RNA, which are often transported from cell to cell where they can continue to be functional (Valadi et al., 2007). Exosomes are constituents of urine, with a degree of variability in urine specimens. Because they often carry genetic components that come directly from tumors, such vesicles may be a useful noninvasive source of markers in screening for renal diseases and PCa. A recent study reported the presence of PCA3 and TMPRSS2-ERG fusion, two known PCa biomarkers, in exosomes from urine samples of PCa patients (Nilsson et al., 2009), shedding more light on its clinical

use. The presence and quantification of exosomes as a potential noninvasive source of tumor markers could be used to diagnose, monitor the status of PCa concerning drug resistance and metastasis. It may also serve as a target in cancer therapy (Pan et al., 2017).

Ki-67

Ki-67, a cell proliferation-associated marker (and probably the only one with an expression pattern under a level of cell cycle regulation) (Scholzen and Gerdes, 2000), has been described as one of the most promising biomarkers of PCa. Ki-67 has been suggested as a prolific predictive biomarker, for men who have low-grade, low-stage PCa and PSA relapse after radical-prostatectomy (Khatami et al., 2009). In a 6-year study, involving 808 patients diagnosed with PCa, an immunohistochemical assessment of Ki-67 expression was evaluated for its relationship to the specificity of the cancer and overall survival. Compared to information from the Gleason score and PSA, Ki-67 provided additional prognostic information (Khatami et al., 2009). In another study of a group of men treated with radiotherapy and androgen deprivation for PCa, Ki-67 expression levels in conjunction with MDM2 were found to be correlated to distant metastasis and survivability (Khor et al., 2009). A recent study enrolling 535 patients showed that Ki-67 expression was an independent biomarker for high Gleason grade, larger tumor size, and biochemical failure (Richardsen et al., 2017). Also a recent metaanalysis showed that low Ki-67 is associated with improved overall and disease-specific survivor. Furthermore, the review suggests a decreased risk of developing metastasis (Berlin et al., 2017). The results of this study mount evidence on Ki-67 robustness and clinical validity, warranting prospective validation accounting for well-established clinical prognostic factors Nevertheless, further studies will be needed to validate these results and explore the possibility of combining Ki-67 with existing prognostic tools as a powerful biomarker for localized PCa.

Golgi Phosphoprotein 2 and 3

Golgi phosphoprotein 2, GOLPH2, is a gene that codes for type II Golgi membrane antigen GOLPH2/ GP73. It is usually expressed in various epithelial cells and is reported to be frequently overexpressed in PCa, although its function is currently unknown. Golgi phosphoprotein 3 (GOLPH3/GPP34) is also a membrane protein and the presence of the GOLPH3 gene was found in several human cancers, including prostate (Hua et al., 2012). The overexpression of GOLPH3 has been associated with cancer's aggressiveness and

proliferation of PCa in androgen-independent cell lines (Dai et al., 2015; Li et al., 2015a). A study has observed a higher level of GOLPH2 in the Golgi apparatus in PCa cells compared with that of normal cells, thereby indicating that GOLPH2 can be used as a biomarker in distinguishing between normal cells and cancer cells (Wei et al., 2008). Another study revealed that an increase in the levels of GOLPH2 (along with some of the other biomarkers assayed) was not only a critical but also a better indicator for PCa than PSA or PCA3 alone (Laxman et al., 2008). A comparative study of GOLPH2 and AMACR in benign and malignant prostate lesions revealed that GOLPH2 expression was considerably higher in PCa tissues compared with normal tissues, and in about 90% of the cases studied, GOLPH2 protein was upregulated. Furthermore, this upregulation was noticed in about 85% of PCa cases that were negative for AMACR (Kristiansen et al., 2008) Also a recent study examined GOLPH2 as a potential target for cancer therapy. Particularly GOLPH2-regulated oncolytic adenovirus GD55 was showed to have antitumor effects on PCa cells (Ying et al., 2017). Another recent study about GOLPH3 expression in PCa correlated with the Gleason score and poor overall survival (Abd El-Maqsoud et al., 2016). Another study showed that patients with GOLPH3 expression presented shorter overall survival and biochemical recurrence-free survival. In consequence, GOLPH3 may be a prognostic biomarker for patients who have undergone radical prostatectomy (Zhang et al., 2015). These findings show that both GOLPH3 and GOLPH2 could be promising targets for new therapeutic strategies for the treatment of androgen-dependent PCa and castration-resistant PCa and as potential diagnostic—prognostic tools.

DAB2 Interacting Protein

DAB2-interacting protein (DAB2IP) is a Ras GTPase-activating protein that functions as a tumor suppressor. The human DAB2IP gene is frequently observed to be downregulated in PCa cell lines (Chen et al., 2003). Studies have shown that loss of expression of DAB2IP may be a result of altered epigenetic regulations such as DNA methylation and histone modification (Chen et al., 2005). The abnormal methylation in the promoter region of the DAB2IP gene has been reported to be responsible for transcriptional silencing and consequently performing a significant function in the progression of PCa (Chen et al., 2003). Also a loss of DAB2IP expression in CRPC cells was associated with chemoresistance (Wu et al., 2013). A link between a genetic variation in DAB2IP and the risk of aggressive PCa was reported (Duggan et al., 2007). This research indicates

that DAB2IP protein, after further studies, can potentially be used as a very effective novel biomarker for PCa diagnosis.

Other Emerging Prostate Cancer Biomarkers

A recent study demonstrated that CCL11 (Eotaxin-1), a new diagnostic serum biomarker, helps distinguish between prostatic enlargement and PCa among men demonstrating low, but detectable, serum PSA values (Agarwal et al., 2013). The use of multigene signature-based prognosis, such as the triproliferation markers of Ki-67, TOP2A (DNA topoisomerase II, alpha), and E2F1, has shown potential to improve the prediction and treatment stratification of PCa (Malhotra et al., 2011). Another study used a 7-gene microarray panel of blood samples and demonstrated their value as potential blood-based biomarkers for a minimally invasive test for PCa aggressiveness (Liong et al., 2012). Other identified novel predictors of PCa include the ratio of serum testosterone to PSA (Gurbuz et al., 2012), micro-RNA expression profile (Yin et al., 2010), epigenetic biomarkers APC and RASSF1 (Van Neste et al., 2012), an epigenetic assay detecting methylation of GTSP1, RASSF1, and APC (SelectMDx) (Partin et al., 2016), prognostic tissue biomarkers Bcl-2 and p53, and blood- and urine-based biomarkers, including human glandular kallikrein 2 (hK2), TGF-β1, endoglin, IL-6, urokinase plasminogen activator (uPA), and its receptor (uPAR) (Shariat et al., 2011). In addition, the urine RNA marker SPINK1 was shown to serve as a promising alternative or addition to serum-based biomarkers (Roobol et al., 2011). Other promising biomarkers under investigation include ANPEP, ABL1, EFNA1, HSPB1, INMT, and TRIP13 (Larkin et al., 2012).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

PCa is currently the most frequently diagnosed cancer in males and constitutes a major health issue in developed countries. On the other hand, the majority of PCa cases are not considered clinically significant and certainly not lethal. Thus, it is particularly important to balance the risks of overtreatment for indolent disease with undertreatment for a potentially aggressive tumor. The discrepancies in the case of PCa emphasize the need to identify reliable biomarkers for the early detection of the disease that have aggressive features and for early and radical intervention. The current clinical use of PSA toward this end is obviously not adequate because PSA is prostate-specific, but not a PCa-specific marker, as it is known to increase in other prostate diseases such as BPH and inflammation.

A critical point that has been reiterated is the fact that an ideal biomarker has to show a high level of specificity and sensitivity to prevent false-positive screening tests, which will create anxiety in patients and lead to more expensive and invasive testing. Thus far, studies, although inconclusive, have found that the likelihood of identifying a biomarker with such sensitivity and specificity remains low. Therefore, combining markers is thought to be the next best thing to improve the accuracy of diagnosing, treating, and surveillance of recurrence.

The technology used to discover potential biomarkers has advanced significantly in recent years. Recent gene expression analyses have revealed several promising biomarkers in the areas of epigenetics, genomics, and the transcriptome, some of which are currently under investigation as clinical tests for early detection and better prognostic prediction of PCa. Despite several biomarkers having displayed some potential in early phase studies, few so far appear likely to possess the appropriate level of sensitivity and specificity required to reliably determine the choice and course of therapeutic treatment for PCa. This may explain why only a small number of biomarkers are routinely validated for use in drug development or qualified for clinical applications, despite the apparent progress in this research field. Several limitations still exist with the current technology that hinders the discovery and development of new biomarkers for all forms of cancer, including PCa. Some of these impediments may be overcome through the development of new technologies and improved strategies. For example, one strategy proposed would pair the diagnostic test with the therapeutic agent. Another strategy calls for more attention to studies that can generate quantified biomarkers related to cell signaling pathways, as these biomarkers can be applied across a wide range of tumor types and diseases, as well as in different tests and drugs.

In conclusion, substantial discoveries still lie before us in this field, and methodologies for the clinical evaluation of existing and novel biomarkers need to be further explored. Although much could be gained from the discovery of novel biomarkers for early detection of PCa, prediction of the malignant potential of the disease, and guidance of individualized therapy for patients, the near future of PCa prognosis may eventually come to count on a few "elite club" biomarkers, which hopefully will accurately predict the incidence, stage, and progression of the disease, as well as reliably evaluate drug response and related toxicity. From a safety standpoint, biomarkers that can be measured and monitored for the toxicity are particularly useful in terms of minimizing toxicity of cancer drugs and therapy. Although extensive clinical validation of these novel biomarkers remains one of the most significant and daunting

challenges, overcoming this impediment will by no means eliminate all the problems hampering the identification and development of biomarkers for this disease. However, in the process of searching for novel biomarkers, particularly those that help analyze risk stratification and predict toxicity of intervention, we may discover valuable insights into the mechanisms of PCa and its response to therapy that could in the long run lead to a cure of this disease.

Biomarkers of Alzheimer's Disease

Jason Pitt

University of Evansville, Evansville, IN

INTRODUCTION

Alzheimer's disease (AD) is the most common form of dementia, affecting an estimated 5.4 million Americans in 2012, with this estimate rising to 11−16 million by 2050 (Alzheimer's Association, 2012). AD patients exhibit episodic memory impairments, judgment deficiencies, confusion, altered mood, and motor impairments at later stages. Although AD is diagnosed clinically, confirmation requires postmortem examination demonstrating brain atrophy and the positive identification of two AD neuropathological hallmarks: (1) *neurofibrillary tangles* that contain aggregated forms of the microtubule-associated protein tau and (2) *amyloid plaques* that are predominantly composed of the peptide Aβ. Brain atrophy involves the loss of neurons and synapses. The loss of synapses correlates highly with the memory dysfunction observed in patients. This synaptic and neuronal deterioration most likely results from synaptotoxic Aβ oligomers (AβOs), which appear to cause subtle forms of synaptic dysfunction through altered glutamatergic signaling (see LTP Impairments and Excitotoxicity Through Glutamatergic Dysfunction) and cell death through mechanisms involving tau dysfunction (see Posttranslational Modifications of Tau Cause Aggregation and Synaptic Starving).

Although no cure exists for AD, there are two types of drugs currently being used for treatment of AD. The *NMDA receptor antagonist* memantine (Namenda) prevents glutamate excitotoxicity caused by overactivation of the NMDA receptor (Chen et al., 1992). Although Namenda can slow the cognitive decline in patients with moderate to severe AD, Namenda neither reverses nor prevents cognitive impairments and offers no apparent benefit to patients with mild to moderate AD. The second class of AD therapeutics are the *cholinesterase inhibitors* (ChEIs) Aricept, Exelon, Razadyne, and Cognex. ChEIs elevate acetylcholine levels, which partially offsets the loss of cholinergic input to the cerebral cortex that occurs in AD. ChEIs are effective for mild to moderate AD, unlike Namenda, with clinical trials reporting slower rates of cognitive decline and functional improvements. As with Namenda, the long-term effectiveness of ChEIs is questionable.

Another promising therapy currently in Phase III clinical trials is Aβ immunization. In a case study, active immunization with aggregated Aβ (AN-1792) reduced plaque burden and the associated dystrophic neurites and reactive astrocytes in cortical areas, although neurofibrillary tangles were still present (Nicoll et al., 2003), suggesting that immunization may be more successful if employed early on in disease progression. However, aseptic meningoencephalitis in a subset of patients forced early termination of active immunization trials (Orgogozo et al., 2003). *Passive immunization*, in which anti-Aβ antibodies are administered directly to boost patient titers, shows promise in mouse models (Bard and Cannon, 2000). However, human trials have shown mixed results. In one trial, immunized patients had reduced deterioration of cognitive functions measured with a battery of neuropsychological tests, although no differences were observed with standard measures of cognitive function (e.g., the Alzheimer's Disease Assessment Scale—Cognitive subscale [ADAS-cog] and the Mini-Mental State Exam [MMSE]), and the trial was stopped because of meningoencephalitis in 18 of the 300 (6%) immunized patients (Gilman et al., 2005). Currently, no Aβ immunotherapy has been successfully implemented in human subjects (reviewed in Pul et al., 2011).

There is some debate regarding the reason for the clinical trial failures of Aβ immunotherapies. One possibility is that therapies are focusing on the wrong target (i.e., Aβ does not play a causative role in AD).

Based on the genetic risk factors for familial AD, this does not seem likely (see Genetic Risk Factors for AD). A more plausible explanation is that clinical trials are not started early enough to be effective. It is widely believed that after the onset of dementia, neural function has been compromised to a degree that is not likely to be reversed (Petersen, 2003). As an example, brain atrophy involves a significant loss of synapses and, more importantly, neurons that will not be replaced. No amount of pharmacological intervention is likely to reverse cognitive impairments in severely atrophied brains.

Because the prospect of treating AD after dementia onset appears grim, there is substantial interest in identifying at-risk, predemented individuals for therapeutic intervention. Several large-scale preventative clinical trials are underway to test whether preventive immunization can prevent familial AD (Lambracht-Washington and Rosenberg, 2013) is in preparation to study prevention of familial AD. However, because the vast majority of AD cases are sporadic, AD biomarker studies have focused largely on subjects with *mild cognitive impairment* (MCI), which is viewed as an intermediate stage between normal aging and AD. It is acknowledged that, although MCI is clearly associated with an elevated risk for developing AD, a diagnosis of MCI does not guarantee disease progression. Hence, identification of biomarkers that (1) predict conversion to AD and (2) identify underlying etiologies in MCI patients has considerable potential to improve therapeutic approaches, potentially reducing the cost and sample sizes of clinical trials by 60% and 67%, respectively. This chapter discusses current AD biomarkers that may fulfill these functions.

TABLE 49.1   Alzheimer's Linked Mutations

Gene	Mutations	Outcome
Amyloid precursor protein (APP; Gene ID 351)	K670N/M671L (Swedish)	Increased $A\beta$ production through potentiated BACE1 activity; elevated risk of AD
	A673T	Decreased $A\beta$ production through disrupted BACE1 activity; reduced risk of AD
	A692G (Flemish)	Increased $A\beta$ production through disrupted α-secretase activity; elevated risk of AD
	E693G (Arctic)	Increased $A\beta$ polymerization; elevated risk of AD
	I716V (Florida)	Increased $A\beta_{42}$:$A\beta_{40}$ ratio; elevated risk of AD
	V717I (London)	Increased $A\beta_{42}$:$A\beta_{40}$ ratio; elevated risk of AD
Presenilin 1 (PSEN1; Gene ID 5663)	150+ mutations, mostly missense	Increased $A\beta_{42}$:$A\beta_{40}$ ratio; elevated risk of AD
Presenilin 2 (PSEN2; Gene ID 5664)	10+ mutations	Increased $A\beta_{42}$:$A\beta_{40}$ ratio; elevated risk of AD

AD, Alzheimer's disease.

GENETIC RISK FACTORS FOR ALZHEIMER'S DISEASE

There is strong evidence that $A\beta$ plays a critical role in initiating AD. Although roughly 99% of AD cases are sporadic, heritable forms of AD provide insights into disease etiology. Each of the genes identified in cases of familial AD is involved in the formation of $A\beta$, and the only known mutation that decreases the incidence of AD impairs $A\beta$ production (Table 49.1). This section (1) explains the apparent causative role of $A\beta$ in AD progression, (2) highlights the importance of soluble, oligomeric forms of $A\beta$, and (3) discusses AD risk factors in the context of $A\beta$-induced neural dysfunction.

$A\beta$ accumulation is central to AD progression and involves proteolytic liberation from a longer parent peptide and rapid self-association. $A\beta$, the main component of amyloid plaques, is derived from the amyloid precursor protein (APP) through proteolytic cleavage by two enzymes, β- and γ-secretase. β-secretase (BACE1) cleaves the extracellular portion of APP between amino acids 671M and 672D. γ-Secretase is a multiprotein complex consisting of at least presenilin proteins, nicastrin, aph-1, and pen-2 that cleaves APP within the plasma membrane at variable sites to produce $A\beta$ monomers ranging from 32 to 43 amino acids in length. $A\beta_{40}$ is the most common form of $A\beta$, while $A\beta_{42}$ is more prone to aggregate into oligomeric and fibrillar forms because of the additional hydrophobic amino acids. For this reason, circulating levels of $A\beta_{42}$ are more closely associated with AD progression, and AD biomarkers that target $A\beta_{42}$ have better prognostic value than those targeting $A\beta_{40}$ (see Decreased CSF $A\beta_{42}$).

Evidence for a causal role of $A\beta$ in AD pathogenesis comes from the only genetic risk factor for sporadic AD—the presence of at least one apolipoprotein E4

(ApoE4) allele. Aβ is cleared from the brain through a variety of mechanisms, one of which is receptor-mediated removal by ApoE and its receptors. Aβ is bound by ApoE, either directly or indirectly, and brought into neurons and glia for proteolytic degradation or transported across the blood–brain barrier through interactions with a variety of ApoE receptors, including low-density lipoprotein receptor (LDLR), low-density lipoprotein receptor-related protein 1 (LRP1), and very low-density lipoprotein receptor (VLDLR). The ApoE gene has three polymorphic alleles (ApoE2, ApoE3, and ApoE4) that differ by a single amino acid. Although it is not clear exactly how ApoE4 promotes AD onset, findings indicate several possible mechanisms, including increased Aβ production and aggregation, decreased Aβ clearance, and synaptic impairments (reviewed in Bu, 2009). Regardless of the mechanism(s) involved, the presence of two ApoE4 alleles decreases the mean age of AD onset from 84 to 68 years of age and increases an individual's risk of developing AD by roughly fourfold (Corder et al., 1993).

Much stronger evidence for a causative role of Aβ in AD progression is provided by mutations associated with familial AD. Mutations responsible for familial AD occur either in APP or the presenilins and result in an increased production in Aβ$_{42}$. Interestingly, a recently identified mutation in APP (A673T) near the site of BACE1 cleavage decreases Aβ production, thereby protecting carriers against AD onset. Although still somewhat debated, it is relatively well accepted that insoluble amyloid plaques represent pathological end points, rather than disease-initiating agents: amyloid plaques are found in the brains of cognitively normal individuals (Morris et al., 1996), and AD can occur in the absence of apparent plaque formation compared with age-matched controls (Tomiyama et al., 2008). It is now widely accepted that soluble AβOs, rather than insoluble amyloid plaques, are the toxic-initiating factors in AD (reviewed in Wilcox et al., 2011).

MECHANISMS OF SYNAPTIC DYSFUNCTION AND NEURONAL LOSS

One of the currently hypothesized cellular mechanisms of memory storage is termed long-term potentiation (LTP). In LTP, there is an activity-dependent boost of excitatory glutamatergic transmission that persists for hours to days. In the canonical mechanism of LTP induction, calcium influx through the NMDA receptor leads to increased AMPA receptor conductance and content at postsynaptic sites. Because of its memory-relevant functions, altered glutamatergic signaling in the hippocampus is likely to account for at least some of the AD-associated memory deficits.

Long-Term Potentiation Impairments and Excitotoxicity Through Glutamatergic Dysfunction

AβOs bind at or near synapses and induce a biphasic alteration in glutamatergic signaling. Initially, AβOs potentiate glutamatergic signaling through activation of both ionotropic and metabotropic glutamate receptors. This leads to calcium dysregulation and inevitably loss of synapses. This is evidenced by experiments in transgenic AD mice which showed impaired synaptic transmission in the Schaffer collateral that coincides with a decreased AMPA:NMDA ratio. This early synaptic impairment can be relieved by the ionotropic glutamate receptor antagonist kynurenate, demonstrating that, early on, AβOs activate glutamatergic signaling.

After initiating synaptic loss through potentiated glutamatergic signaling, AβOs alter synaptic plasticity and decrease glutamatergic transmission. In a mouse model of AD, synaptic loss precedes impairments in LTP by roughly 1 month. Interestingly, while LTP is inhibited, mechanisms of long-term depression remain intact. Although a vast oversimplification, this suggests that AβOs make synapses unable to store memory (i.e., disrupt LTP formation) while leaving them fully capable of losing memories (i.e., LTP is unaffected). In addition to inhibiting LTP, AβOs also impair baseline transmission by reducing CaMKII-dependent AMPA receptor phosphorylation at a site that increases its single-channel conductance.

Although it is possible that AβOs potentiate ionotropic glutamate receptor activity directly, it may also be the case that AβOs increase glutamate receptor activation by inhibiting glutamate uptake. Indeed, there is evidence that AβOs impair glutamate uptake at hippocampal synapses. One study reported a 30% reduction of glutamate uptake in hippocampal synaptosomes in the presence of AβOs (Li et al., 2009). It should be noted that synaptosomes contain pre- and postsynaptic components, as well as associated astrocytic processes, so it is unclear whether AβOs are targeting neurons, astrocytes, or both. Based on work from isolated cell cultures, it seems that AβOs are capable of reducing glutamate uptake in both cell types. These data demonstrate multiple ways in which AβOs alter synaptic transmission: (1) potentiating glutamatergic signaling, (2) inducing synapse loss, (3) reducing glutamatergic signaling and impairing synaptic potentiation, and (4) preventing glutamate uptake in neurons and astrocytes.

Posttranslational Modifications of Tau Cause Aggregation and Synaptic Starving

Tau is a microtubule-associated protein found abundantly within axons, where it likely plays a role in

controlling the rate of axonal transport and microtubule assembly. In AD, tau becomes hyperphosphorylated and subsequently cleaved by caspases, causing it to aggregate into neurofibrillary tangles (reviewed in Binder et al., 2005). Tau hyperphosphorylation is a useful AD biomarker (see Elevated CSF Total-Tau and Phospho-Tau) and is likely responsible for the redistribution of tau from axons to the somatodendritic compartment. This disturbance in tau localization and function disrupts microtubule transport of vesicles and energy sources, leading to synaptic and neuronal degeneration.

Although both tau and Aβ are critical players in AD-associated neuronal dysfunction, tau-mediated toxicity appears to act downstream of Aβ, as cultured neurons from tau knockout mice are resistant to Aβ-induced toxicity. These roles are supported by findings from AD biomarker studies, which suggest (1) that Aβ accumulation occurs early on in AD progression and (2) that the severity of neural damage correlates better with tau biomarkers than those for Aβ.

BIOMARKERS

A significant step toward identifying reliable AD biomarkers was taken by the Alzheimer's Disease Neuroimaging Initiative (ADNI), which hosts a public database of potential cerebrospinal fluid (CSF) and imaging biomarkers (UCLA LONI, 2013). By collecting biological and clinical measures in a standardized manner across time, ADNI is expected to provide a wealth of information regarding the validity of candidate biomarkers.

The standardized measures taken by ADNI help alleviate some of the shortcomings of many AD biomarker studies. Although not always feasible, studies should (1) test their prognostic value, (2) correlate with continuous measurements of disease progression, such as the ADAS-cog (the standard primary neuropsychological measure for AD trials) or the MMSE, (3) compare biomarker covariance and combinatorial utility, such as the p-tau$_{T181}$:Aβ$_{42}$ ratio (see Elevated CSF p-Tau$_1$:Aβ$_{42}$ Ratio), and (4) validate AD progression postmortem.

AD biomarker research is in its early stages, with studies characterizing biomarkers in select, at-risk populations. Many studies include MCI subjects as a sort of prodromal, predemented stage of AD. Although individuals with MCI have a higher annual rate of conversion to AD (6%–15%) than the general population (1%–2%) because MCI is of low specificity for AD, the inclusion of clinically diagnosed MCI patients in clinical trials as an intermediate phase along the AD spectrum is likely flawed. The National Institute on Aging/Alzheimer's Association Diagnostic Guidelines for AD has

suggested the use of AD biomarkers to estimate whether MCI is likely to be "MCI due to AD":

> **MCI due to AD, Low Likelihood**—MCI patients with negative biomarkers for both Aβ and neuronal injury.
> **MCI due to AD, Intermediate Likelihood**—MCI patients with either (1) a positive Aβ biomarker or (2) a positive biomarker for neuronal injury.
> **MCI due to AD, High Likelihood**—MCI patients with positive biomarkers for both Aβ and neuronal injury.

The National Institute on Aging/Alzheimer's Association Diagnostic Guidelines for AD also suggested classifying AD biomarkers into three groups: (1) biomarkers of Aβ deposition, (2) biomarkers of neuronal injury, and (3) associated biochemical change. However, some of the biomarkers of neuronal injury are likely to reflect dysfunction in glial cells, such as ^{18}F-2-deoxy-2-fluoro-D-glucose (FDG) positron emission tomography (PET) and single-photon emission computed tomography (SPECT) perfusion imaging. Furthermore, the distinction between biomarkers of neuronal injury and associated biochemical changes is not necessarily clear. For example, markers of synaptic damage (i.e., neuronal injury) are classified as associated biochemical changes. To simplify the matter, this author has chosen to organize AD biomarkers into two groups: (1) prognostic biomarkers (may predict AD onset) and (2) diagnostic biomarkers (reflect neural damage). All biomarker data are summarized in Table 49.2.

Prognostic Biomarkers

Biomarkers for Aβ and tau abnormalities are useful for predicting conversion to AD, especially when used together. The formation of Aβ plaques and tau tangles are the defining hallmarks of AD; biomarkers based on these likely reflect AD-associated pathology. Biomarkers of Aβ deposition are potentially useful predictive tools, as Aβ accumulates in the brain 10–20 years before clinical symptoms are evident (Price and Morris, 1999), whereas tau biomarkers are considered to reflect neuronal damage and are clearly associated with AD (Fig. 49.1).

Decreased Cerebrospinal Fluid Aβ$_{42}$

Aβ can be measured from plasma and CSF samples with minimally invasive procedures using an enzyme-linked immunosorbent assay (ELISA) to distinguish between Aβ peptides of different lengths. Here, the focus is on CSF Aβ$_{42}$ measurements because (1) Aβ$_{42}$ is considered to be more disease-relevant than Aβ$_{40}$ and (2) a large number of studies find that plasma Aβ levels do

TABLE 49.2 Selected Alzheimer's Disease Biomarkers With Highly Evidenced Prognostic and Diagnostic Value

Category	AD Pathology	Biomarker	Change in AD
1. Prognostic biomarkers	Increased amyloid burden	CSF Aβ$_{42}$	Decreased
		PiB-PET	Increased
	Increased tau (total-tau and phospho-tau)	CSF Tau	Increased
		CSF p-Tau (T181, S199, T231)	Increased
		CSF Tau:Aβ$_{42}$	Increased
2. Diagnostic biomarkers	Regional brain atrophy	CT and MRI	Regional atrophy, particularly in the hippocampus
	Hypometabolism	FDG-PET (glucose uptake)	Regional hypometabolism

	Oxidative damage	Isoprostanes	Increased

AD, Alzheimer's disease; *CT*, computed tomography; *MRI*, magnetic resonance imaging; *PiB*, Pittsburgh compound B; *SPECT*, single-photon emission computed tomography.
FIGURE 49.1 Cellular and temporal characteristics of Alzheimer's disease (AD) pathology. (A) Cellular pathology of AD. Active neurons (A) produce Aβ (E), which is released extracellularly. After release, Aβ is rapidly cleared by microglia ((C); the macrophages of the brain) and astrocytes (B), which contact blood vessels (D) to fulfill their protective and supportive functions. In healthy neurons (left), tau is localized in the axon (F). In AD (right), the overproduction of aggregation-prone forms of Aβ leads to several distinctive pathologies. First, tau relocates to the cell body and dendrites (H), leading to synaptic starving and neuritic dystrophy (G) and eventually cell death (I). Glial activation (L) is observed around Aβ plaques (J). The aggregation of Aβ into plaques acts as a sink, soaking up soluble Aβ from the CSF (K). (B) Significant brain atrophy occurs in AD. (C) Time course of AD. Aβ pathology precedes cognitive dysfunction by 10−20 years. Tau pathology follows, reflecting neural damage associated with compromised neural and synaptic integrity.

not associate with disease severity. While detection of other Aβ fragments through unbiased proteomic approaches has been used successfully to distinguish AD patients from nondemented controls, proteomics is not as well established as ELISA-based quantification of Aβ$_{42}$ (see "Concluding Remarks and Future Directions").

Although counterintuitive, reduced CSF levels of Aβ$_{42}$ are associated with an increased risk of developing AD. Indeed, CSF levels of Aβ$_{42}$ are decreased in AD patients compared with nondemented controls. Decreased CSF Aβ$_{42}$ also predicts conversion to AD in MCI patients. This drop in Aβ$_{42}$ is apparently caused by the formation of insoluble amyloid, throughout the course of AD, which acts as a sink for soluble Aβ, as CSF Aβ$_{42}$. This is supported by a negative correlation between CSF Aβ$_{42}$ and insoluble amyloid levels (Fagan et al., 2006). However, it is also possible that the self-association of Aβ into oligomeric toxins may preclude detection with antibodies raised against monomeric Aβ (see Concluding Remarks and Future Directions). Currently, detection of AβOs as an AD biomarker is not standard practice, although a negative correlation between the level of high molecular weight AβOs in CSF and performance on the MMSE were reported in patients with AD or MCI (Fukumoto et al., 2010).

Although CSF levels of Aβ$_{42}$ are reliable in many small-scale, single-site studies, multicenter studies revealed the unstable nature of Aβ. Because of the aggregation-prone nature of Aβ, it is a problematic peptide to keep in solution. Furthermore, the circadian fluctuations in CSF Aβ levels create an additional source of variability (Huang et al., 2012). Although CSF Aβ$_{42}$ levels are more prone to interpatient and intersite variability, they are still critical to the diagnosis of AD.

Increased Positron Emission Tomography Amyloid Imaging

One potential solution to the problem of measuring Aβ in CSF is to measure Aβ pathology in vivo. This is accomplished by the use of amyloid-sensitive PET ligands. The most successful amyloid imaging agent is ^{11}C-labeled Pittsburgh compound B (PiB), which binds to Aβ fibrils with nanomolar affinity ($K_d = 4.7$ nM) (Mathis et al., 2003). PiB binding is increased in AD patient brains, showing a similar pattern to that of amyloid detected postmortem. PiB binding has also been used to distinguish MCI patients that convert to AD—PiB levels correlate with reductions in CSF Aβ$_{42}$, elevated CSF tau and phospho-tau levels, episodic memory impairments, cerebral atrophy, and reduced cerebral glucose uptake (Forsberg et al., 2008).

It should be noted that amyloid imaging has more prognostic, rather than diagnostic, value. High PiB binding is observed in some cognitively normal individuals (Fagan et al., 2006), and while PiB levels remained stable across a 2-year longitudinal study of AD patients, cerebral glucose uptake continued to decline (Engler et al., 2006). This supports the idea that amyloid deposition plateaus before dementia becomes severe.

Elevated Cerebrospinal Fluid Total-Tau and Phospho-Tau

Tau aggregation is the second neuropathological hallmark of AD. It is thought that when neurons become sufficiently damaged, they leak tau into the extracellular milieu, although it is also possible that pathological forms of tau may spread between cells in a prion-like fashion (Clavaguera et al., 2009). Regardless of how tau enters the CSF, elevated CSF tau levels predict AD with specificity and sensitivity well above 80% in most studies. As with total-tau, levels of phosphorylated tau (e.g., T181, S199, and T231) are also elevated in AD and converting MCI patients.

Measuring CSF tau offers some advantages over Aβ measurements. The levels of total and phosphorylated tau in the CSF correlate better with brain atrophy (i.e., cell damage) than CSF Aβ or amyloid (Apostolova et al., 2010), CSF tau appears to be more stable than Aβ (Lewczuk et al., 2006), and CSF tau/p-tau may have better predictive value, at least in presymptomatic carriers of familial AD-associated mutations (Ringman et al., 2008). Despite these advantages, Aβ biomarkers are likely to have more prognostic value than tau biomarkers and even greater predictive power is achieved when CSF tau measurements are interpreted in conjunction with CSF Aβ.

Elevated Cerebrospinal Fluid p-tau:Aβ$_{42}$ Ratio

AD is characterized by significant synaptic and neuronal degeneration in the presence of amyloid plaques and tangles. Based on this, many investigators measure the ratio of CSF p-tau and Aβ$_{42}$ as a means to better distinguish AD from control subjects with specificity and sensitivity of 72%–94% and 83%–95%, respectively (De Meyer et al., 2010). When compared with measures of CSF tau, p-tau, or Aβ$_{42}$, CSF p-tau:Aβ$_{42}$ generally has greater predictive value (Herukka et al., 2005). The p-tau:Aβ$_{42}$ ratio can also be used to distinguish AD from other dementias, including semantic dementia, frontotemporal dementia, posterior cortical atrophy, and primary progressive nonfluent or logopenic aphasia (de Souza et al., 2011).

Elevated CSF tau:Aβ$_{42}$ also predicts conversion of MCI patients to AD. In one study, ADNI subjects with low CSF Aβ$_{42}$ (<192 pg/mL) and high p-tau$_{T181}$ (>23 pg/mL) were considered to have pathological CSF and had significantly reduced MMSE scores and

elevated genetic associations for AD (Schott and ADNI Investigators, 2012). The predictive value of the CSF p-tau$_{T181}$:Aβ_{42} ratio was tested on MCI converters and nonconverters from 198 MCI subjects from the ADNI trial (Samtani et al., 2013). In this study a cutoff value of -1.86 for log CSF p-tau$_{181p}$:Aβ_{42} was used to distinguish pathological CSF (>-1.86; i.e., elevated p-tau$_{181p}$ and reduced Aβ_{42}) and nonpathological CSF (≤-1.86) with a negative predictive value of 84% and a positive predictive value of 57%. This study suggests that CSF biomarkers, particularly p-tau:Aβ_{42} ratios, can be used to estimate likelihood of disease progression in MCI patients.

MicroRNA Biomarkers

MicroRNAs (miRNAs) have received considerable attention as potential biomarkers for disease states for a few reasons. First, miRNAs regulate the expression of a variety of genes in eukaryotes—changes in the miRNA expression profile reflect changes in the overall gene expression profile. Second, miRNAs are secreted from cells, allowing them to be harvested from blood or CSF. Lastly, miRNA libraries are available to allow the screening of hundreds of miRNAs in a given sample.

A large number of miRNAs have been associated with AD. For example, Alzheimer's patients show altered expression of several miRNAs involved in the processing of tau and Aβ (reviewed in Femminella et al., 2015). If these miRNAs play a causative role in disease progression, as these data suggest, then they should be able to act as biomarkers of the disease. Although we can detect different levels of specific miRNAs in blood and brain samples from Alzheimer's patients, these changes in miRNA expression are not specific to AD. For example, miR-9 is one of the miRNAs found at altered levels in Alzheimer's patients—miR-9 levels are lowered in the serum and higher in the brain. MiR-9 expression is also deregulated in Huntington's patients, Parkinson's patients, and several different types of cancer. This lack of specificity is inherent in miRNAs, as they regulate a large number of genes. Given this, even sufficiently large miRNA profiles will not likely be used to make specific diagnoses without additional, specific readouts (e.g., CSF p-tau:Aβ_{42} ratio).

Diagnostic Biomarkers

The underlying cause of AD dementia is multivariant, particularly in sporadic AD. Biomarkers of neural damage may provide insight into disease mechanisms, allowing clinicians to choose appropriate therapies when available. More importantly, biomarkers that estimate neural damage may distinguish MCI patients likely to remain stable or decline across time, which will aid in patient selection for clinical trials. However, biomarkers of neural damage are not likely to allow a definitive diagnosis of AD in the absence of positive Aβ and tau biomarkers.

Brain Atrophy

The progressive nature of AD dementia is a consequence of the severe synaptic and neuronal degeneration that occurs throughout the course of the disease. Given the characteristic pattern of tau neuropathology and concomitant neurodegeneration observed in AD patients, one would expect to observe associated decreases in brain volume throughout the course of the disease. Such measurements are attainable with computed tomography and magnetic resonance imaging (MRI), with MRI being the technique of choice in more recent work. A number of studies have shown that AD patients exhibit increased atrophy in medial temporal regions, in particular the hippocampal formation, as well as general brain atrophy. Measurements of hippocampal atrophy also support the idea that biomarkers of tau, rather than Aβ, are more closely associated with neural damage—the degree of hippocampal atrophy correlates better with tau than Aβ biomarkers (Apostolova et al., 2010). In addition to the regional differences noted above, there are also temporal differences. Longitudinal studies have shown that brain atrophy is higher in AD, occurring two- to tenfold more rapidly than in age-matched controls. Although structural MRI can clearly distinguish AD patients from age-matched controls, its ability to identify MCI patients who later convert to AD is not yet established (reviewed in Fayed et al., 2012).

^{18}F-2-Deoxy-2-Fluoro-D-Glucose Positron Emission Tomography

Cerebral metabolism is estimated using FDG, a radio-labeled glucose analog that is not metabolized because of the lack of a 2′ hydroxyl group. Using PET, the rate of FDG uptake can be measured (FDG-PET) as a surrogate measure of the cerebral metabolic rate of glucose consumption. In AD patients, decreased FDG-PET typically occurs in temporoparietal, posterior cingulate, and precuneus cortices (Minoshima et al., 1997; Hoffman et al., 2000; Sakamoto et al., 2002; Nestor et al., 2003). Severe cases of AD have additional hypometabolism in prefrontal cortices (Mosconi, 2005), which likely underlies disturbances in higher-level cognitive tasks. Decreased FDG-PET has also been reported to distinguish MCI patients who later convert to AD.

As noted previously, alterations in FDG-PET may reflect changes in neuronal and astrocytic function. It

is estimated that astrocytic end-feet cover the vast majority (>99%) of the vascular surface in the brain, and astrocyte-derived signals can control local blood supply (Iadecola and Nedergaard, 2007). This leads to the speculation that changes in FDG-PET and SPECT (see below) observed in AD may result from altered astrocytic function, which in turn leads to neuronal impairments and atrophy.

Single-Photon Emission Computed Tomography Perfusion Imaging

SPECT has shown that regional reductions in cortical perfusion occur in AD. Areas with reduced perfusion show a similar pattern to that of FDG-PET, with AD patients having reduced perfusion in temporoparietal, posterior cingulate, and precuneus cortices. Hypoperfusion also correlates with the degree of parietotemporal atrophy and postmortem Braak staging (Jobst et al., 1992). SPECT also distinguishes MCI patients who convert to AD from those who remain stable (Hirao et al., 2005). Taken together, this work suggests that cortical hypoperfusion is a useful measure of AD progression that tracks neural damage along the course of the disease.

F_2-Isoprostanes

Isoprostanes are the result of lipid peroxidation and serve as markers of oxidative damage. F_2-isoprostanes are increased in CSF of AD patients, and this increase correlates with cognitive decline in APOE4 carriers (Duits et al., 2013), cortical atrophy (Montine et al., 1999), and dementia severity (Praticò et al., 2000). CSF F_2-isoprostanes may also have predictive value, as presymptomatic carriers with familial AD-associated mutations had significantly elevated CSF F_2-isoprostane levels (Ringman et al., 2008). Although far less work has focused on isoprostanes compared with more standard AD CSF biomarkers, such as tau or Aβ, this work suggests that CSF F_2-isoprostanes are potentially useful AD biomarkers.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The biomarkers discussed in this chapter are the most widely studied AD biomarkers. There are many other biomarkers that are newly emerging or of debatable prognostic or diagnostic value. One future approach that is particularly appealing is an unbiased proteomic analysis of CSF samples. Unlike antibody-based recognition, proteomic mass spectroscopy analysis allows the identification of many different proteins, as well as variants of the same protein. One study used proteomic methods to identify novel

biomarkers to distinguish AD from cognitively normal controls and other neurodegenerative disorders (Hu et al., 2010). In a separate study, the pattern of Aβ fragments (Aβ$_{1-16}$, Aβ$_{1-33}$, Aβ$_{1-39}$, and Aβ$_{1-42}$) was found to be different in CSF from AD patients compared with nondemented controls (Portelius et al., 2006). However, due to technical limitations, proteomic analyses are not likely to be adopted as standard practice.

CSF is in direct contact with the brain and is rich in molecular components that are thought to reflect changes in brain function. In fact, CSF biomarkers have proven far more reliable than serum biomarkers for detecting changes that occur in AD. Aβ biomarkers are likely to be of great prognostic value, especially when coupled with tau biomarkers. Biomarkers of neural damage are more likely to aid in estimating disease progression, rather than distinguishing AD from other forms of dementia or predicting which MCI patients are likely to convert to AD (Small et al., 2006). Because of the unstable nature of Aβ and tau, the collection, handling, and storage of CSF samples is a major source of variability within and between study sites. This variability may be reduced by adopting the National Institute on Aging's *Biospecimen Best Practice Guidelines for the Alzheimer's Disease Centers* (National Institute on Aging, 2007). As of yet, there are no validated cutoff values for any AD biomarkers. A significant step in this direction was started by ADNI, which hosts a public database of AD biomarkers acquired across multiple sites (UCLA LONI, 2013). Earlier detection is expected to aid in clinical trial design and may allow individuals to better plan for their future. However, in the absence of effective therapies, a positive diagnosis may do more harm than good.

INTRODUCTION

Parkinson's disease (PD) is a neurodegenerative disorder of the central nervous system (CNS) first described in the medical literature by British physician James Parkinson in 1817 (Parkinson, 1817; Goetz, 2011; Pan et al., 2018). According to data available from the European Parkinson's Disease Association, 6.3 million people have PD worldwide, making it the second most common neurodegenerative disease after Alzheimer's disease (AD) (Jankovic, 1988; Tanner, 1992). In the United States, this disease affects more than 1 million people at an estimated annual cost of $28 billion, and about 50,000−60,000 new cases are diagnosed annually. These figures are expected to increase substantially as the median age of the population continues to rise in the coming decades, creating an even greater public health issue (Olanow, 2004). Both PD prevalence and incidence are age-dependent, with approximately 1% of the population older than 65 years being affected, rising to 4%−5% of the population over 85 years (Van Den Eeden et al., 2003; Farrer, 2006). Typical clinical symptoms of PD include resting tremor, rigidity, bradykinesia, and postural abnormalities. As the disease progresses, patients often show reduced facial expressions, speak softly, and have difficulty chewing and swallowing. In addition to motor deficits, PD patients often exhibit a number of nonmotor symptoms as well, such as autonomic dysfunction, cognitive and neurobehavioral disorders, and sensory and sleep abnormalities (Jankovic, 2008). Many of these symptoms can arise prior to motor dysfunction (Abbott et al., 2005, 2007; Haehner et al., 2007; Odin et al., 2018).

The pathological hallmark of PD is progressive loss of dopaminergic neurons within the substantia nigra pars compacta (SNc), leading to a profound depletion of dopamine in the striatum, a central component of the basal ganglia responsible for the initiation and control of body movement. Such depletion is believed to underlie many of the clinical manifestations of PD (Crossman, 1989; Dunnett and Bjorklund, 1999; Zhang et al., 2000). The onset of disease symptoms is marked by a level of depigmentation in the SNc encompassing approximately 60% of the SNc dopaminergic neurons and by

about 80% of the putamen dopamine having been lost (Kirik et al., 1998). Another important pathological feature for PD is the formation in the neuron's cytoplasm of round eosinophilic inclusions (Lewy bodies [LB]) containing aggregates of many different proteins and lipids, and thread-like proteinaceous deposits within neurites (Lewy neurites) of surviving dopaminergic neurons (Werner et al., 2008).

Thus far, there is no cure for PD. All current treatments are symptomatic; none slow or prevent neuronal death progression in the dopaminergic system (Olanow, 2004; Obeso et al., 2010; Lang and Espay, 2018; Ullah and Khan, 2018). Current standard treatment therapy is based on levodopa, one of the intermediate molecules in the genesis of dopamine (Clarke, 2004). As a dopamine replacement therapy, levodopa is initially effective at improving PD symptoms for most patients, but with continued treatment, patients may develop dyskinesia, dystonia, and other motor complications, as well as nonmotor adverse effects. Thus, the beneficial effects of levodopa wear off over time, and its clinical efficacy gradually declines as the disease advances (Lewitt, 2008).

Early diagnosis or even preclinical identification of individuals prior to the onset of resting tremor is essential to optimally managing PD. However, clinical diagnosis, especially in the early stages of disease, can be challenging owing to its insidious, asymmetrical, and unilateral onset and lack of pathognomonic signs or symptoms (Brooks, 2002; Caslake et al., 2009; Scorza et al., 2018). A definite diagnosis requires the findings of neuronal loss and depigmentation in the SNc and the presence of LBs in the brain stem, all of which can only be documented postmortem (Farrer, 2006). Currently, making a diagnosis of PD is clinical in nature, mainly relying on the presence or absence of various clinical features (bradykinesia, resting tremor, muscle rigidity, and postural instability) as well as the experience of the treating physician, and frequently requires a long-term watchful waiting (Pahwa and Lyons, 2010; Jann, 2011; Crosiers et al., 2012; Marsili et al., 2018). In many cases, diagnostic accuracy, particularly in the early stages of disease, is quite low, even among neurological specialists. An early study pointed out a more than one-third rate of misdiagnosis in PD found at autopsy (Ward and Gibb, 1990). This appreciable misdiagnosis arises partly from the clinical and pathological overlaps between PD and other movement disorders. These atypical Parkinsonian disorders, including multiple system atrophy (MSA), progressive supranuclear palsy (PSP), corticobasal ganglionic degeneration, and Lewy body dementia, display specific features of PD in addition to other complex neurological symptoms resulting from neuronal damage to brain areas other than the nigrostriatal dopaminergic system. Differentiating PD

from these disorders remains problematic, and as a result, an early PD diagnosis may be revised years later when atypical features indicating other forms of Parkinsonism are apparent.

Based on the aforementioned challenges in diagnosing PD, there is a critical need for robust biomarkers with the ability to confirm diagnosis in the early stages of disease. Such biomarkers are needed as well to optimize the development of drugs targeting these early stages. Furthermore, a validated biological marker that reflects PD severity/progression is also urgently required. Despite the continuing lack of reliable biomarkers for PD, extensive research has been concentrated on the development of neuropathological, biochemical, neuroimaging, molecular, and genetic biomarker candidates of the disease. This has created considerable excitement in recent years, leading to novel diagnostic approaches and contributing to the development of new drugs and therapeutic biological products. This chapter will focus on the most promising PD biomarkers.

GENETIC BIOMARKERS

Extensive genetic research during the past two decades has led to the identification of not only several monogenic forms of PD, but also numerous causative mutations in several genes that increase the risk of PD. Although monogenic forms of PD appear to be rare, accounting for about 30% of familial and 3%–5% of sporadic cases, understanding these genetic variations will aid in identifying the underlying disease mechanisms, thereby accelerating the search for disease-specific biomarkers. In the following section, we will discuss the most important genetic mutations.

α-Synuclein

The *SNCA* gene coding for the protein α-synuclein was the first gene implicated in the familial forms of PD when a missense mutation A53T within the gene was isolated from a large Italian−Greek family with autosomal dominant PD, characterized by early onset (50 years) and rapid disease progression (Polymeropoulos et al., 1996, 1997). Subsequent studies identified two further point mutations (A30P and E46K) in the *SNCA* gene in a German and Spanish family, respectively (Kruger et al., 1998; Zarranz et al., 2004). All these families had clinical and pathological features similar to those observed in sporadic PD and responded to levodopa medication, although some atypical phenotypes also have been observed. For example, cognitive decline and severe central hypoventilation have been noted in several

A53T-associated patients (Polymeropoulos et al., 1997; Spira et al., 2001), and interestingly, patients with the E46K mutation exhibit some clinical features typical of DLB in addition to Parkinsonism (Zarranz et al., 2004). Apart from these missense substitutions, genomic rearrangements, including duplication (Chartier-Harlin et al., 2004; Ibanez et al., 2004; Nishioka et al., 2006; Ahn et al., 2008) and triplication (Singleton et al., 2003) of the wild-type *SNCA* gene, were also reported to cause autosomal-dominantly inherited PD in several families. In contrast to families with gene triplications, who were affected in their thirties and often presented with severe phenotypes, such as rapid progression, early dementia, and reduced life span, the clinical phenotype in patients with *SNCA* duplications resembles more closely those of sporadic PD patients (Chartier-Harlin et al., 2004; Fuchs et al., 2007). Interestingly, a Rep1 microsatellite polymorphism located on the *SNCA* gene promoter (Maraganore et al., 2006) and several single-nucleotide polymorphisms at the 5′ and 3′ regions have been associated with higher risk for sporadic PD (Mueller et al., 2005; Mizuta et al., 2006; Winkler et al., 2007; Pankratz et al., 2009). Although the cases of familial PD associated with α-synuclein mutations are extremely rare (Lee and Trojanowski, 2006), a significant role for α-synuclein in the pathogenesis of PD is highlighted by the identification of α-synuclein as the major component of LBs in both sporadic and familial PD (Spillantini et al., 1997, 1998; Takeda et al., 1998; Bayer et al., 1999). Using α-synuclein as a biochemical marker of PD will be discussed at length in this chapter (see Section 3.1).

LRRK2

The PARK8 locus encompassing the *LRRK2* gene was initially mapped in a large Japanese family with late-onset autosomal dominant PD (Funayama et al., 2002). Subsequently, two groups concurrently identified mutations within the *LRRK2* gene as the causative gene for PARK8-linked familial PD (Paisan-Ruiz et al., 2004; Zimprich et al., 2004). Since then, six point mutations with definite pathogenicity (R1441C, R1441G, Y1699C, G2019S, I1122V, and I2020T) and numerous putative pathogenic mutations have been identified in the *LRRK2* gene in both familial and sporadic PD (Cookson, 2005; Funayama et al., 2005; Gilks et al., 2005; Nichols et al., 2005; Mata et al., 2006; Tomiyama et al., 2006; Lu and Tan, 2008; Hatano et al., 2009; Haugarvoll and Wszolek, 2009). *LRRK2* mutations are the most frequently known cause of autosomal dominant forms of familial PD (Klein and Schlossmacher, 2007; Mizuno et al., 2008). The known *LRRK2* variants are estimated to account for approximately 2% of sporadic and 10% of familial PD cases (Berg et al., 2005; Di Fonzo et al.,

2005; Mata et al., 2006). In particular, the *LRRK2* G2019S mutation is the best studied and most frequent substitution in the Caucasian population, accounting for approximately 0.5%–2.0% of apparently sporadic and 5%–6% of familial PD cases (Di Fonzo et al., 2005; Farrer et al., 2005; Gilks et al., 2005; Kachergus et al., 2005; Nichols et al., 2005; Tomiyama et al., 2006). However, the G2019S mutation frequency appears to vary with ethnicity (Tan et al., 2005; Lesage et al., 2006), with an extremely high frequency (30%–40%) of familial and sporadic PD patients from North Africa (Lesage et al., 2006) and 10%–30% of Ashkenazi Jews (Ozelius et al., 2006), but very rarely found in Asia (Tan et al., 2005), South Africa (Okubadejo et al., 2008), and some European countries (Xiromerisiou et al., 2007). Additionally, two polymorphic mutations R1628P and G2385R have been found to confer susceptibility to PD in Asian populations (Funayama et al., 2007; Ross et al., 2008). The penetrance of G2019S-associated disease appears to be age-dependent (Kachergus et al., 2005), but variations have been subsequently reported (Lesage et al., 2005; Clark et al., 2006; Goldwurm et al., 2007). The clinical and neurochemical phenotypes of patients with *LRRK2* mutations usually resemble sporadic PD, with neuronal degeneration accompanied by LB and responsiveness to levodopa. However, the disease pathologies can be quite variable, even within the same family (Tan and Skipper, 2007). Recent evidence showed that LRRK2 could play a role in mediating neuroinflammation (Schapansky et al., 2015; Taymans et al., 2017; Chen et al., 2018). The expression of LRRK2 in microglia is higher compared with that in neurons (Schapansky et al., 2015), and LRRK2 inhibition can attenuate microglia-mediated inflammatory responses (Moehle et al., 2012). At the molecular level, LRRK2 was reported to regulate microglial activity through modulation of chemokine (C-X3-C) receptor 1- or NFκB-mediated signaling pathways (Russo et al., 2015; Ma et al., 2016).

Parkin

Mutations in the *parkin* gene were originally identified in Japanese families with autosomal recessive juvenile-onset Parkinsonism (Ishikawa and Tsuji, 1996; Kitada et al., 1998). Subsequent studies have identified a wide variety of *parkin* mutations in PD cases, including point mutations, exonic rearrangements, deletions, and duplications (Lucking et al., 2001; Tan and Skipper, 2007). To date, more than 100 different *parkin* mutations have since been identified (Tan and Skipper, 2007). *Parkin* mutations are the most commonly known cause of autosomal recessive early-onset PD (Mizuno et al., 2008; Hatano et al., 2009), accounting for about 50% of

familial and 20% of sporadic early-onset PD cases (Lucking et al., 2000). In general, *parkin*-proven disease has typical signs of PD but with an earlier age of onset (typically before 40 years), dystonia at onset, a slower progression, and a dramatic response to levodopa manipulation (Lohmann et al., 2003). However, several mutations in *parkin* may lead to a clinical presentation indistinguishable from typical late-onset idiopathic PD (Abbas et al., 1999; Klein et al., 2000; Foroud et al., 2003; Oliveira et al., 2003; Hatano et al., 2009). The pathological features of *parkin*-associated Parkinsonism typically include a loss of nigral neurons and a moderate loss of neurons in the locus coeruleus region (Mori et al., 1998). However, LBs are usually absent (Mizuno et al., 2001; Mizuno et al., 2001; Mata et al., 2004). Nevertheless, for the sporadic forms of PD, *parkin* has been identified as a component of LB.

PINK1

PINK1 mutations were initially identified in a large Italian family with an autosomal recessive form of PD (Valente et al., 2001). Since then, more than 50 pathogenic *PINK1* mutations have been identified (Hatano et al., 2009). These mutations include point mutations, as well as insertions and deletions that result in frameshift and truncation of the protein (Atsumi et al., 2006; Exner et al., 2007). Mutations in the *PINK1* gene were estimated to account for 1%–8% of familial or early-onset PD (Klein and Schlossmacher, 2007), and as such, *PINK1* mutations are the second most commonly known cause of autosomal recessive PD, after *parkin* mutations (Hatano et al., 2004; Valente et al., 2004). The clinical phenotype of *PINK1*-associated PD resembles sporadic PD with rare atypical features such as dystonia at onset and dementia similar to those with *parkin* mutations (Hatano et al., 2004; Valente et al., 2004a, 2004b; Steinlechner et al., 2007). It is not clear whether LBs are present in this PINK1-linked disease, because no neuropathological examination of the homozygous pathogenic mutation has been reported (Hardy et al., 2009).

DJ-1

Mutations in *DJ-1* were first identified in one Dutch family with autosomal recessive early-onset PD (van Duijn et al., 2001). Additional mutations including missense, exonic deletions, and splice-site alterations were further identified (Bonifati et al., 2003, 2004; Hering et al., 2004). The *DJ-1* mutations are extremely rare, accounting for less than 1% of early-onset PD cases (Clark et al., 2004; Lockhart et al., 2004). In general, patients with *DJ-1* mutations exhibit a clinical presentation similar to that of *parkin* or *PINK1* mutation-associated

Parkinsonism (Hatano et al., 2009). Like *PINK1* mutations, a neuropathological investigation has not yet been reported, and for this reason it is not clear whether the LB phenotype is present in this disorder (Hardy et al., 2009). Although DJ-1 is not an essential component of LBs, it appears to be consistently colocalized with neuronal tau-positive inclusions and glial cytoplasmic inclusions (Neumann et al., 2004), providing a link between DJ-1 and distinct neurodegenerative diseases. DJ-1 has been extensively evaluated as a biochemical marker of PD (see Section 3.2.1).

BIOCHEMICAL MARKERS

Although the specific etiology of PD remains largely unknown, extensive evidence suggests that several pathogenic pathways play a key role in the development of the disease, including oxidative and nitrosative stress, mitochondrial dysfunction, impairment of the ubiquitin-proteasome system, apoptosis, and inflammation. Therefore, characterizing body fluids like cerebrospinal fluid (CSF), urine, or blood or the tissue concentration profiles of selected key proteins or other molecules involved in PD pathogenesis is necessary if we are to uncover promising biomarkers for PD.

α-Synuclein and Abnormal Protein Accumulations

Impaired protein degradation, leading to the aggregation of misfolded, mutant, and toxic variants of proteins, plays a key role in the molecular pathogenesis of PD and other neurodegenerative diseases (Kopito, 2000; Goldberg, 2003; Ross and Poirier, 2004; Bentea et al., 2017; Sharma and Priya, 2017). As described previously, the presence of intracytoplasmic proteinaceous inclusions in the SNc, known as LBs, is one of the neuropathological hallmarks of PD. LBs are composed of a variety of free and ubiquitinated proteins, including α-synuclein, ubiquitin, parkin, proteasome subunits, UCHL1, torsin-A, synphilin-1, chaperons, and neurofilaments (Forno, 1996). During the past decade, significant efforts toward biomarker development in PD have been underway to validate certain proteins that are present in LBs and seem to be associated with abnormal protein aggregation, particularly α-synuclein.

α-Synuclein is a primary component of LB and neurites, and the formation of oligomeric aggregates of α-synuclein has long been associated with PD and other synucleinopathies, including DLB and MSA among others (Galvin et al., 2001; Marti et al., 2003). Levels of α-synuclein in the CNS are tightly regulated by a balance of α-synuclein synthesis, clearance, aggregation,

and secretion (Lashuel et al., 2013). The mechanism of α-synuclein clearance remains elusive, but some reports suggest that α-synuclein is degraded mainly through the proteasomal system (Xilouri et al., 2013) and autophagy pathway via lysosomes (Lee et al., 2004; Xilouri et al., 2008). α-Synuclein at first was considered to be an exclusively intracellular protein due to its lack of endoplasmic reticular signal peptides. However, growing evidence suggests that both soluble monomeric and oligomeric forms of α-synuclein can be detected in the biological fluids, such as plasma and CSF, of healthy and diseased individuals (Borghi et al., 2000; El-Agnaf et al., 2003; Tokuda et al., 2006). Interestingly, more recent discoveries indicate that the toxic α-synuclein monomers, oligomers, and fibrils can propagate via the prion-like mechanism of cell-to-cell transfer via exosomes. These transferred proteins possess the capacity to seed aggregation in recipient cells, thereby spreading disease to other brain regions (Lee et al., 2008; Desplats et al., 2009; Hansen et al., 2011). As exosomes contain a lipid membrane with moieties similar to those seen on the plasma membrane of various cells, it is easy for a distant cell to either engulf these extracellular vesicles or simply allow entry via plasma membrane fusion and diffusion into the cell cytosol. This cell-to-cell transfer of aggregated α-synuclein proteins is thought to cause the progression of PD. A recent study suggests that the exosomal/total α-synuclein ratio in plasma is associated with disease severity in PD patients. CSF has long been known to be optimal for measuring brain metabolism in both healthy and unhealthy individuals due to the relatively free exchange of molecules between the brain and CSF (Anoop et al., 2010). Indeed, previous studies of CSF concentrations of biomarkers for AD, such as β-amyloid and tau, have displayed a good correlation with disease progression (Mattsson et al., 2009; Mattsson and Zetterberg, 2009). For these reasons, levels of α-synuclein in CSF have great promise as potential biomarkers for PD and other synucleinopathies. The possible presence of α-synuclein in CSF first came to light in 2000 when a method combining immunoprecipitation and immunoblotting was applied. In this study, however, no significant difference between PD and control subjects was observed (Borghi et al., 2000). More recently, several independent studies using either ELISA or bead-based Luminex assays have demonstrated significantly reduced levels of total CSF α-synuclein in PD patients compared to healthy controls (Tokuda et al., 2006; Mollenhauer et al., 2008, 2011; Hong et al., 2010; Kasuga et al., 2010; Parnetti et al., 2011). However, most of these studies did not highlight a correlation between disease severity/duration and total CSF α-synuclein levels, suggesting that total CSF α-synuclein may not be a sensitive biomarker for disease progression. Notably, several other investigations reported comparable levels of total CSF α-synuclein between control and PD patients (Ohrfelt et al., 2009). This discrepancy is possibly due to differences in sampling protocols and in methodological quantification of α-synuclein, as well as possible blood contamination of CSF samples during lumbar puncture. In addition to total α-synuclein, several recent studies also investigated the CSF concentration of oligomeric α-synuclein in patients with PD and in age-matched controls (Tokuda et al., 2010; Park et al., 2011; Sierks et al., 2011). Results demonstrated that levels of oligomeric α-synuclein in the CSF are significantly higher in patients with PD as compared to controls, suggesting that α-synuclein oligomers in CSF may be a promising biomarker for PD and other synucleinopathies, although further validation is required.

Besides CSF, detection of α-synuclein in blood as a potential PD biomarker also has been evaluated by several investigators, but the results have been variable and inconclusive, mainly due to the fact that more than 98% of blood α-synuclein is contained in red blood cells, and various in vitro or in vivo hemolytic changes are confounders in these studies. In some of these studies, increased levels of α-synuclein (El-Agnaf et al., 2006; Lee et al., 2006; Duran et al., 2010) or phosphorylated α-synuclein (Foulds et al., 2011) in plasma from PD patients have been detected relative to controls. In contrast, in other studies, comparable (Shi et al., 2010) or significantly decreased (Li et al., 2007; Laske et al., 2011) levels of plasma α-synuclein between groups was found. Interestingly, a recent study indicates that plasma α-synuclein can predict cognitive decline in PD (Lin et al., 2017). Additionally, several studies have detected α-synuclein in other tissue types, including skin (Hoepken et al., 2008) and saliva (Del Tredici et al., 2010; Devic et al., 2011). Skin and salivary biomarkers have received special attention because they are highly accessible and easily obtained. However, potential biomarkers based on skin and salivary α-synuclein remain preliminary and need further confirmation.

Mitochondrial Dysfunction and Oxidative Stress Markers

Over the last several decades, mitochondrial dysfunction and increased oxidative stress have gained wide acceptance as pathogenic pathways contributing to PD pathogenesis. There is considerable evidence for mitochondrial dysfunction and increased oxidative stress in the brains of PD patients. Impairment of complex I activity of the mitochondrial electron transport chain has been detected in the SNc, skeletal muscle, lymphocytes, and platelets of patients with PD (Mizuno al. 1989; Parker et al., 1989; Schapira et al., 1989; Yoshino et al., 1992; Barroso et al., 1993; Mann et al., 1994; Haas et al.,

1995; Penn et al., 1995; Blandini et al., 1998). Increased oxidation of complex I subunits and reduced rates of electron transfer through complex I, as well as misassembly of complex I, were also demonstrated in PD brains (Keeney et al., 2006). Moreover, increased mtDNA deletions were detected in nigral neurons in PD brains (Bender et al., 2006). Similarly, postmortem studies have consistently observed high levels of oxidation of lipids (Dexter et al., 1989), proteins (Yoritaka et al., 1996; Floor and Wetzel, 1998), and nucleic acids (Alam et al., 1997) in the SNc of sporadic PD brains. In addition, significant alterations of the antioxidant defense system, in particular reduced glutathione, are found in the SNc of PD patients (Sian et al., 1994). Thus, metabolites and proteins linked to mitochondrial dysfunction and oxidative stress are increasingly the focus of biomarker studies of PD.

DJ-1

DJ-1 is a ubiquitously expressed protein and its mutations are associated with an autosomal recessive form of PD and cancers. This protein is also believed to play an important role in sporadic PD, particularly owing to its antioxidative activity and associated neuroprotective function (Taira et al., 2004; Menzies et al., 2005; Yang et al., 2005). DJ-1's protective effect has also been linked to its ability to regulate gene transcription, stabilize protective proteins, or mediate cell signal pathways (Shendelman et al., 2004; Zhou et al., 2006; da Costa, 2007). In addition, several lines of evidence point to a mitochondrial regulation function for DJ-1 (Hao et al., 2010; Irrcher et al., 2010; Kamp et al., 2010; Thomas et al., 2011). DJ-1 can be secreted into biological fluids, making it a promising biological marker for PD. Several studies on DJ-1 concentrations in CSF and blood have been carried out; however, the results are mostly contradictory and inconclusive. Using a semiquantitative immunoblot approach, two initial studies by Waragai and colleagues showed that DJ-1 levels are significantly higher in the CSF (Waragai et al., 2006) and blood (Waragai et al., 2007) of PD patients compared to controls. By contrast, Maita et al. (2008) examined DJ-1 with an ELISA-based method, but failed to find a disease-related difference in blood levels of DJ-1. In a more recent study, described above for measuring CSF α-synuclein, CSF DJ-1 levels were found to be significantly reduced in PD cases compared to controls and AD cases (Hong et al., 2010). Notably, there was no correlation of DJ-1 with disease severity in this study. The same group also showed that DJ-1 levels in human blood did not differ between PD patients and controls (Shi et al., 2010). Similar to what was seen with α-synuclein, those divergent results might be due to variations in detection and sensitivity among different experimental systems as well as possible blood contamination of CSF.

More recently, using mass spectrometry analyses, Lin et al. (2012) detected oxidized forms of DJ-1 in blood as potential biomarkers of PD. Among the seven posttranslationally modified isoforms of DJ-1 identified in this study, two of 4-HNE oxidatively modified DJ-1 isoforms in blood were found to differ between PD patients and controls, suggesting that blood-oxidized DJ-1 may be a candidate biomarker of PD. This finding is of special interest because oxidative modifications of DJ-1 are indicative of increased oxidative stress and have been linked to sporadic PD and AD (Choi et al., 2006; Saito et al., 2009; Inden et al., 2011; Ren et al., 2011). Further studies measuring oxidized DJ-1 in CSF or blood are definitely warranted, particularly with the availability of specific antibodies recognizing oxidized DJ-1 (Ooe et al., 2006; Saito et al., 2009).

Urate

Urate (also known as uric acid) represents the main end product of purine metabolism and is present both intracellularly and in all biological fluids (Cipriani et al., 2010). It has been demonstrated to scavenge superoxide (Skinner et al., 1998), peroxynitrite (Whiteman et al., 2002), hydroxyl radical (Cohen et al., 1984; Aruoma and Halliwell, 1989; Kaur and Halliwell, 1990; Regoli and Winston, 1999), and singlet oxygen (Ames et al., 1981), as well as to form chelate complexes with metal ions (Davies et al., 1986), thereby serving as a major antioxidant in body fluids. With these antioxidant and metal chelation propensities, urate has been implicated to exert neuroprotective effects against oxidative damage in both cell culture (Guerreiro et al., 2009) and animal (Duan et al., 2002; Haberman et al., 2007) models of neurodegeneration. Many investigators have reported a significant correlation between urate and PD. The first evidence was reported by Church et al. (1994), who found that urate levels in the substantia nigra of PD were significantly lower compared to age-matched controls, and that adding urate to PD homogenates attenuated oxidative stress as indicated by reduced dopamine oxidation. Subsequently, four prospective cohort studies on blood urate and PD risk were carried out and similar results were obtained (Davis et al., 1996; de Lau et al., 2005; Weisskopf et al., 2007; Chen et al., 2009). They demonstrated that individuals with higher blood levels of urate have a significantly reduced risk of developing PD. This work strengthens the link between oxidative stress and PD pathogenesis and the rationale for considering urate as a potential biomarker for PD risk. Additionally, several studies tested the hypothesis that urate may also be a prognostic biomarker of clinical PD progression. The first prospective study of blood urate and PD progression demonstrated that patients with increasing baseline serum levels of urate progress markedly slower toward

the disability end point that required dopamine treatment (Schwarzschild et al., 2008). Ascherio et al. (2009) confirmed the inverse association between baseline serum urate and clinical progression rate in an independent cohort with early PD. In this study, they also identified an inverse link between CSF urate and clinical PD progression. Although all these findings indicate that urate could be a promising marker of the pathophysiological changes underlying PD, the biomarker utility of urate for PD diagnosis and prognosis remains limited due to its largely nonspecific action as an antioxidant.

8-OHG and 8-OHdG

Oxidative damage to nucleic acids has often been used as a marker for various diseases involving abnormally high oxidative stress, such as certain cancers, cardiovascular and neurodegenerative diseases (Cooke et al., 2003; Nakabeppu et al., 2007; Moreira et al., 2008). Among multiple adducts of nucleoside oxidation, 8-hydroxydeoxyguanosine (8-OHG) and 8-hydroxy-2′-deoxyguanosine (8-OHdG) are two of the most common modifications of nucleic acids under conditions of oxidative stress (Fiala et al., 1989; Loft and Poulsen, 1996; Wamer and Wei, 1997). Using highly specific antibodies against 8-OHG and 8-OHdG, higher levels of 8-OHG/8-OHdG have been found in the caudate nuclei and SNc of PD patients compared to age-matched controls (Alam et al., 1997; Shimura-Miura et al., 1999; Zhang et al., 1999). Interestingly, several studies have demonstrated increased concentrations of 8-OHG/8-OHdG in the CSF of PD patients (Kikuchi et al., 2002; Abe et al., 2003; Michell et al., 2004). In another study investigating the link between urinary 8-OHG and PD progression, Sato et al. (2005) found that urinary 8-OHG levels in PD patients were associated with the stages of PD, suggesting that urinary 8-OHG may be a potential marker of PD progression, although it has yet to be replicated independently. With regard to serum 8-OHG/8-OHdG concentrations in PD patients, however, available data are highly variable and inconclusive (Kikuchi et al., 2002; Abe et al., 2003).

Neuroinflammation Markers

Growing evidence supports the involvement of neuroinflammation in the pathogenesis of PD and many different brain diseases (Mosley et al., 2006; Gao et al., 2008; Przedborski, 2010; Qian et al., 2010). Neuroinflammation in the brain is characterized by the activation of microglia and astrogliosis as well as the expression of major inflammatory mediators (Barnum and Tansey, 2012; Hirsch et al., 2012; Sekiyama et al., 2012; Taylor et al., 2013). The first evidence of neuroinflammation in PD came from postmortem studies, which showed microglial

activation, astrogliosis, and lymphocytic infiltration in the nigra of PD patients. Epidemiological data indicated that nonsteroidal anti-inflammatory drugs might reduce the risk of PD (Chen et al., 2003). Interestingly, a plethora of proinflammatory cytokines such as interferon-γ (IFN-γ), interleukin1-β, 6, and 2 (IL1-β, IL-6, IL-2), tumor necrosis factor-α (TNF-α), transforming growth factor-α (TGF-α), and TGF-β1 (Boka et al., 1994; Mogi et al., 1994a, 1994b, 1994c; Mogi et al., 1995a, 1995b; Mogi et al., 1996a, 1996b; Hunot et al., 1999), as well as several inflammatory enzymes such as inducible nitric oxide synthase (iNOS), cyclooxygenase (COX-1 and COX-2), and gp91phox, the main component of NADPH-oxidase (Hunot et al., 1999; Knott et al., 1999; Teismann et al., 2003; Teismann et al., 2003a, 2003b; Wu et al., 2003; Przedborski, 2010), have also been found to be upregulated in PD brains. These findings raise the possibility that examining the CSF and serum concentrations of these inflammatory mediators may be a sensitive biomarker for PD. Indeed, several studies on CSF (Blum-Degen et al., 1995; Muller et al., 1998; Guo et al., 2009) and serum (Dufek et al., 2009; Scalzo et al., 2011) proinflammatory cytokines and chemokines have been published; however, these results remained largely inconclusive. In addition, the lack of disease specificity is a major drawback limiting the use of inflammation and glial activation markers in clinical trials and in practice.

Apoptosis Markers

Apoptosis has been widely implicated in PD for mediating dopaminergic neuron death, although it continues to be debated (Mattson, 2000; Vila and Przedborski, 2003). Initially, it was demonstrated that increased numbers of TUNEL-positive dopaminergic neurons exist in the postmortem brains of PD patients. Further studies showed the activation of different initiator and effector caspases, including caspase-8, -9, and -3 in the brains of PD patients (Hartmann et al., 2000, 2001; Viswanath et al., 2001), although other studies failed to find such activation (Banati et al., 1998; Jellinger, 2000). In MPTP-intoxicated animals, substantial evidence exists demonstrating all major events of an intrinsic apoptotic pathway, including cytochrome C release, caspase-3 activation, and further cell death after MPTP administration. Furthermore, there is abundant evidence that some of the genetic causes of PD, including α-synuclein (Manning-Bog et al., 2003; Sidhu et al., 2004; Chandra et al., 2005; Machida et al., 2005; Leng and Chuang, 2006), parkin (Darios et al., 2003; Jiang et al., 2004; Machida et al., 2005), PINK1 (Petit et al., 2005; Plun-Favreau et al., 2007), and DJ-1 (Canet-Aviles et al., 2004; Junn et al., 2005; Xu et al., 2005), are directly and primarily involved in the regulation of apoptotic

pathways. So far, biomarker studies in this area remain rare. An early CSF study demonstrated reduced levels of CSF Annexin V in PD patients; however, their CSF Annexin V levels did not correlate with dementia, duration of symptoms, age, sex, or PD treatment (Vermes et al., 1999).

NEUROIMAGING MARKERS

The potential utility of structural and functional neuroimaging as biological markers for diagnosing PD and its progression has been extensively advanced in recent years (de la Fuente-Fernandez et al., 2011; Stoessl, 2011; Di Biasio et al., 2012). Various imaging techniques have been increasingly investigated, including single photon emission computed tomography (SPECT), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI) (Godau et al., 2012; Seibyl et al., 2012). Based on a number of radiotracers whose uptake reflects the integrity of the nigrostriatal tract, both PET and SPECT imaging are able to detect several important PD pathological parameters, such as dopaminergic dysfunction, motor symptoms, and protein aggregation (Niethammer et al., 2012; Stoessl, 2012). Multiple radiotracers have been developed to evaluate the functionality of dopamine terminals in PD. *First*, [^{18}F]-6-fluorodopa (FDOPA) PET assesses the activity of aromatic amino acid decarboxylase (AADC). It has been demonstrated that striatal FDOPA binding is markedly reduced in patients suffering from PD and is inversely correlated with motor disability (Brooks et al., 1990; Eidelberg et al., 1990; Otsuka et al., 1996; Broussolle et al., 1999; Thobois et al., 2004). Furthermore, several lines of evidence indicate that this radiotracer can also be used to monitor the stages of dopaminergic degeneration in PD (Fearnley and Lees, 1991; Bruck et al., 2009; Pavese et al., 2011). *Second*, various tropane-based PET and SPECT tracers label dopamine transporters (DAT) on the presynaptic dopamine nerve terminals and thus directly determine the integrity of the nigrostriatal system in PD (Aquilonius, 1991; Marie et al., 1995). *Third*, the ^{11}C-dihydrotetrabenazine (DHTBZ) PET radiotracer examines vesicular monoamine transporter (VMAT2) density (Stoessl, 2007; de la Fuente-Fernandez et al., 2009). These DAT and VMAT2 radiotracers routinely showed reduced binding in PD patients and have been shown to correlate with disease progression (Vingerhoets et al., 1994; Booij et al., 1997; Lee et al., 2000; Hilker et al., 2005; Panzacchi et al., 2008). Dopaminergic imaging using PET and SPECT tracers has demonstrated enhanced sensitivities in differentiating clinically probable early PD from non-PD controls, thus showing promise in improving diagnostic accuracy (Marek et al., 1996; Seibyl et al., 1996; Meara et al., 1999; Pirker et al., 2002; Marshall et al., 2009). However, neither PET nor SPECT can distinguish between causes of dopamine deficiency and also differentiate PD from atypical Parkinsonism including MSA, CBD, and PSP. Additionally, fMRI imaging may be used to differentiate PD from atypical Parkinsonism (Gupta et al., 2010), but its use is not widely accepted. In general, all these brain imaging markers are able to monitor disease pathology and are intended as an adjunct to other diagnostic procedures. However, their use is primarily limited to research applications due to their cost and availability.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

This chapter discusses promising biomarkers for PD. Overall, there is increasing evidence that a number of potential biochemical and genetic biomarkers show promise for earlier, accurate diagnosis of PD. Nonetheless, a major limitation for using these markers in clinical practice is their lack of specificity and sensitivity. On the other hand, functional imaging markers are more specific and sensitive, but their utility has not been widely accepted due to their high cost and limited access. Clearly, a panel of diagnostic assays combining multiple biomarkers from different categories and even within the same category, together with thorough neuroimaging testing and clinical work-up, may be more effective in diagnosing and tracking PD progression, as well as accelerating the pace of developing more meaningful disease-modifying therapies for PD.

Biomarkers for Drugs of Abuse and Neuropsychiatric Disorders: Models and Mechanisms

Pushpinder Kaur Multani[1], Nitin Saini[1], Ravneet Kaur[2], Vandana Saini[3]

[1]Johnson & Johnson, Janssen Research & Development, Malvern, PA, United States;
[2]Aveley, Western Australia; [3]Washington, United States

INTRODUCTION

Drug abuse and mental health problems are common in the United States and worldwide. Most drugs of abuse exert their initial reinforcing effects by activating reward circuits in the brain and, although initial drug experimentation is largely a voluntary behavior, continued drug use impairs brain function by interfering with the capacity to exert self-control over drug-taking behaviors and rendering the brain more sensitive to stress and negative moods. Addiction changes the brain significantly, causing alterations in a person's personality and disturbing the normal functioning of the brain and leading to neuropsychiatric (NP) disorders. The shared neurobiological substrates (brain regions), overlapping genetic vulnerability, environmental stress, and developmental issues are some of the factors causing an individual to be susceptible to drug addiction, comorbid with NP illness such as depression, anxiety, and bipolar disorder. The mechanism of action of drugs of abuse is attributed toward their interaction with distinct neurotransmitter transporter, receptors signaling, epigenetic changes with upregulation or downregulation expression of genes implicated in neuroplasticity followed by interruption of the intracellular key proteins. This modify the information processing of neuronal circuits in the brain areas involved in reward, executive function, control, awareness, mood, and stress resulting in behavioral dysfunctions. This chapter is focused on the cellular and molecular mechanisms of drug of abuse, their involvement in NP disorders, and animal models and biomarkers of NP disorders.

DRUGS OF ABUSE

Addiction to drugs of abuse (psychostimulants) is a brain disease resulting in a loss of control over drug-taking or compulsive drug-seeking, despite noxious consequences (Nestler and Hyman, 2010). It is a serious social burden and has a destructive influence on the health and standard of living of an addicted person. Addiction to psychostimulants is characterized by at least three phases: (1) the continued use of a substance despite adverse consequences; (2) the diminishing effectiveness of the substance over time or the need for larger doses to achieve the same desired effect (tolerance); and (3) physical and psychological symptoms of distress, discomfort, or impairment on reduction or cessation of substance use (withdrawal) (DSM-IV, 1994). These three phases of addiction are associated with structural and functional changes in the brain that can be explained collectively as neuronal plasticity.

Psychostimulants such as cocaine, opioids, amphetamines, methamphetamine (Meth), methylphenidate, and other recreational drugs, such as 3,4-methylene dioxymethamphetamine (MDMA, "ecstasy"), cannabis, alcohol, morphine, and gamma-hydroxybutyric acid, influence the central nervous system (CNS) remarkably by acting on various molecular targets, resulting in neuroadaptive changes responsible for the dependence and addiction that they create. A psychostimulant is a substance that enhances arousal and euphoria acutely, and psychosis and addiction chronically.

At the cellular level, the drug of abuse upsets neuronal functions by imitating (opiate drugs—endogenous

opioids, nicotine—acetylcholine), stimulating (cocaine, amphetamines—dopamine [DA]; ecstasy—serotonin), or blocking (alcohol—glutamate [GLU]) the effects of the neurotransmitters.

Neuronal Basis of Drug Dependence

Essentially all drugs of abuse exert their acute reinforcing properties via the mesocorticolimbic DA pathway, encompassing DA neurons that originate in the ventral tegmental area (VTA) and project to the striatum and other limbic regions, including the prefrontal cortex (PFC), amygdala, and hippocampus. Specifically following brain circuits and structures mediate reward (nucleus accumbens [NAc] and ventral pallidum), memory and learning (amygdala and hippocampus), motivation/drive (orbitofrontal cortex [OFC] and subcallosal cortex), and control (PFC and anterior cingulate gyrus). These brain centers are innervated by dopaminergic and glutamatergic projections, mediating neuroadaptations in drug addiction. The reward pathway is acutely activated by all the drugs of abuse and mediates the reinforcing effects of these drugs.

Neurotoxicity of Psychostimulants

The known mechanism of psychostimulants is that these substances increase the extracellular level of several neurotransmitters including DA, serotonin (5-HT), and norepinephrine (NE) by competing with monoamine transporters (dopamine transporter [DAT]; serotonin transporter [SERT]; or norepinephrine transporter [NET] or on the vesicular monoamine transporter-1,2 [VMAT-1,VMAT-2], Multani et al., 2012) or their receptors, resulting in their rewarding effects and dependence.

AMPHETAMINE

Amphetamine, methamphetamine (Meth), methylenedioxy congeners, and MDMA, or ecstasy, are the best-known psychostimulants belonging to the class of "amphetamines" with disparate molecular sites of action in the CNS. Meth, due to its low cost and long duration of action, is the most abused drug (more than heroin and cocaine), used by more than 25 million people in the world; 5.2% of American adults have used Meth at least once, with populations in the Western, Southern, and Midwest states being the most affected in the United States (Rathinam et al., 2007). Meth abuse has reached epidemic proportions worldwide and is a major public concern as it is associated with deficits in attention, memory, and executive functions in humans. Norephedrine, hydroxyamphetamine, and

hydroxynorephedrine are active metabolites of amphetamine, and *N*-methyl-α-methyldopamine α-methyldopamine and 6-hydroxy-α-methyldopamine are active metabolites of ecstasy (or MDMA) and act as neurotoxicants in the brain. The NP complications might, in part, be related to drug-induced neurotoxic effects, demonstrated by damage to dopaminergic and serotonergic terminals, induced oxidative stress, activation of transcription factors, DNA damage, excitotoxicity, blood—brain barrier (BBB) breakdown, and neuronal apoptosis, as well as activation of astroglial and microglial cells in the brain.

The potential clinical neuropathological consequences of Meth abuse include agitation, anxiety, aggressive behaviors, paranoia, hypertension, hyperthermia in acute users, and deficits in attention, working memory, and executive functions in chronic psychostimulant abusers. In addition to its effect on the brain, ingestions of large doses of Meth cause life-threatening hyperthermia (above 41°C), cardiac arrhythmias, heart attacks, cerebrovascular hemorrhages, strokes, seizures, renal failure, and liver failure. Here we attempt to discuss some of the mechanisms that underlie Meth-induced neurodegenerative effects.

Oxidative Stress Due to High Dopamine Content in Methamphetamine-Induced Neurotoxicity

Meth toxic effects are due to its similar chemical structure to DA, by virtue of which Meth has high affinity for the DAT (Iversen, 2006), allowing its entry into dopaminergic neurons, replacing endogenous DA, and depleting vesicular stores of DA by release from synaptic vesicles into the cytoplasm and by reverse transport into the synaptic cleft, thereby promoting high DA levels in the brain. The neurotoxic effects due to DA release by Meth are due to the formation as well as redox cycling of DA quinones and superoxide radicals within nerve terminals. Meth intoxication induces increased DA levels and its metabolism by monoamine oxidase increases hydrogen peroxide production, which further has the capacity to interact with metal ions to form very toxic hydroxyl radicals. Various studies have shown that Meth neurotoxicity is further increased by shifting the balance between reactive oxygen species (ROS) production and the reduced capacity of the antioxidant enzyme system to scavenge ROS. The excessive generation of ROS due to Meth intoxication has the ability to damage the building blocks of the cell, such as lipids, proteins, and mitochondrial and nuclear DNA (Potashkin and Meredith, 2006). Meth reduces the levels of glutathione and antioxidant enzymes and increases lipid peroxidation and the formation of protein carbonyls. The use of

antioxidants selenium, melatonin, ascorbic acid, vitamin E, the free radical scavenger, edaravone, and 7-nitroindazole completely blocks the formation of 3-nitrotyrosine (3-NT) striatal DA, 5-HT depletion, and tyrosine hydroxylase (TH), providing evidence of NO- and peroxynitrite-based mechanisms underlying Meth-induced monoaminergic neurotoxicity.

Fos B Transcription Factor Is Responsible for the Synaptic Modification Following Meth Abuse

Gene expression changes in the mesocorticolimbic system of an abused brain modify synaptic transmissions that underlie some of the enduring behavioral characteristics of addiction. Activation and suppression of transcription factors and epigenetic mechanisms and induction of noncoding RNAs are some of the mechanisms through which drugs of abuse contribute their long-lasting changes in the brain. ΔFosB is one such transcription factor, a truncated splice variant of the FosB gene, and it shares homology with other Fos family members including c-Fos, FosB, Fra1, and Fra2, which all heterodimerize with Jun family proteins (c-Jun, Jun B, or Jun D) to form activator protein-1 (AP-1) transcription factors. Meth effects are in part mediated by the activation of AP-1 transcription factors including upregulation of c-Jun, c-Fos, Jun B, and Jun D expression. c-Fos heterozygote mice showed substantial neuropathology in terms of DA axonal degeneration, neuronal cell death, and decreased basal levels of cell adhesion receptors integrins following Meth administration, supporting a protective role of c-Fos as well as integrins against Meth damage (Gilcrease, 2007).

Meth Neurotoxicity Involving DNA Damage

Meth-induced oxidative stress leads to DNA damage by the formation of oxidative DNA products such as 7,8-dihydro-8-oxoguanine. The threat of this oxidative DNA damage involves mutations and transcriptional delay contributing to teratogenic effects because developmental events must occur within a specific time window and any delays may result in structural or functional abnormalities of the developing brain (Pastoriza-Gallego et al., 2007). Cell cycle arrest or apoptosis resulting from oxidative DNA damage may also play a role in developmental abnormalities, which account for developmental deficits observed in children born to Meth-abusing mothers. Global gene expressions hint that Meth administration causes changes in the expression of a number of genes that participate in DNA repair, including multifunctional DNA repair

enzyme (APEX), polymerase β (PolB), and ligase1 (LIG1).

Meth Excitotoxicity Is Mediated by Glutamate Release and Activation of Glutamate Receptors

GLU is the most abundant excitatory amino acid in the CNS and is capable of producing neuronal damage. MDMA administration in animals induces neuroadaptive changes in gene transcript expressions of glutamatergic N-methyl-D-aspartate (NMDA) and AMPA receptor subunits, metabotropic receptors, and transporters in cortex, caudate putamen, hippocampus, and hypothalamus brain regions, regulating the reward-related associative learning, cognition, memory, and neuroendocrine functions. In addition, NMDA GLU receptor antagonist MK-801 can attenuate Meth-induced dopaminergic toxicity (Battaglia et al., 2002). Memantine, an antagonist of NMDA-receptor and alpha-7 nACh receptors, prevents MDMA-induced serotonergic neurotoxicity in rats (Chipana et al., 2008). Knockout mice deficient in either neuronal nitric oxide synthase or inducible nitric oxide synthase (iNOS) showed protection against psychostimulant-induced damage to monoaminergic axons, indicating the GLU/NO pathway as a strong player in Meth neurotoxicity.

Meth Neurotoxicity Is the Result of Blood—Brain Barrier Dysfunction and Hyperthermia

Meth crosses the BBB easily. BBB disruption is investigated by using protein tracers, such as Evans Blue, iodine, and albumin; immunohistochemistry IgGI in the cortex, hippocampus, thalamus, hypothalamus, cerebellum, and amygdala revealed the effect of Meth neurotoxicity. The appearance of albumin immunoreactivity in the neuropil and leakage of serum albumin into the brain tissue had been observed as a consequence of Meth-induced BBB breakdown, further leading to neuronal damage, myelin degeneration, reactive astrocytosis in the parietal and occipital cortices, extensive degeneration of pyramidal cells, and activation of microglia in the amygdala and hippocampus of rats (Sharma et al., 2007). The neurotoxic effects of Meth-induced BBB damage has been linked to hyperthermia, as Meth causes dose-dependent temperature increases, which was generally correlative in different brain sites (NAcc, hippocampus), temporal muscle, and body core. The acute hyperthermia produced by MDMA in laboratory experimental animals is one of the few effects that can be directly compared to humans. Antioxidant H-290/51 pretreatment prevented hyperthermia, neuronal damage, myelin degradation, glial response, and

leakage of serum albumin into brain tissue, establishing the role of free radicals in BBB damage and oxidative stress in Meth neurotoxicity.

Mitochondrial and Endoplasmic Reticulum–Dependent Death Pathway in Meth-Induced Apoptosis

Mitochondria are common targets of ROS and reactive nitrogen species, and GLU-mediated excitotoxicity produced by Meth. Mitochondrial dysfunction due to depletion of ATP, increased energy use, and inhibition of succinate dehydrogenase (complex II of the electron transport chain, ETC) and cytochrome oxidase activity (Complex IV of the ETC) play an important role in mediating the prooxidant and neurotoxic effects of the substituted Meth neurotoxicity. The two major apoptosis-triggering signaling pathways, (1) the mitochondrial (intrinsic) and (2) the death receptor pathways (extrinsic), contribute to the neurotoxic effects of Meth.

In the intrinsic or mitochondrial pathway, apoptosis is triggered by intracellular stress signals, mainly associated with outer mitochondrial membrane permeabilization (MMP). MMP may occur through an increase in ROS production at the mitochondria, favoring permeabilization of the inner mitochondrial membrane, decrease of mitochondrial potential, and, hence, the complete loss of mitochondrial function. Most morphological changes of apoptotic cells are caused by cysteine proteases, termed cysteinyl aspartate–specific proteases or caspases, which are activated by intrinsic and extrinsic pathways and cleave a restricted group of target substrates after an aspartate residue. However, MMP may also be triggered by proapoptotic members of the Bcl-2 family, which facilitate the formation of specific release channels in the mitochondrial outer membrane.

Meth-induced upregulation of proapoptotic proteins BAX and BID, and decreases in antiapoptotic proteins Bcl-2 and Bcl-XL, are accompanied by the release of mitochondrial proteins, cytochrome c, and apoptosis inducing factor Smac/DIABLO into the cytosol, which participates in the execution of Meth-induced apoptosis, resulting in the downstream activation of caspases 9 and 3, and disruption of various cellular proteins (Jayanthi et al., 2004).

Not only do the mitochondria experience the havoc of Meth-induced oxidative stress, cellular organelles, such as the endoplasmic reticulum (ER) regulating synthesis, folding, and transport of proteins, and the main intracellular store for Ca^{2+} can contribute to neuronal cell death. Meth-induced activation of calpain (a calcium-responsive cytosolic protease) is preceded by the generation of ROS in the ER and imbalances in Ca^{2+}

homeostasis appear to conduce ER-dependent apoptosis. Calpain-mediated proteolysis of the cytoskeletal protein spectrin and the microtubule protein tau in the rat cortex, hippocampus, and striatum has been observed following Meth exposure. Calpain inhibitors attenuate Meth-induced spectrin and tau proteolysis neuronal death, strongly implicating ER stress and calpain activation in the mechanisms of Meth neuronal degeneration.

Neuroinflammatory Mechanism in Meth-Induced Neurotoxicity

The role of inflammation in the neurotoxicity of Meth is contributed to by an increase in the activation of microglia. The resident immune cells—microglia—within the CNS protect the brain against any injury and toxic damage (Raivich, 2005). Under normal physiological conditions, microglia typically exist in a resting state characterized by ramified morphology, continuously scanning the neuronal environment. However, on toxic insult, microglia are readily activated, transforming from a resting ramified state into an amoeboid morphology, which is necessary for immune response and neuron survival, but overactivation of microglia results in the secretion of a variety of reactive species including proinflammatory cytokines, prostaglandins, nitric oxide, and superoxide, all of which can damage neuronal tissue. It has been noted that the activation of microglia occurs prior to the damage of dopaminergic neurons and axons by Meth. The NMDA-receptor antagonist MK-801, dextromethorphan, and antiinflammatory drug ketoprofen inhibit microglial activation. Microglial activation can be used as a selective biomarker for neuronal axonal damage following Meth exposure. Meth-induced increase in the levels of tumor necrosis factor-α (TNF-α), IL-1β, and microglial activation describe the neuroinflammatory mechanism of Meth neurotoxicity.

COCAINE

Cocaine is a crystalline tropane alkaloid obtained from the leaves of the coca plant. Cocaine comprises nearly 1% of the coca leaf when the plant is grown in high altitudes, and people living in the Andes Mountains have chewed these leaves for at least 1200 years. Cocaine metabolism gives rise to active compounds that cross the BBB, namely benzoylecgonine, norcocaine, and cocaethylene. Cocaine and norcocaine are cationic amphiphiles, which penetrate into acidic intracellular organelles such as mitochondria, thereby leading to the neurotoxic effects of cocaine. Repeated cocaine

administration in animals reduces DA, which provides an explanation for depression, irritability, anxiety, and suicide in cocaine-addicted individuals.

Epigenetic Regulation (ΔFos-B and Cyclic Adenosine Monophosphate Response Element Binding Protein) in Cocaine-Induced Neuropsychiatric Disorders

ΔFos and cyclic adenosine monophosphate (cAMP) response element binding protein (CREB) are the two main transcription factors that induce gene expression following cocaine exposure. Transcription factors can recruit chromatin-modifying enzymes executing long-lasting changes in neuronal circuits responsible for NP disorders. Epigenetic regulation of transcription is a coordinated interplay of mechanisms involving chromatin-modifying enzymes, nucleosome remodeling complexes, histone variant incorporation (transcriptionally active state), and DNA methylation (transcriptional repression), which translates incoming signaling events by altering chromatin structure in a specific and precise manner that in turn regulates the genes carrying out neuroadaptive changes following cocaine abuse. Cocaine promotes alterations in histone acetylation, phosphorylation, and methylation levels, as well as DNA methylation levels in the NAc mediating drug–induced behaviors. Cocaine increases H4 acetylation at the proximal promoters of the immediate early genes c-Fos, Fos-B (in NAc), and of cdk5 and brain-derived neurotrophic factor (BDNF) genes (in PFC) required for the development of cocaine-induced behaviors (Renthal et al., 2009). Cocaine-induced ΔFosB accumulation acts as a molecular "switch" in the transition from drug abuse to addiction due to the longer persistence of activated ΔFos-B.

Acute or chronic cocaine administration leads to an increase in the phosphorylation of CREB within the PFC, NAc, dorsal striatum, and amygdala. Once phosphorylated, CREB dimers, bound to specific CRE (cAMP response element) sites on target genes such as BDNF, corticotrophin releasing factor (CRF), and dynorphin produce behavioral, learning, and memory effects.

Cocaine-Induced Changes in Synaptic Plasticity Is Mediated Through Brain-Derived Neurotrophic Factor

BDNF is the most prevalent neurotropin in the brain and is involved in the regulation of activity-dependent synaptic plasticity, survival, and differentiation of neurons. BDNF is synthetized as pro-BDNF (32 kDa) and secreted as a mixture of pro-BDNF and mature BDNF (14 kDa); it plays a vital role in learning and memory cognitive functions (Bekinschtein et al., 2008).

BDNF is an endogenous ligand for tropomyosin-receptor kinase (Trk) receptors. BDNF binding at the cell surface initiates autophosphorylation of the tropomyosin receptor kinase B (TrkB) receptor through one of at least three signaling cascades: (1) the mitogen-activated protein (MAP) kinase pathway, which has been implicated in neuronal differentiation and neurite outgrowth; (2) the PI3-kinase pathway, which enables cell survival; and (3) The PLCγ pathway, involved in synaptic plasticity and transmission. These cascades converge on nuclear transcription factors such as CREB and ELK to regulate gene expression and induce neuroadaptations. Cocaine-induced BDNF exonIV expression within brain regions is associated with reward circuitry (Boulle et al., 2012). The promoter region of exonIV contains specific binding sites for the transcriptional regulators cAMP response element-binding (CREB) and methyl CpG binding protein 2 (MeCP2), both of which have established associations with regulation of gene expression at the epigenetic level. Cocaine increases BDNF messenger RNA (mRNA) in the PFC, and NAc is associated with increases in cocaine craving, suggesting a causal relationship between BDNF and drug-mediated responses. Increased BDNF expression is associated with enhanced cocaine cravings, and impaired BDNF signaling is associated with a variety of neurological and psychiatric conditions, including depression, schizophrenia (SZ), obsessive–compulsive disorder, dementia, anorexia, and epilepsy.

OPIOIDS

Opium has been known for centuries for its medicinal and recreational use. The active ingredient of opium is morphine, which is used for the treatment of acute and chronic pain. In the market, opioids are known by various names such as codeine, morphine, and tebanine (natural opioids); methadone (synthetic opioid); and heroin, oxymorphone, and idrossimorfon (semisynthetic opioids). The opioid system carries out the nociceptive (pain) processing, and modulation of gastrointestinal, endocrine, and cognitive functions. The opioid system comprises various receptors (OP) and they are named based on the targets of opioids: mu, KOP (kappa), DOP (delta), and NOP for the nociceptin orphanin FQ peptide receptor. The beneficial and the addictive effects of opioid use are evident from their interaction with endogenous opioids: endorphins, enkephalins, dynorphins, and endomorphins. The interaction of exogenous opioid with endogenous opioid and their receptors (mostly MOP) is responsible

for the aberrant synaptic plasticity underlying addiction. μ-Receptors mediate analgesia, euphoria, physical dependence; K-receptors mediate sedation analgesia and mitosis; and δ-receptors mediate analgesia and release of growth hormones.

Opioid Actions Are Orchestrated Through Inhibitory G Protein (Gi/Go)

All of the opioid receptors are G-protein-coupled receptors (GPCRs) characterized by seven transmembrane domains (Koneru et al., 2009). Opioids convey their message to their effector protein via inhibitory G-protein (Gi/Go). Opiates disturb G-protein concentration and expression in discrete brain regions, resulting in adaptive changes in multiple intracellular signaling, accounting for opiate tolerance. Activation of opioid receptors with morphine mainly leads to: (1) closing of voltage sensitive calcium channels; (2) stimulation of potassium efflux leading to hyperpolarization; and (3) reduced cAMP production via inhibition of adenylyl cyclase, followed by reduced neuronal cell excitability and nerve impulses along with inhibition of neurotransmitters release.

Intracellular Targets of Opioid Activation: cAMP, Ca^{2+}, MAPK, CREB, AP-1 Transcription Factors

The slowing down of neurological functions after opioids is due to inhibition of Ca^{2+} current, increase in potassium conductance, and inhibition of formation of cAMP. In addition to this, opioids also display excitatory activity through increased mobilization of Ca^{2+} from its intracellular stores as a result of stimulation of inositol lipid hydrolysis and production of IP3 and diacylglycerol (DAG) (Cunha-Oliveira et al., 2008). Opioids activate the MAPK/extracellular signal-regulated kinase (ERK) pathway integrating signals from second messenger systems, such as Ca^{2+} and DAG, and control activity-dependent regulation of neuronal functions, neuronal differentiation, and survival. MAPK/ERK phosphorylation is PKC/CAMK-II dependent (acute opioid exposure) and protein kinase A (PKA) dependent (chronic opioid exposure), and it has the ability to activate downstream transcription factors, such as Ca^{2+}/CREB, which regulate numerous genes such as c-Fos, CRF, TH, and BDNF, and enkephalins and dynorphin. The 32-kDa dopamine- and adenosine 3′,5′-monophosphate-regulated phosphoprotein plays an extensive role in the pathogenesis of opioid addiction by acting as a mediator of the activity of the ERK signaling cascades, and it represents a thrilling

hub for drug-induced changes in long-term synaptic plasticity.

Neurotoxic Effects of Opioids Linked with Oxidative Stress, Mitochondrial Dysfunction, and Apoptosis

Opioids decrease enzymatic cellular activity of superoxide dismutase (SOD), catalase, and glutathione peroxidase (GPX) and reduce glutathione levels. Lipid peroxidation and oxidative DNA and protein damage are the consequences of increased oxidative stress in opioid abuse and constitute a fundamental component of neurotoxicity. Neuronal dysfunction due to apoptotic cell death is a strong feature of opioid neurotoxicity observed in mouse cortex and hippocampus, rat spinal cord in fetal human neurons, and rat cortical neurons. Opioids cause release of cytochrome c, activate caspase, decrease the Bcl-2/Bax ratio, and upregulate proapoptotic proteins Fas, FasL, and Bad (Tramullas et al., 2008), causing loss of mitochondrial membrane potential, and thus implicating mitochondria as a substantial component of opiate-related neurotoxic effects.

Cognitive Deficits During Opioid Addiction Are Due to Inhibition of Neurogenesis

Decreased hippocampal neurogenesis due to opioids affects the ability of the brain to build new neurons. In adult mammalian brain there are two main neurogenic regions, the subventricular zone (SVZ), and the subgranular zone (SGZ) of the dentate gyrus in the hippocampus. Morphine and heroin decrease SGZ and SVZ neurogenesis (Eisch and Harburg, 2006), resulting in long-lasting effects on learning, memory, and cognition.

CANNABINOIDS/MARIJUANA

The derivative (marijuana) of the *Cannabis sativa* plant has been known for recreational and therapeutic uses for centuries; 3.3% of young adults (19–28 years of age) use marijuana on a daily basis and 54% of people aged between 26 and 34 have used it at least once, making marijuana the most commonly used drug of abuse in the United States. The Δ9-tetrahydrocannabinol metabolite of marijuana is the major psychoactive compound, causing its euphoric effects in the brain by acting on several neurotransmitters, including DA, γ-aminobutyric acid (GABA), GLU, serotonin, and noradrenaline. Cannabinoids, by acting collectively as a retrograde messenger, target both excitatory as well as inhibitory synapses (Alger, 2012). The biological action of

marijuana and its endogenous ligands (endocannabinoids [eCBs]: made by the human body) occurs through cannabinoid receptors (CBRs: CB1R and CB2R), so-called reward pathways implicated in the neuropathophysiology of addiction. In addition to the euphoric effects of marijuana, increased appetite, anxiety, paranoia, and reversible cognitive impairment with deficits in memory and learning are also NP features of cannabis toxicity.

Cannabinoid Signaling Is Mediated by Cannabinoid Receptors and Endocannabinoids

Three major components of cannabinoid (CB) signaling consist of (1) Gi/Go protein-coupled receptors (GPCRs), mainly cannabinoid type 1 and type 2 receptors (CB1R and CB2R); (2) the endogenous cannabinoid ligands (eCBs): anandamide (AEA) and 2-arachidonoylglycerol (2-AG); and (3) synthetic, degradative enzymes and transporters modulating eCB expression and their action at receptors. The retrograde mechanism by which eCBs regulate synaptic function involves the backward flow of eCB postsynaptically to the presynaptic CB1 receptors and inhibits neurotransmitter release.

Endogenous Cannabinoid Ligand Interaction With Cannabinoid Type 1 Receptor Regulates Expression of Genes Involved in Long-Term Depression

CB1R is highly expressed in the cortex, substantia nigra pars reticulata, globus pallidus, cerebellum, hippocampus, and brainstem, thereby modulating a wide range of neural functions, such as motor activity, learning, and memory. CB1R, located presynaptically on GABA and GLU neurons, decreases their release by inhibition of presynaptic Ca^{2+} influx through voltage-gated Ca^{2+} channels (VGCCs). CB1R activation is coupled with inhibition of adenylyl cyclase, downregulation of the cAMP/PKA pathway, and activation of the MAP kinase/ERK pathway, thereby regulating expression of genes involved in the reinforcement behavior of marijuana use. eCBs are the best characterized retrograde messenger for carrying out neurological actions of endocannabinoids. Formation of 2-AG occurs through the influx of Ca^{2+} via VGCCs and by activating the enzyme phospholipase Cb (PLCb), which triggers short- and long-term plasticity (Hashimotodani et al., 2007). eCBs interaction with CB1R is capable of inducing presynaptic forms of long-term depression (eCB-LTD) at both excitatory and inhibitory synapses. Marijuana alters eCB levels, resulting in the disruption of memory and learning associated with marijuana use.

ALCOHOL

Interaction between genetic, environmental, and neurobiological factors can produce great risks for developing chronic alcoholism. Initial recreational use of alcohol can later on become alcohol dependence, featuring craving a strong desire to drink, impaired control, and withdrawal symptoms such as nausea, sweating, and anxiety. Despite the serious health and social concerns, people consume alcohol because of their vulnerability to relapse. The principal psychoactive ingredient of alcoholic beverages is ethanol, which is responsible for a wide range of clinical symptoms associated with alcohol consumption.

Modulation of γ-Aminobutyric Acid Type A and N-Methyl-D-aspartate Receptors by Ethanol Contributes to Anxiety, Arousal, and Dysphoria-Like Symptoms

The neurotransmitter system including DA, serotonin, GABA, glutamic acid, adenosine, and neuropeptides are neurobiological substrates underlying short- and long-term adaptations to ethanol dependence. Specifically, ethanol is a positive allosteric modulator of GABA receptors (i.e., reinforces inhibitory neurotransmission) and negative allosteric modulator of NMDA glutamatergic receptors (i.e., inhibition of excitatory neurotransmission). The acute sedative effects of ethanol are therefore due to the potentiation of GABAergic inhibition with long-term adaptive changes in the NMDA glutamatergic receptors, promoting alcohol dependence. Upregulation of the glutamatergic system and a downregulation of the GABAergic system due to chronic exposure to ethanol lead to compensatory changes in the expression of ethanol-responsive ion channels and receptors. This explains the consequences such as arousal, anxiety, and sleeplessness, along with the persistence of negative craving during alcohol withdrawal. In alcoholics, there is considerable interaction of opioid systems, as ethanol releases endorphins, endogenous opioid peptides, in the brain, thereby indirectly activating the dopaminergic reinforcement/reward system. Furthermore, ethanol disrupts the cholinergic system by activation of nicotinic acetylcholine receptors on dopaminergic neurons, leading to excitotoxic damage of cholinergic functions and to psychiatric disorders.

Astrocytes Are the Main Site of Ethanol-Induced Oxidative Stress and Neurotoxicity

Astrocytes represent the major cellular site of ethanol metabolism within the brain, and protect neurons from

ethanol-induced oxidative stress. In the nervous tissue, ethanol can be metabolized by catalase, cytochrome P450, and alcohol dehydrogenase, and it upregulates antioxidant enzymatic activities of SOD, catalase, GPX, and heat shock proteins such as HSP70, protecting astrocytes from oxidative damage (Henderson, 2006). Ethanol in astrocytes with other cell types impairs cellular redox status, cell growth, and differentiation, interfering with the stimulatory effect of trophic factors or altering the expression of cytoskeletal proteins consequently perturbing the neuron–glia interactions and generating developmental defects in the brain (Rathinam et al., 2007; González et al., 2007). ROS generation by ethanol inside mitochondria impairs oxidative phosphorylation, ion channel modification, lipid peroxidation, and causes DNA damage, thus activating cellular death pathways responsible for alcohol-related NP disorders. Ethanol's ability to form inflammatory molecules in astrocytes occurs through nuclear factor kappa B (NF-κB) activation involved in the upregulation of cyclooxygenase 2 (COX-2) and iNOS expression.

Generation of Proinflammatory Molecules Activates Mitogen-Activated Protein Kinase Signaling by Ethanol

Glial cell activation by ethanol generates inflammatory molecules such as iNOS, COX-2, and IL-1β, which leads to signaling of MAP kinases, including ERK1/2, p-38, and JNK, causing caspase-3 activation and apoptosis. Imbalance in calcium homeostasis as a result of ethanol exposure induces nuclear fragmentation, DNA laddering, cell contraction, membrane blebbing, and chromatin condensation of astrocytes.

Abused Substances and Neuropsychiatric Disorders

Long-term exposure to drugs of abuse and being dependent on them involve changes in cognitive and executive functioning (high order skills, selective attention, inhibition, and flexibility). As discussed previously, the rewarding and reinforcing effects of these drugs are due to their interaction with the VTA, striatum, PFC (motivation and cognitive control), amygdala, and hippocampus (memory). These neuronal circuits show changes in the gene and protein levels of synaptic architecture in various NP diseases such as SZ or mood disorders (bipolar disorder), anxiety, and depression, explaining the comorbidity of mental illness as well as substance use disorder (SUD) (Fig. 51.1). The lifetime prevalence rate of any bipolar disorder with SUD is 47.3%, bipolar I disorder and any SUD, 60.3%, and major depression and alcohol dependence comorbidity, 40.3%.

NP disorders such as SZ, major depression disorder (MDD), bipolar disorder (BPD), and obsessive–compulsive disorder account for one of the top category of mental ailments worldwide. According to the WHO report, by the year 2020, 4 out of 10 diseases will be NP-related diseases, with depression ranking first for both sexes and BPD ranking seventh (WHO, 2009). The critical current challenge in NP research is the development of novel interventions due to the complex pathophysiology of the NP diseases, which arise from the high level of etiologic heterogeneity and involvement of several multifactorial environmental and genetic factors. The following section of the chapter gives a brief overview of the clinical symptoms and underlying cellular mechanisms of the three main NP diseases: SZ, MDD, and bipolar disorder (BPD).

SCHIZOPHRENIA

The unknown etiology of SZ makes it a very complex psychiatric disorder, affecting 0.5%–1% of the world's population. The clinical symptoms of SZ are presented in three ways (Lewis and Sweet, 2009). Positive or psychotic symptoms include delusions, hallucinations, thought disorder, and abnormal psychomotor activity. Negative symptoms include social withdrawal, impairments in initiative and motivation, a reduced capacity to recognize and express emotional states, and poverty in the amount or content of speech. Cognitive symptoms include disturbances in selective attention, working memory, executive control, episodic memory, language comprehension, and social emotional processing. Schizophrenic individuals also experience severe depression and suicidal thoughts, abuse drugs excessively, and carry a high risk of cardiovascular disease and diabetes.

The most prominent features of SZ are as follows:

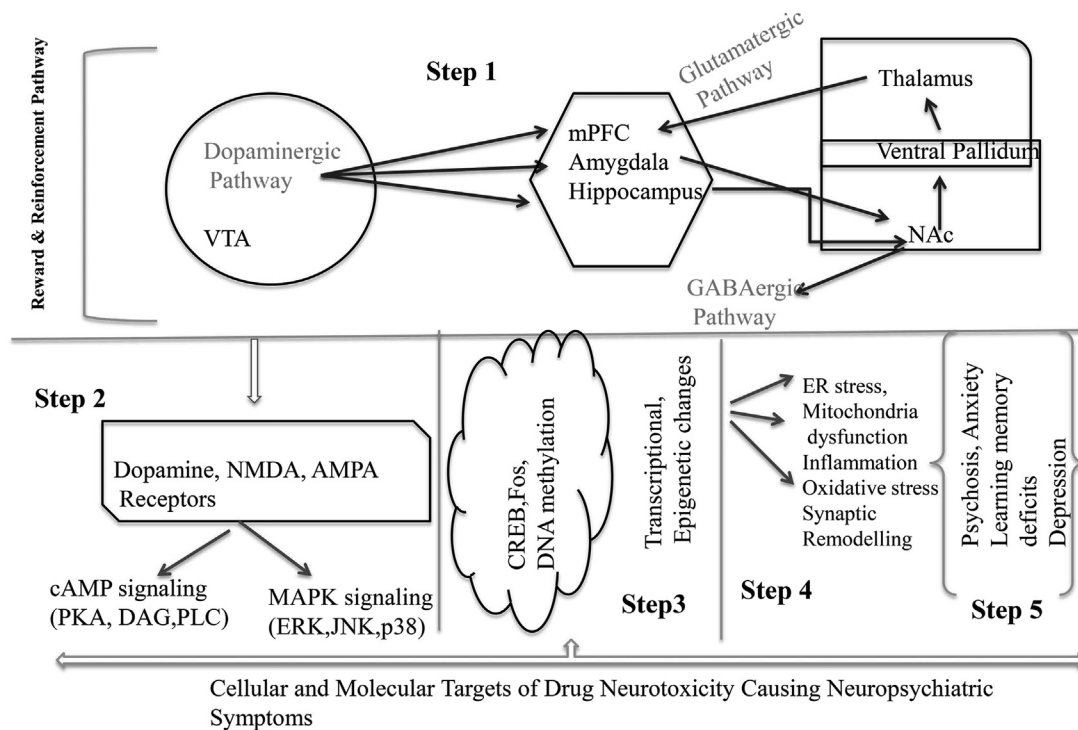
- **SZ has a strong genetic component**: Adoption, family, and twin studies strongly document heritability of SZ. The risk of developing SZ in first-degree relatives of a proband is approximately 10%, as opposed to 3% in second-degree relatives. Genome-wide linkage studies have identified at least 15 susceptible genetic loci with weak to moderate linkages to SZ including DISC1, Neuregulin 1, Dysbindin, D-amino acid oxidase activator, and catechol-o-methyl transferase.
- **Environmental and nongenetic factors are linked to SZ**: Season of birth, geographical variation, substance abuse, uterine environment, prenatal stress, prenatal exposure to environmental toxicants, family size, and availability of adequate maternal diet are contributing factors in the development of SZ.


FIGURE 51.1   **Relationship between drug of abuse and neuropsychiatric disorders. Step 1**: The main brain circuits and structures implicated in the effects of the drugs are the ones that mediate reward (nucleus accumbens [NAc] and ventral pallidum), memory and learning (amygdala and hippocampus), and control (prefrontal cortex). These brain centers are innervated by dopaminergic and glutamatergic projections, mediating neuroadaptations in drug addiction. The reward pathway is acutely activated by all the drugs of abuse and mediates the reinforcing effects of these drugs. Arrows indicate innervations from one brain region to another.**Step 2:** Neurotoxicity by drugs of abuse upsets neuronal functions by imitating, stimulating, or blocking monoamine transporters (DAT; SERT; or NET) or their receptors, resulting in the activation of MAPK signaling and the cAMP pathway. **Step 3:** Activation of MAPK and cAMP pathway transduces signals to nuclear protein (CREB) and immediate early genes (fos) in the nucleus for the long-lasting changes through transcriptional and epigenetic mechanisms. **Step 4:** Protein and gene expression changes lead to structural and functional changes in the mitochondria and endoplasmic reticulum causing oxidative stress, DNA damage, apoptosis, and synaptic remodeling by altering neurotrophic levels. **Step 5:** The combined effect of step 1 through step 4 is the manifestations of neuropsychiatric symptoms such as anxiety, mood disorder, schizophrenia, and learning memory deficits.

- **Neuroanatomical alteration in SZ**: Schizophrenic PFC and hippocampus undergo substantial neuroanatomical changes. The brain and gray matter volume is reduced, whereas third and fourth ventricular volume is increased.

- **Neuronal circuits undergo functional changes in SZ**: Changes in neural substrates such as AMPA and NMDA receptors and their affiliated signaling, trafficking, scaffolding, and anchoring proteins impact learning, memory, and other cognitive functions that underlie neuroplasticity. Disruption of both NMDA and AMPA receptor subtypes, with change in binding sites as well as altered stoichiometry of subunit composition contribute to psychopathology in SZ. The expression of NMDA-associated protein postsynaptic density (PSD95, 95 kDa), SAP102 (synapse associated protein (102 kDa), neurofilament-L in the thalamus, occipital cortex, PFC, and hippocampus are found to be altered in schizophrenic postmortem brains. These NMDA-associated proteins facilitate the interface of

NMDA receptors and intracellular signaling processes. AMPA receptor−related molecules such as SAP97 (synapse associated protein, 97 kDa), and NSF (*N*-ethylmaleimide-sensitive fusion protein) expression is changed in SZ. NSF and SAP97 are components of the intracellular machinery that mobilize AMPA receptors to the plasma membrane from constitutive and newly synthesized pools of receptors, respectively. Disordered signaling due to alteration in the NMDA and AMPA receptor associated molecules is one of the potential causes of impaired neuroplasticity in SZ. The reduced transcription of synaptic proteins suggests that SZ is a disorder of neuronal miswiring.

- **Disrupted synaptic transmission in SZ**: Magnetic resonance spectroscopy of schizophrenics showed glutamatergic abnormalities due to decreased levels of the amino acid N-acetyl aspartic acid in the PFC, temporal cortex, thalamus, basal ganglia, and cerebellum. Schizophrenic brain also has reduced expression of DA receptor subtypes or dopaminergic

synaptic function, reduced GABA synthesis, and GLU receptor hypofunction.

- **Cytokines in SZ**: Dysregulation in the cellular and humoral immune responses by shifting a type 2 immune response (Th2) to a type 1 (Th1) response is seen in SZ. The levels of interferon-γ gene, Th1 proinflammatory cytokine, IL-1β, TNF-α, IL-6, IL-2, IL-10, and IL-4, critical antiinflammatory cytokines, are elevated in the SZ disorder.

- **MAP kinase signaling proteins are altered in SZ:** ERK, JNK, and p38 are the three MAP kinase groups that modify protein and gene expression in neurons following exposure to abused drugs. Because of the cardinal role of MAP kinase in mediating synaptic plasticity, learning, and memory, alterations in the expression and/or function of various intermediates of MAP kinase cascades are involved in the neuropathophysiological events such as apoptosis in SZ. The altered protein expression of ERK, JNK, and p38 MAP kinase and their downstream gene target, such as Elk-1, CREB, ATF-2, c-Jun, and c-Fos, increases in the cerebellum and thalamus in SZ (Todorova et al., 2003).

- **Mitochondrial functional and structural changes account for multifactorial inheritability in SZ:** Morphological deformation and a reduction in the number and density of mitochondria, followed by changes in the protein as well as mRNA levels of the mitochondrial oxidative phosphorylation system (OX-PHOS), cytochrome *c* oxidase (complex IV), and NADH ubiquinone dehydrogenase (complex I), indicate that mitochondrial dysfunction constitutes an important component of impaired brain energy metabolism, developmental aberrations, abnormal neurotransmission, and neuronal connectivity, thus accounting for the multifactorial inheritability in SZ.

Bipolar Disorder/Mood Disorder

Bipolar disorder (BD) is a mood disorder characterized by recurrent episodes of mania and depression. The major depressive disorder (unipolar disorder), depression, and bipolar disorder are the most commonly diagnosed mood disorders. Elated mood and hyperactivity along with diminished sleep are the features of the manic episode, whereas the depressive episode is characterized by depressed mood, loss of interest, appetite loss, sleep disturbance, psychomotor retardation, feelings of worthlessness, and suicidal ideation. It is estimated that 12%–17% of individuals suffer from mood disorders at some point in their lifetime, with treatment costing the United States alone 100 billion dollars each year. The clinical symptoms of BD

suggest that it is a neuroprogressive disorder with changes in tissue damage, and neuronal structure and functions that form the neural substrate for the regulation of mood.

The mechanisms of BD include the following:

- **Genetic heritability is the major risk factor for BD**: The most established finding is the familial nature of mood disorders, evidenced by the role of genetic factors in twin studies. Genetic factors are liable for 37%–75% of major depressive disorder and 60%–85% for bipolar disorder (Smoller and Finn, 2003). In twin studies, monozygotic twins have two- to threefold higher concordance for major depressive disorder than dizygotic twins and four- to eightfold higher concordance in BD. Genetic studies have implicated chromosomes 18, 11, and X.

- **Structural and functional CNS changes in BD**: Structural abnormalities in BD are reflective of ventricular enlargement and progressive loss of gray matter thickness. Voxel-based morphometry studies of gray matter in BD found gray matter reduction in left rostral anterior cingulate cortex (ACC) and right frontoinsular cortex, brain areas linked to executive control and emotional processing (Bora et al., 2010). Genetic studies indicate that individuals with BD and Val66Met BDNF genotype had significantly lower anterior cingulate volumes than those with a homozygous Val/Val genotype.

- **High levels of cytokines are associated with BD**: Inflammation in BD is characterized by increased plasma levels of proinflammatory cytokines, such as interleukin-IL-6 and tumor necrosis factor-α; increased acute phase protein levels, including haptoglobin, CRP, and complement factors, C3C or C4 concentrations; and increased IL-1β, NF-κB, and IL-1RA protein and mRNA levels in postmortem frontal cortex of bipolar patients. High levels of cytokines are associated with depression, mania, and cognitive decline in BD (Goldstein et al., 2009). Gene association studies showed -511C/T polymorphism of IL-1β with gray matter deficits in bipolar patients.

- **Oxidative stress and mitochondrial dysfunction in BD:** Oxidative stress and mitochondrial dysfunction is the fundamental abnormality in BD. High rates of comorbidity of BD with mitochondrial diseases, impaired brain energy metabolism, the effects of mood stabilizers on mitochondria, increased mitochondrial DNA deletion, mitochondrial DNA mutations/polymorphisms, and downregulation of mitochondrial gene expression in BD suggest that mitochondrial impairment is a critical component of the pathophysiology of BD. Reduced activity of mitochondrial ETC complex I, and altered expression

of subunits from mitochondrial ETC complex I, also contribute to the mitochondrial dysfunction in BD. Genome-wide linkage scans suggested linkage of chromosome 19p13 in BD, where the majority of complex I subunits genes are located. Pharmacological use of glutathione precursor and the free radical scavenger N-acetyl cysteine reduces depressive symptoms and improves functioning and quality of life in BD.

- **cAMP second messenger system is crucial in BD:** The cAMP actions are carried out through serotonergic (5-HT) and adrenergic G-protein-coupled receptors (GPCR) and are thought to play a central role in mood regulation. These receptors bind to stimulatory Gs and inhibitory Gi/Go proteins, activating adenylyl cyclase (AC), the enzyme that catalyzes the formation of cAMP from ATP. cAMP regulates many cellular functions of CNS, including metabolism and gene transcription, through the activation of PKA, which further processes the upstream information by phosphorylating the cellular substrates, such as cAMP regulatory element binding protein (CREB), leading to transcription of potentially relevant CRE-containing genes such as BDNF that regulate cell proliferation, development, plasticity, and survival of neurons. Various tricyclic antidepressants increase the expression of CRE-containing genes, such as CREB and BDNF, suggesting that the cAMP system is downregulated in depressed subjects and pharmacological upregulation of cAMP signaling produces protective effects. Mood stabilizers such as lithium elevate basal AC activity, and VPA decreases the cAMP response to stimuli.

Anxiety Disorders

The development of a mild form of anxiety and fear are crucial components of adaptive changes for the overall behavioral and autonomic "stress" response to dangerous situations that threaten to perturb homeostasis. Anxiety disorders have a lifetime prevalence of 15%–20%. The most common is generalized anxiety disorder, with lifetime prevalence close to 5%; social anxiety prevalence ranges from 2% to 14%, panic disorder ranges from 2% to 4%; and posttraumatic stress disorder has a prevalence of 8%. Any peripheral adverse stimuli activating sympathetic activity has the potential to activate brain areas, such as the locus coeruleus, amygdala, hypothalamus, and hippocampus, which are of prime importance in the formation of anxiety and fear. Various biochemical and cellular studies have identified that centrally acting neurotransmitters (DA, 5-HT, GABA, NE), corticotrophin

releasing hormone, neuropeptide Y, cholecystokin, and substance P and their relevant neural circuits are implicated in the development of anxiety. A substantial number of transgenic studies investigating anxiety-like behavior have identified the key intracellular signaling enzymes, including calcium/calmodulin-dependent protein kinase-II (CAMK-II) α, adenylate cyclase type VIII, and PKCε and γ. The knockout of PKCε and γ provides resistance to anxiety and inhibition of PKC has anxiolytic effects in humans. Inositol, the building block of the PI signaling pathway, has been examined as a potential anxiolytic in the clinical trials of pain and depression.

ANIMAL MODELS IN NEUROPSYCHIATRY

Animal models have increased our understanding of psychiatric diseases tremendously. Animal models are designed based on behavior and psychopharmacology theories, mimicking a human condition, and the substantive contribution of animal models to fundamental aspects of human psychopathology is quite convincing. Two major goals of psychiatry for which animal models are designed are: (1) to know the underlying mechanisms of psychiatric diseases, and (2) to accurately determine the behavioral and pharmacological treatments of psychiatric diseases. To achieve these goals, the following approaches are applied:

1. Genetics: Selective breeding, random mutation and screening, transgenic animals (for example, knockouts, knockins, and overexpression), viral-mediated gene delivery to brain.
2. Pharmacology: Administration of neurotransmitter agonist or antagonist.
3. Environmental: Chronic social stress (adult or during development) and chronic physical stress.
4. Electrical stimulation and lesions: Brain stimulation, including optogenetic approaches and anatomical lesions.

The validity of psychiatric animal models in mimicking human symptoms is still being investigated. There are four measures that describe validity: construct validity, face validity, content validity, and predictive validity.

1. Construct validity is "the degree to which a score can be interpreted as representing the intended underlying construct" (Cook and Beckman, 2006). Construct validity in animal models incorporates a conceptual similarity to the cause of human disease.
2. Face validity is "the extent to which an animal model recapitulates important features of a human disease" (Nestler and Hyman, 2010).

3. Content validity "evaluates whether all dimensions of the target are measured by the given test or recapitulated by the given model" (Nestler and Hyman, 2010).
4. Predictive validity is "measure of agreement between results obtained by a new instrument or model and the results obtained from previously accredited tools or models (Gold Standards)." The predictive validity is often quantified by the use of statistical correlation coefficients between two sets of measurements for the same population. Predictive validity in animal models "incorporates specificity of responses to treatments that are effective in human disease" (Nestler and Hyman, 2010).

Besides validity, the reliability, efficacy, and practicality of animal models should also be evaluated and considered for a particular animal model to support clinically productive hypotheses.

Animal Models of Depression

"Learned helplessness" or "behavioral despair" have been used to demonstrate how animals stop struggling in an inescapable situation, and thus model depression. The most employed behavioral tests in labs to study depression are the "forced swim test" (FST) and "tail suspension test" (TST).

1. **FST:** Based on the fact that animals subjected to an inescapable situation of being located in water for an unlimited time, will eventually stop swimming (Porsolt et al., 1977).
2. **TST:** Based on the fact that mice under inescapable stress of being suspended become immobile (Steru et al., 1985). FST and TST are used for primary antidepressant screening and they mimic acute stress only.
3. **The foot shock escape:** This is another test that has been proposed as a model of learned hopelessness in mice in which an animal can escape an environmental stressor (Fukui et al., 2007). This test has a limitation, as it displays symptomatic overlap between depression and anxiety manifestations.
4. **Chronic social defeat test (CSDF):** CSDF is another advanced behavioral model of learned helplessness in which long experience of defeat in daily social confrontations can lead to patterns of passive submissive behavior (Venzala et al., 2012). In one form of this paradigm, a mouse is repeatedly subjected to a more dominant mouse, creating chronic stress. As opposed to FST and TST, which mimic acute stress only, CSDF overcomes this problem, mimicking chronic stress, as the majority of stress stimuli in humans leading to psychopathology are of a social

nature, and the CSDF model has an advantage over other models in its resemblance to human stress-related psychopathologies.
5. **Olfactory bulbectomy:** Bilateral ablation of olfactory lobes is the most recommended fit model of depression. Olfactory ablation disrupts the limbic−hypothalamic axis with neuroendocrine changes compatible with depression in humans. Bilateral ablation of the olfactory lobes of rats results in behavioral changes, gender recognition, and social dominance among male rodents. Validity instruments have shown a significant overlap between these symptoms in rats and patients with major depression.

Animal Models of Anxiety

Anxiety and fear emotions are essential components of endurance in a living species. Adverse life events shape anxiety-related pathologies, such as generalized anxiety, panic disorders, or social phobia, which reflect extremes in trait anxiety. Animal models of anxiety are required to expose the neuroendocrine, neurochemical, and neurogenetic mechanisms of complex behavioral phenotypes for potential targets for psychotherapy. The following animal models are the best studied for anxiety traits:

1. **Fear-potentiated startle (FPS):** The FPS test includes two steps in which an intrinsically aversive unconditioned stimulus United States (foot shock) is paired with a conditioned stimulus (CS, e.g., light) initially. In the next step, the CS is subsequently used to elicit a startle reflex. Fear-potentiated startle is defined as greater startle amplitude in the presence of the CS (vs. absence). The acoustic startle response (ASR) is enhanced in certain anxiety disorders (Bijlsma et al., 2010).
2. **Contextual fear conditioning:** The animal is placed in a novel environment where an aversive stimulus is provided. When the animal is returned to the environment again, it may demonstrate a fear response if it remembers the environment. Freezing (a period of watchful immobility except for respiration) is measured as an indicator of fear.
3. **Cued fear conditioning:** Cued fear conditioning is theoretically similar to contextual conditioning, with an exception that a cue is added as a CS to exclude the effect of context itself. This is because the context (environment) is not as accurate as a shock to elicit the fear responses. Moreover, to separate contextual effects from conditioning induced by the cue, some investigators preexpose the animals to the context without the cue. On a second exposure to the context, the cue is administered to evaluate the amount of fear.

4. **Open-field test:** Unconditioned fear and anxiety is assessed by open field test. The standard open field is a brightly lit, circular arena with opaque walls and a floor scored in a grid. The animal is placed on a small stage in the open field. The test examines the internal dilemma between the innate fear of being in the central open area versus the tendency to explore new environments. When they are anxious, animals prefer to stay close to the walls (thigmotaxis).

5. **Elevated plus maze:** The maze is a cross-shaped device with two open and two closed arms elevated above the floor. The elevated plus maze examines the conflict between desire to explore a novel environment and the tendency to escape from the elevated open arms of the maze. When anxious, the natural tendency of rodents is to prefer enclosed dark spaces. An increase in proportion of open arm activity (duration and/or entries) reflects less anxiety (Carter et al., 2011).

6. **Light−dark transition:** The concept of the light−dark transition test is the same as for the elevated plus maze. The apparatus consists of a dark chamber and a brightly illuminated chamber. This forces the animal to choose between exploring the brightly lit area of the open field or staying in the dark area. When anxious, the mice tend to stay in the dark area. Anxiety-reducing drugs increase the number of entries into the bright chamber and the duration of time spent there (Savignac et al., 2011).

7. **Social interaction test:** This test is designed to see the natural reaction of an animal meeting a stranger animal. This test provides a choice between going into an empty chamber or a chamber containing a stranger mouse. Various behavior measures such as sniffing, following, allogrooming, biting, and mounting are considered as dependent variables. Other investigators may compare time spent by the animal examining an inanimate object to time spent interacting with the stranger (Flint and Shifman, 2008).

8. **Vogel conflict test:** The Vogel conflict test has been widely used for detecting anxiolytic-like effects of drugs. In this test water-deprived animals are given water. After a short period of drinking, all or some licks on the drinking are punished by mild electrical shocks leading to a significant reduction of water consumption in deprived animals. There are differences in water deprivation, water access periods, and punishment schedules, and drinking responses are reestablished by anxiolytic drugs (Gleason and Witkin, 2007).

9. **Defensive probe burying:** This test measures the effects of an aversive stimulus and anxiolytic drugs on behavior. A stationary electrified probe is used for shock, following which, rats exhibit varying periods of inactivity, immobility (a passive response), and bouts of burying behavior (an active response) consisting of vigorous burrowing, shoveling, and flicking movements with the forepaws and head to displace the cage-bedding material toward the probe.

Animal Models of Schizophrenia

SZ, with its positive, negative, and cognitive deficit symptoms, is one of the most difficult psychiatric disorders to model. Delusion-like symptoms of SZ have not yet been modeled, but others such as deficits in sensorimotor gating, working memory, and social recognition have been modeled in mice. A majority of the animal models of SZ are based on the induction of abnormal behaviors by psychostimulants and hallucinogens.

1. **Psychostimulant model:** Amphetamine exposure is the most widely used drug-induced model of SZ and exhibits similarities between the effects of amphetamine in humans and the symptoms of SZ (face validity). Amphetamine releases DA by acting directly on presynaptic dopaminergic terminals. Animals receiving amphetamine challenge exhibit excessive locomotor activation; this is an excellent measure of face validity given that individuals with SZ have excessive striatal DA release in response to an amphetamine challenge compared with healthy controls.

2. **Sensorimotor gating model:** The impairments in gating or filtering, leading to sensory overload and cognitive fragmentation, are prominent clinical features of SZ; this is termed as *sensorimotor gating*. The model of sensorimotor gating, such as prepulse inhibition (PPI), which measures sensorimotor gating, is the attenuation of the startle reflex following a sudden intense startling stimulus when a weaker sensory stimulus is previously applied. PPI provides an opportunity for normal individuals to filter or block most of the unnecessary sensory and cognitive stimuli on a daily basis, which reflects a protective function; lack of this ability is often seen in patients with SZ. A slight variation of PPI is the ASR, observed following the presentation of a sudden loud noise. ASR measures startle activity by coupling the startle platform to a 0020 strain gauge transducer. Habituation to the startle response reflecting abnormal stimulus processing is a clinical feature observed in SZ. Another model of sensory gating is latent inhibition (Li), a measure of reduced learning or attentional dysfunction. It is based on the hypothesis that nonreinforced, incidental stimulus exposure disregard the stimulus, which suggests inhibition of memory formation. Li has reasonable construct validity, as attention and information processing is disrupted in SZ.

3. **Social interaction model:** The core negative symptom in SZ is the lack of socialization in the affected individuals. A social interaction test model in animals is used to see the interaction between the mouse and an unfamiliar stranger mouse in an open field. The unfamiliar mouse moves freely (Miyakawa et al., 2003) or is contained in an enclosure (Sankoorikal et al., 2006).

BIOMARKERS OF BIPOLAR DISORDER AND SCHIZOPHRENIA

The quest for identification of biomarkers involved in psychiatric disorders has been going on for many years. According to National Institutes of Health "a biomarker is a characteristic that is objectively measured and evaluated as an indicator of normal biological and pathogenic processes, or pharmacological responses to a therapeutic intervention." The task of identifying a biomarker for NP disorder is quite daunting because of the overlap and complexity of symptoms between disorders. The diagnosis of most NP disorders is based on self-report and behavioral observations, so the strategies to improve therapeutic selectivity, which largely rely on the identification of biomarkers, will lead to improved diagnosis and potentially pave the way for more effective treatment of patients.

Biomarkers for bipolar disorder (BD) have been categorized into neurobiological factors, peripheral markers, and genetic variables.

1. Neurobiological factors: Earlier studies revealed that biological factors such as expansion of the third and lateral ventricles, white matter hyperintensities, condensed gray matter in the hippocampus and cerebellum, and enlarged size of the amygdala indicate structural abnormalities in bipolar disease. Individuals with hyperactivation of the frontal polar cortex and increased memory load are more prone to develop BD, making these two factors markers for BD (Thermenos et al., 2010).

2. Peripheral markers: Serial monitoring of peripheral markers could be useful as a simple, rapid, low cost, and dependable method for prediction and treatment outcome in bipolar disease. The markers that have been assessed in BD patients include BDNF, glial involvement, biochemical markers—inflammation (pro- and antiinflammatory cytokines)—and oxidative stress and mitochondrial dysfunction.
   - BDNF: BDNF, a 27 kDa polypeptide synthesized from proBDF, belongs to neutrophins, which are homodimeric proteins. It is a significant mediator for cell survival and functions by binding to TrkB, so it may result in advancement of bipolar disease (Hashimoto, 2010). Studies have shown that BDNF 196G/A gene polymorphism results in hippocampal activation, decreased hippocampal N-acetyl aspartate and periodic memory suggesting its involvement in bipolar disease. Its serum level was reported to be decreased in depressed, hyper, and unmedicated patients in the late stage of illness. Further study revealed decreased levels of mRNAs of lymphocyte-derived BDNF and of protein BDNF levels in platelets of hyper patients. Therefore, BDNF plays an important role in BD pathogenesis.
   - Glial involvement: Astrocytes secrete calcium-binding protein, S100B, which causes paracrine and autocrine effects on neurons. Glia S100B toxicity is directly proportional to its concentration in serum (Andreazza et al., 2007). It is also an important marker in various psychiatric disorders such as SZ and major depression. Studies have reported that during mood variations, the activity of astrocytes is altered, resulting in increased extracellular levels of S100B. Higher serum levels of this protein during depressive and hyper mood cause brain damage. Therefore, the alteration of glial and astrocyte cells in mood disorders may be involved in the pathogenesis of BD.
   - Inflammatory factors: Various studies have shown that proinflammatory cytokines IL-2, IL-6, IL-8 (interleukins) and TNF-α were found to be increased in depressive and late stages of BD patients as compared to controls. This is in conformity with the results that showed that IL-6 and TNF-α mRNA levels were increased in BD patients with hyper state of illness. It has been postulated by proteomics study that BD involves inflammatory pathways of IL-13, TNF-α, and apolipoprotein A1 (Herberth et al., 2011). One of the studies also revealed that high sensitivity C-reactive protein is associated with worsening of the hyper state in youngsters with BD (Berk et al., 2011). Antiinflammatory cytokine IL-10 was found to be decreased in the hyper state. Therefore, evaluation of proinflammatory factors may enlighten the role of these important markers in the progression of BD.
   - Oxidative stress: Oxidative stress is caused by an imbalance between ROS and antioxidants. Malondialdehyde (MDA), the end product of lipid peroxidation, can be produced from free radical attack on polyunsaturated fatty acids (PUFAs) (Andreazza et al., 2008). It is a marker of oxidative stress, which can be evaluated through the levels of thiobarbituric acid reactive substances (TBARS). Oxidative stress causes disruption in lipid messenger signaling systems and alters the conformation of proteins. An increment in TBARS levels has been postulated in BD patients in hyper, depressive, and reduction stages leading to

continuous oxidative damage to the lipid structure during BD. Therefore, TBARS can be used to categorize BD in different stages, with higher levels of TBARS during later stages of BD. The other free radical that has been extensively studied is nitric oxide. Nitric oxide (NO) is derived from L-arginin through the Ca^{2+}-dependent enzyme, nitric oxide synthase (NOS). It is an essential physiological signaling molecule that mediates various cellular functions, but also induces cytotoxic and mutagenic effects when present in excess. Studies have shown that persons with BD have higher levels of GLU, glutamate + glutamine, and lactate in the PFC (Frye et al., 2007). Increased GLU levels leads to an increase in Ca^{2+} levels, which activates NOS. NOS forms nitric oxide, which disturbs normal protein function through the following equations:

$$\bullet NO + \bullet O_2^- \rightarrow ONOO^- \text{ (neurotoxic)}$$

$$(\bullet NO, \text{Nitric oxide}) + (\bullet O_2, \text{Superoxide})$$

$$\rightarrow (ONOO^-, \text{Peroxynitrite})$$

$$ONOO^- + \text{Protein} - SH \rightarrow \text{Disturbed protein functions}$$

$$(\text{Protein} - SH, \text{thiol groups of amino acids and proteins})$$
Therefore, oxidative stress causes DNA fragmentation in the ACC and lymphocytes resulting in telomere shortening, a biomarker in BD patients.

3. Genetic variables: The Alpha 1C subunit of the L-type voltage-gated calcium channel (CACNA1C) and ankyrin 3 (ANK3) are the two genetic markers that are the risk loci in BD. CACNA1C facilitates different calcium-dependent processes such as regulation of dendritic calcium influx in neurons. Increase in gray matter volume and intensity in the right amygdala and hypothalamus has been found to be due to CACNA1C rs1006737 risk allele (G to A) (Perrier et al., 2011). ANK3, ankyrin protein, modifies the neuronal sodium channel activity and plays an important role in cell motility, stimulation, and proliferation, and maintenance of specialized membrane domain. Therefore, several genetic studies confirmed these genes in modulating pathways involved in the pathogenesis of BD.

BIOMARKERS OF SCHIZOPHRENIA

Diagnosis of SZ is still complicated because of its unknown pathogenesis and etiology. The current criteria for its diagnosis include positive symptoms (hallucinations, delusions), negative symptoms (depression, lack of motivation), and cognitive impairment reported by patients, mental status examination, and clinical presentation. Because of advances in genetics, genomics, and proteomics, the overall burden of SZ can be reduced in early stages by discovering new biomarkers for it (Pillai and Buckley, 2012). The biomarkers for SZ can be categorized as *trait markers*, *peripheral biomarkers*, and *proteomic candidate markers*. These three categories are described as follows:

1. **Trait markers**: Trait markers include endophenotypes that are examined during SZ. Endophenotypes are assumed not only to be due to genetic abnormalities, but also to nongenetic factors and interaction between environmental stressors and a genetic disposition; for example, interaction between fetal hypoxia and predisposing genes has been studied in the pathogenesis of SZ (Pillai and Buckley, 2012). The different endophenotypes are cognitive measures, neurophysiological measures, and structural and functional abnormalities. Cognitive measures include selective attentions, working memory, face memory, and emotion processing. Neurophysiological measures include PPI of startle reflex, eye tracking dysfunctions, and mismatch negativity, whereas neuroimaging includes frontal hypoactivation in response to intellectual tasks, magnetic resonance imaging, and whole brain nonlinear pattern classifications. These endophenotypes, when studied together in different combinations, resulted in improved prognostic outcomes as compared to single endophenotypes (Greenwood et al., 2011). Therefore, trait markers can be assessed during the progression of SZ.

2. **Peripheral biomarkers:** These play an important role in SZ. Some of the useful peripheral biomarkers are blood-based biomarkers, such as inflammation, microRNA (miRNA), oxidative stress, and neurotransmitters and neuronal signaling molecules, such as BDNF.
   a. Blood-based biomarkers, which are analyzed in serum/plasma using a multi-analyte profiling (MAP) platform, signify the role of immunological and inflammatory processes during the first stage of SZ. The innate immune system consists of humoral and cellular components. Humoral components are activated by the complement system and acute phase proteins (APPs), which participate in systemic nonspecific reactions in response to disturbances in homeostasis called acute phase response. During stress, proinflammatory cytokines IL-6 and TNF-α are secreted in the blood, causing variations in the adrenocorticotrophic hormone (ACTH) and

glucocorticoid levels by hyperactivating the hypothalamic–pituitary–adrenal axis (Bradley and Dinan, 2010), complement system stimulation, and alterations in the APPs levels, inducing behavioral neuroendocrine and metabolic changes during SZ. The cellular component is activated by monocytes, macrophages, granulocytes, and natural killer cells. Activated T and B lymphocytes of the cellular immune system produce active immunotransmitters IL-2, IL-12, IL-18, and TNF-α, which reveal that the innate immune response is activated against stressors in SZ.

b. **miRNA:** This plays a regulatory role in SZ by inhibiting the translation of mRNA, which makes it one of the possible biomarkers for this disease. Postmortem brain studies have shown that around 30 miRNA expressions were varied in patients with SZ (Beveridge et al., 2010). Further studies revealed that the gene expression between CNS tissue and peripheral blood is thought to be the same, as peripheral leukocyte gene expressions are affected by the CNS through cytokines, neurotransmitters, and hormones. Altered miRNA expressions of blood mononuclear leukocytes were found in patients with negative symptoms, neurocognitive performance scores, and event-related potentials. This is in concordance with the study that showed that seven miRNA gene expressions were altered in leukocytes, with hsa-miR-34a most differentially expressed in SZ patients (Lai et al., 2011). Therefore, miRNA can be assessed as a noninvasive biomarker for SZ.

c. **Oxidative stress:** Free radicals generated during oxidative stress mainly affect brain because of high levels of PUFAs, relatively low levels of antioxidants, and high metal content and oxygen utilization in the brain. Oxidative stress in the form of lipid peroxidation and a compromised antioxidant system plays a key role in the pathophysiology of SZ (Ciobica et al., 2011). The products of lipid peroxidation, which were assessed during SZ, are MDA in the form of TBARS and 4-hydroxy nonenal (HNE), a highly cytotoxic reactive α,β-aldehyde. Neuronal functions are disturbed by TBARS at high levels, which change the membrane fluidity or alter the membrane receptors. Studies have examined the increased levels of 4-HNE and MDA in leukocytes, erythrocytes, and plasma in SZ patients as compared to controls. The results on antioxidant levels in SZ are ambiguous. The variations in antioxidant levels may be due to illness duration, symptom severity, and therapeutic features. Some authors have shown no difference in SOD levels, whereas some have shown both decrease and increase in SOD levels. Similar results were reported for GPX with increased and decreased levels in SZ patients.

d. **BDNF:** BDNF is one of the significant and most studied markers in SZ, which is expressed in the hippocampus, cerebral cortex, basal forebrain, striatum, and hypothalamus and regulates neuronal structure and function along with their growth, differentiation, and survival, such as GABA neurons. Different studies have reported the decrease in BDNF levels of cerebrospinal fluid and serum in first episode SZ patients (Thompson Ray et al., 2011). Similar results were observed in the PFC of SZ patients with decreased BDNF levels. BDNF knockout mice were found to have deficits in spatial learning and memory as BDNF facilitates the strengthening of hippocampal synapses associated with learning and memory. Therefore, BDNF can be considered as a potential biomarker of SZ.

3. **Proteomic analysis:** Dysfunctions of oligodendrocytes and glycolysis were observed by proteomic studies in the mediodorsal thalamus of SZ patients (Martins-de-Souza et al., 2010). Oligodendrocytes form myelin around axons and also maintain myelin in the CNS. It has been found that sphingomyelin and galactocerebrosides 1 and 2 (myelin membrane components) were decreased along with upregulation of myelin basic protein and myelin oligodendrocyte glycoprotein in the thalamus of SZ patients. Glycolysis alterations were studied by differential expression of enzymes such as triose phosphate isomerase and glyceraldehyde phosphate dehydrogenase (GAPDH) in SZ patients. Consequent studies of glycolysis alterations further revealed lower levels of pyruvate (end product of glycolysis) in SZ. Because of variations in glucose metabolism, the levels of NADPH, essential for oxidative phosphorylation, were affected. NADPH levels are regulated by proteins transketolase, μ crystallin, glutathione s-transferase, and GAPDH, which were found to be increased in SZ patients.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Addiction to drugs of abuse adversely affects the CNS by altering neurotransmitter release and their actions on their respective receptors. Chronic abuse of amphetamine, cocaine, cannabis, and alcohol is associated with deficits in attention, memory, and executive functions, suggesting their neurotoxicity to brain. Studies on the neurotoxic effect of abused drugs have identified cellular and molecular pathways involving

oxidative stress, activation of transcription factors, DNA damage, excitotoxicity, BBB breakdown, microglial activation, and various apoptotic pathways through mitochondrial dysfunction and inhibition of neurogenesis. The comorbidity among drug addiction and NP disorders is because both share common neural substrates and brain areas that underlie depression, anxiety, and SZ. Genetic and pharmacological manipulations have made animal models available to understand the causes of NP symptoms. Blood-based biomarkers, such as BDNF, 4-HNE, and MDA in leukocytes and erythrocytes, and those in genetic studies, have given us more hope to diagnose and treat NP diseases effectively.

Despite the significant strides made in understanding the neurotoxic consequences of drug addiction and NP diseases, due to overlapping symptoms and shared pathways, significant challenges still exist for the complete spectrum of treatment of pathophysiology associated with NP disorders. Future studies require successful translational research on animal models, which can illuminate the path to disease mechanisms and their therapeutic targets.

Abbreviations

ADAMTS A disintegrin and metalloprotease with thrombospondin motifs
AMPK AMP-activated protein kinase
COMP Cartilage oligomeric matrix protein
K-L Grade Kellgren−Lawrence Grade
LACS Local-area cartilage segmentation
MMPs Matrix metalloproteinases
MMP-3/-9 Matrix metalloproteinases-3/-9
sRAGE Soluble receptor for advanced glycation end products
SIRT1 Sirtuin 1
TSG-6 Tumor necrosis factor-stimulated gene-6

INTRODUCTION

Osteoarthritis (OA) is an inflammatory joint disease characterized by chronic and progressive cartilage degeneration, osteophyte formation, subchondral sclerosis, bone marrow lesions, hypertrophy of bone at the margin, and changes in the synovial membrane. OA is a disease of the entire joint and surrounding muscles, and it commonly affects humans, dogs, and horses. OA can affect any joint in the body, but more commonly the knee, hip, arm, and foot. Currently, worldwide estimates are that 9.6% of men and 18.0% of women over the age of 60 have symptomatic OA. Almost 80% of patients with OA have some degree of limitation of movement, and 25% cannot perform their major daily activities of life (Lourido et al., 2014). Aging is the main causative factor for OA, although many other factors are also involved, such as injury/trauma, excess or lack of exercise, dietary habits, obesity, joint malalignment (e.g., varus or valgus deformity), genetic predisposition, infection, etc. (Abramson and Attur, 2009; van Meurs, 2017). As a result of aging, the pathophysiology of OA is very complex, and multiple mechanisms and signaling pathways are involved in inflammation, pain, and cartilage degeneration/loss.

Biomarkers play a pivotal role in the diagnosis of OA, which is often based on clinical (synovial fluid, serum, and urine biomarkers), radiographic, and MRI assessments. During the past decade, significant progress has been made in identification, confirmation, and validation of biomarkers, some of which are used in early disease diagnosis, prognosis, drug development, and monitoring recovery progress during treatment. The application of proteomic technologies has generated several new nonconventional biomarkers (Patra and Sandell, 2011; Ruiz-Romero and Blanco, 2009, 2010; Mobasheri, 2012; Lourido et al., 2014; Sanchez et al., 2017). Although values of biomarkers in various aspects of OA have been recognized for a long time, quests for novel biomarkers will continue forever (Lotz et al., 2013; deBakker et al., 2017; van Meurs, 2017). This chapter describes contributing factors and pathophysiology of OA; classification of OA biomarkers; and recent developments in identification, qualification, and validation of biomarkers of OA in humans and animals.

PATHOPHYSIOLOGY AND SIGNALING PATHWAYS IN OSTEOARTHRITIS

OA has been recognized as a heterogeneous disease of the entire joint, encompassing multiple tissues, including cartilage, bone, adipose, and skeletal muscle, thereby causing remodeling and/or failure of the joint (Abramson and Attur, 2009; Thote et al., 2013; Yuan et al., 2014; Tonge et al., 2014; Svala et al., 2017). Degradation of articular cartilage is a hallmark of OA, which occurs in two phases: anabolic phase, in which chondrocytes attempt to repair the damaged extracellular matrix (ECM), and a catabolic phase, in which enzymes produced by different cells (including chondrocytes) digest the extracellular matrix (Svala et al., 2017). This catabolic

phase also includes inhibition of matrix synthesis, thereby ensuing accelerated erosion of the cartilage.

In the early stages of OA, progressive depletion of the cartilage proteoglycan leads to a net loss of matrix from the cartilage (Thote et al., 2013). Normally, the joint cartilage consists of 5% chondrocytes and 95% ECM. In OA, chondrocytes serve as mechanosensors and osmosensors, altering their metabolism in response to physicochemical changes in the microenvironment. OA is characterized by the degradation of cartilage matrix components, including cartilage-specific type II collagen and the proteoglycan aggrecan, ultimately resulting in the loss of cartilage structure and function. Breakdown and deterioration of the cartilage have been correlated with increased activities of certain enzymes, including matrix metalloproteinases (MMPs). Fig. 52.1 shows an OA joint with thinning and destruction of the cartilage and cartilage remnants in joint space.

In OA cartilage, decreases in the number of chondrocytes and in their ability to regenerate the ECM in response to stress has been described (Portal-Núñez et al., 2016). OA chondrocytes show a senescence secretory phenotype (SSP) exhibiting overproduction of cytokines (IL-1 and IL-6), matrix metalloproteinases (e.g., MMP-3, MMP-8, and MMP-13), and growth factors (e.g., epidermal growth factor). Of the three major MMPs that degrade native collagen, MMP-13 appears to be the most important in OA because it preferentially degrades type II collagen, and it has been shown that expression of MMP-13 greatly increases in OA (Abramson and Attur, 2009). During cartilage degeneration in OA, the inflammatory processes cause excess production of ROS, RNS, oxygen, and PGE2, and as a result, their increased levels are found within the joint (Bakker et al., 2017; Wan and Zhao, 2017). Evidence suggests that in chondrocytes, excessive ROS production leads to hyperperoxidation, protein carbonylation, and DNA damage, which all play a major role in the induction of SSP (Portal-Núñez et al., 2016). Activity of proinflammatory cytokine IL-1β can be detected in synovial fluid from OA joints where it induces gene expression of matrix-degrading enzymes in chondrocytes. In the synovial fluid of OA patients, another proinflammatory molecule from natural killer cells has been shown to be expressed, i.e., protease granzyme A, which may contribute to chronic articular inflammation (Jaime et al., 2017).

Nuclear factor kappa B (NF-κB) appears to be a key transcription factor that drives the expression of OA-inducer genes in response to the activation of toll-like receptors (TLR) and interleukin receptors by ECM fragments and IL-1β. Proinflammatory cytokines, such as IL-1β, are produced in the OA-stimulated mitogen-activated protein kinase (MAPK) pathways through the extracellular signal-regulated kinases (ERK)½, p38 kinase, and c-Jun N terminal kinase (JNK). Elevated MAPK phosphorylation results in activation of transcription factors, which in turn upregulates the production of several molecules, such as MMPs and aggrecanases, which are responsible for matrix degradation. In OA, IL-1β induces activation of the NF-κB signaling pathway in human chondrocytes, thereby causing low-grade pain (Wan and Zhao, 2017). Sluzalska et al. (2017) demonstrated that NF-κB, p38, MAPK, and JNK signaling pathways are all involved in IL-1β—induced phospholipids biosynthesis (PLs). PLs are key molecules for cartilage maintenance, and their presence in synovial fluid plays a major role in joint lubrication to protect cartilage surfaces. Signaling pathways directly mediated by lipids and those that involve mammalian target of rapamycin (mTOR) pathways are reported both in normal and OA cartilage (Villalvilla et al., 2013).

Evolution of Osteoarthritis

1. Bone
2. Cartilage
3. Thinning of cartilage
4. Cartilage remnants
5. Destruction of cartilage
Sillat et al. (2013) demonstrated that mature chondrocytes express TLR1 and TLR2 and may react to cartilage matrix/chondrocyte-derived danger signals or degradation products, which leads to synthesis of proinflammatory cytokines; and that stimulates further TLR and cytokine expression, establishing a vicious circle. Evidence also suggests that hyaluronan and fibronectin may act as TLR pathway stimuli in development and progression of OA involving innate immune system (Scanzello et al., 2008). Furthermore, during the inflammatory response, dysregulation of AMPK and Sirtuin 1 in articular chondrocytes modulate intracellular energy metabolism (Liu-Bryan, 2015). These findings suggest that OA can act as an autoinflammatory disease and links the old mechanical wear-and-tear concept with modern biochemical views of OA. In essence, the chondrocyte itself is the earliest and most important inflammatory cell in OA.

In an interesting investigation, Koskinen et al. (2011) reported that adipocytokine leptin alone, and in combination with IL-1β, upregulated production of MMP-1, MMP-3, and MMP-13 in human OA cartilage. Effects of leptin on production of all three MMPs were mediated through TNF-κβ, protein kinase C, and MAPK pathways. Leptin concentrations in synovial fluid from OA patients correlated positively with MMP-1 and MMP-3 in synovial fluid and cartilage.

In a recent report, Ishimaru et al. (2014) delineated the role of chondroitin sulfate (CS) glycosyltransferase in cartilage growth and degeneration. By now, six CS glycosyltransferases [CS synthase 1 (CSS1/CHSY1); chondroitin polymerizing factor (CHPF); CS synthase 3 (CSS3); chondroitin polymerizing factor 2 (CHPF2); CS N-acetylgalactosaminyltransferase 1 (CSGALNACT1); and CS N-acetylgalactosaminyltransferase 2 (CSGALNACT2)] have been known to be involved in CS biosynthesis in mammals. The concentration and chain length of CS were found to be reduced closer to the more degraded cartilage. Inhibition of CS glycosyltransferase gene expression may reduce CS chain length, which may contribute to OA progression.

Yuan et al. (2014) described that a bone−cartilage modulatory pathway, transforming growth factor β (TGFβ), is required for the maintenance of metabolic homeostasis and structural integrity of healthy cartilage. The factor is highly expressed in normal cartilage, but almost absent in OA cartilage. Wang et al. (2017) further emphasized that TGFβ/ALK5 signaling maintains articular cartilage homeostasis, in part, by upregulating proteoglycan 4 (PRG4) expression through the PKA−CREB signaling pathway in articular chondrocytes. Loss/interruption of TGFβ signaling in cartilage results in loss of proteoglycans and cartilage degeneration. Thus, inhibition of endogenous TGFβ leads to increased damage to cartilage.

Wnt/β-catenin is another signaling pathway, which plays a critical modulatory role in maintaining the bone−cartilage biochemical unit (reviewed in Gupta, 2016). Increased expression of Wnt signaling agonists, such as Wnt-induced signaling protein-1, Wnt-16, and Wnt-28, have been reported in human OA cartilage and may contribute to cartilage degradation by upregulating MMPs and aggrecanases (Blom et al., 2009). Recently, Huang et al. (2017) reported that Wnt5a as a signaling pathway may contribute to OA by promoting MMP-1, MMP-3, and MMP-13 expression, as well as MMP-1 and MMP-13 protein productions in chondrocytes. Wnt5a activated beta-catenin−independent signaling, including calmodulin-dependent protein kinase II (CaMKII), JNK, p38, ERK½, p65, and Akt. Inhibition of JNK, p38, ERK, pl-3 kinase, and CaMKII by specific signaling inhibitors suppressed Wnt5a-mediated MMP-1 and MMP-13 production.

Involvement of the endocannabinoid system in OA and bone remodeling has been well reported (Idris and Ralston, 2012; La Porta et al., 2014; Valastro et al., 2017). To date, two cannabinoid receptors (CBR1 and CBR2) and two endogenous endocannabinoids (arachidonoylethanolamide and 2-arachidonoylglycerol) have been identified in synovial fluid (Valastro et al., 2017). Cannabinoid receptor activation can modulate inflammation and nociception in animal models of joint inflammation.

Recent evidence suggests that the initiation and progression of OA are contributed to various expression patterns and enhanced activation of histone deacetylases (HDACs) (Lu et al., 2014; Carpio and Westendorf, 2016). Overexpression of HDAC4 promotes matrix-degrading enzyme levels and enhances catabolic activity of chondrocytes in OA cartilage (Lu et al., 2014). Both HDAC1 and HDAC2 suppress the expression of genes encoding ECM, such as type II collagen (Cil2a1), aggrecan (ACAN), and cartilage oligomeric protein (COMP). It has also been demonstrated that HDAC inhibitors can reduce the expression of matrix-degrading enzymes in chondrocytes and fibroblasts (Young et al., 2005). Most recently, Mao et al. (2017) found that miR-92a-3p functions as a negative regulator by downregulating HDAC2 in both chondrogenesis and OA pathogenesis. To explore its potential application as a therapeutic agent, in vivo studies need to be carried out. In another study, it has been shown that miR-140 is expressed specifically in cartilage and regulates ECM-degrading enzymes (Si et al., 2017).

Recently, proteomic technologies have helped researchers in understanding novel insight into the mechanisms of human articular cartilage degradation and a number of new cartilage-characteristic proteins with possible biomarker value for early diagnosis and prognosis of OA (Ruiz-Romero and Blanco, 2009, 2010;

Lourido et al., 2014; Sanchez et al., 2017). Lourido et al. (2014) identified a panel of 76 proteins and found decreased osteoprotegerin and increased periostin release from OA cartilage. Increased levels of periostin were detected in the synovial fluid of OA patients.

Finally, several candidate genes encoding proteins of the extracellular matrix of the articular cartilage have been associated with early-onset OA (Holderbaum et al., 1999). Mutations in genes expressed in types II, IV, V, and VI collagens, as well as in COMP, have been noted. Candidate genes that are not structural proteins for OA have also been identified, such as frizzled-related protein 3, asporin, and von Willebrand factor gene (Reginato and Olsen, 2002; Ikegawa, 2007; Abramson and Attur, 2009).

By now, it is clear that it may take decades to fully understand the underlying pathophysiology of OA.

CLASSIFICATION OF OSTEOARTHRITIS BIOMARKERS

Biomarkers are urgently needed for the early detection of OA and monitoring its progression/reversal during treatment. Biomarkers of OA can be classified as markers of biochemical changes, inflammation, cartilage degeneration/loss, etc. (Altman et al., 1986; Bauer et al., 2006). In addition, the US Food and Drug Administration and European Medicines Agency have recently published guidelines recommending a higher level of integration of biomarkers in the development and testing of new drugs to advance decision-making on dosing, time and treatment effect, trial design, risk/benefit analysis, and personalized medicine (Bauer et al., 2006; Karsdal et al., 2009; Bay-Jensen et al., 2016). Currently, the board of directors (D-BOARD) consortium, an EU and PPP (public private partnership) initiative, is working on identification and validation of novel biomarkers and pushing those qualifications forward, by applying the BIPED (Burden of disease, Investigative, Prognostic, Efficacy of intervention, and Diagnostic) criteria for hypothesis testing (http://www.d-board.eu/dboard/index.aspx). Biomarkers of burden of disease are exemplified by the Kellgren and Lawrence radiographic grade (K-L grade), serum COMP, serum hyaluronan, and urinary carbonyl-terminal cross-linking telopeptide of type II collagen (CTXII). Prognostic biomarkers require longitudinal studies (prospective or retrospective) showing an increase in K-L grade by >1 and measurements of biochemical molecules/fragments of protein, DNA, and COMP (>1 unit in serum); CTX-II; serum hyaluronic acid; and pentosidine. In addition, these biomarkers include degree of joint space narrowing (JSN) or change in cartilage volume by MRI and correlated well with

urinary CTX-II levels. Efficacy of intervention biomarkers may be measured prior to therapy to predict treatment efficacy or measure short-term changes that occur as a result of pharmacologic or other interventions (e.g., measuring concentrations of a biomarker of cartilage degradation, such as CTXII). Some examples of diagnostic biomarkers include COMP, CTXII, NTX-I. For detailed BIPED classification and examples of biomarkers, see Rousseau and Delmas (2007). Recently, Bay-Jensen et al. (2016) classified OA biomarkers into three broad categories: (1) inflammatory biomarkers, such as cytokines, chemokines, or cell type markers relevant to OA pathology; (2) biomarkers reflecting the turnover of the ECM of OA cartilage; and (3) biomarkers that target autoantibodies, signaling molecules, or growth factors (discussed above in pathophysiology). It is noteworthy that a biomarker can fall into more than one category.

BIOMARKERS OF COMFORT, MOBILITY, FUNCTION, AND INFLAMMATION AND PAIN

The diagnosis of OA often relies on clinical and radiological examinations of late and irreversible stages. Sensitive serum biomarkers specific for early stages (potentially reversible) of OA are lacking. It is suggested that combining biochemical markers with tissue and cell imaging techniques and bioinformatics (i.e., machine learning, clustering, and data visualization) may facilitate the development of biomarkers enabling earlier detection of OA (Mobasheri, 2012; Mobasheri et al., 2017).

Humans

In OA in humans, several scoring systems are used to measure joint mobility, flexibility, and pain, such as Knee Osteoarthritis Scoring System (KOSS), modified Knee Injury and Osteoarthritis Index (mKOOS) global score, Clinical American College of Rheumatism (ACR) criteria, Whole-Organ Magnetic Resonance Imaging Score (WORMS) of the knee, Boston Leeds Osteoarthritis Knee Score (BLOKS), MRI Osteoarthritis Knee Score (MOAKS), modified Western Ontario and McMaster Universities Arthritis Index (mWOMAC) subscale, and Visual Analog Scales (VAS) (Kornaat et al., 2005; Peterfy et al., 2004; Hunter et al., 2008, 2011; Belo et al., 2009; Runhaar et al., 2014). The global mKOOS test is composed of four categories (symptoms, stiffness, discomfort, and function/daily living activities). Additionally, mWOMAC subscale scores consist of 24 items divided into three subscales assessing discomfort (5 items), stiffness (2 items), and physical function (17

items). Additionally, self-reported feelings of joint health, comfort, mobility, and function are the primary outcome measures of OA (Lopez et al., 2017).

OA severity is often determined using weight-bearing anteroposterior radiographs of the affected joints, which are evaluated according to the Kellgren and Lawrence classification. The grade of OA is described as follows: Grade 0, no radiographic findings of OA; Grade 1, minute osteophytes of doubtful clinical significance; Grade 2, definite osteophytes with unimpaired joint space; Grade 3, definite osteophytes with moderate JSN; and Grade 4, definite osteophytes with severe JSN and subchondral sclerosis.

Animals

Dogs and horses are evaluated for overall pain, pain upon limb manipulation, and exercise-associated lameness using the Glasgow scoring system on a monthly basis for a study period of at least 4–5 months (Gupta et al., 2009, 2012). Overall pain is graded on a scale of 0–10: 0, no pain; 5, moderate pain; and 10, severe and constant pain. Pain upon limb manipulation is evaluated during the extension and flexion of all four limbs for a period of several minutes. Pain level is graded on a scale of 0–4: 0, no pain; 1, mild; 2, moderate; 3, severe; and 4, severe and constant. Pain and lameness are measured after physical exercise and graded on a scale of 0–4: 0, no pain; 1, mild; 2, moderate; 3, severe; and 4, severe and constant. In horses, pain is measured using similar criteria and scales. Additionally, flexibility and range of motion in the affected joints are measured using a Goniometer (May et al., 2015). Hielm-Björkman et al. (2009) used a five-point scale to measure pain in OA dogs [0, no sign of pain; 1, mild pain (dog turns head in recognition); 2, moderate pain (dog pulls limb away); 3, severe pain (dog vocalizes or becomes aggressive); and 4, extreme pain (dog does not allow palpation)].

In dogs, Ground Force Plate (GFP) (Kistler Instrument, Amherst, NY, USA) is utilized to quantitatively measure the lameness-associated pain in each leg of each dog (Gupta et al., 2012). The Kistler's GFP system consists of plates, lasers, and a computer. The GFP measures two major parameters: (1) peak vertical force or g force (Newton/Kg body weight), and (2) impulse area (Newton/Kg body weight). In a similar way, GFP can quantitatively measure the pain level in horses.

Observation of Ortolani and Cranial Tibial Drawer Examination

Along with the external evaluations of pain, such as gait, or lameness, other options may also be performed during the physical examination. The Ortolani Maneuver is a common test performed on canines that are predisposed to hip dysplasia such as German shepherds or larger breed canines (Siberian huskies, Rottweilers, Newfoundlands, and Labradors). Ortolani is performed on the hip joint by flexing the knee and hip to 90 degrees, placing the index finger on the greater trochanters, and abducting the hip (Ortolani's sign, 2007). As the hip is abducted, or moved away from the body, a positive Ortolani will be shown with a "clunk" sound or feeling as the femoral head relocates anteriorly to the acetabulum, or hip socket. The Ortolani is typically used on patients that have been sedated to receive a true positive or negative sign. In moderate arthritis, dogs may exhibit a negative Ortolani sign.

Cranial tibial drawer is another test that can be performed on physical examination to indicate arthritic changes and diagnose the rupture of the cranial cruciate ligament (CCL). In this procedure, the canine is in a laterally recumbency with the veterinarian located behind the patient. The thumb of one hand is placed on the caudal aspect of the femoral condular region, and the index finger of the same hand is placed over the patella. The thumb of the other hand is placed on the head of the fibula, and the index finger is placed on the tibial crest (Devine, 1993). A positive tibial drawer is elicited with the ability to move the tibia cranially or forward in respect to the fixed femur.

Currently, experimental/small animals are heavily used to unravel pathways of pain and develop models to measure OA-associated pain (electrophysiology, von Frey hair algesiometry, acoustic frequency and duration recording for vocalization measurement, and nerve injury marker activating transcription factor-3 (Malfait et al., 2013)).

OSTEOARTHRITIS BIOMARKERS IN SERUM, SYNOVIAL FLUID, AND URINE

There are many biomarkers of inflammation and cartilage degeneration associated with OA that can be determined in synovial fluid, serum, or urine, and they have potential as a diagnostic utility. Synovial changes in OA are regarded by many as a secondary response to the degradation of cartilage (Felson, 2013) though there are others who advocate them as a primary driver for OA, which may be partly responsible for pain and disease progression (Benito et al., 2005; Berenbaum, 2013). Many of the biomarkers of OA are listed in Table 52.1; and some of these are described in brief below.

Biomarkers of Inflammation

Biomarkers of joint inflammation can be detected in serum, synovial fluid, and urine much earlier than irreversible joint damage and radiographic changes (Das et al., 2015).

TABLE 52.1   Biomarkers of Osteoarthritis (OA)

	Biomarkers	References

(2017), van Meurs (2017)

Cytokines/Adipocytokines, Chemokines, and Neuropeptides

In a number of studies, profiles of cytokines/adipocytokines, leptins (Stannus et al., 2010; Koskinen et al., 2011; Berry et al., 2011; Goldring and Otero, 2011; Deligne et al., 2015; Fowler-Brown et al., 2015; Bay-Jensen et al., 2016; Hillstrom et al., 2016; Wan and Zhao., 2017), chemokines (Endres et al., 2010; Daghestani and Kraus, 2015; Bay-Jensen et al., 2016), and neuropeptides (Zhang et al., 2013) have been described in serum and/or synovial fluid in relation to OA inflammation.

Prostaglandin E2 and EP4 Receptor

Prostaglandin E2 (PGE2), a proinflammatory mediator, is produced from arachidonic acid by cyclooxygenase (COX) enzymes. PGE2 plays a pivotal role in the development of joint inflammation and pain in arthritis by binding of PGE2 to the EP4 receptor, one of the four G-proteins (Lin et al., 2006).

Fractalkine

Fractalkine (CX3CL1) plays an important role in inflammation and chronic pain, and its levels were

found to be high in serum and synovial fluid and correlated with WOMAC pain and WOMAC total scores (Huo et al., 2015).

Erythrocyte Sedimentation Rate

In a clinical setting, an increase in erythrocyte sedimentation rate is commonly used as a biomarker of inflammation in OA patients (Murdock et al., 2016).

Biomarkers of Osteoarthritis Progression and Cartilage Degeneration

There is a great need to identify biomarkers of OA progression because the disease process is highly unpredictable. Biomarkers of cartilage degeneration (COMP, MMPs, clusterin, lubricin, bone sialoprotein, N-terminal propeptides of procollagen type I (P1NP), and β−C-terminal telopeptide (β-CTX), and many others) can be detected in synovial fluid, serum, and other bodily fluids (Petersson et al., 1998; Abramson and Attur, 2009). Noncollagenous and nonproteoglycan components of cartilage can also be detected in body fluids following their release due to cartilage turnover (Garvican et al., 2010a,b; Abramson and Attur, 2009).

Early detection of OA and OA progression can be evaluated macroscopically, histologically, immunohistochemically, and via imaging (MRI). In recent years, MRI has demonstrated its relevance for the evaluation of structural changes during the development and progression of knee OA (Guermazi et al., 2013). In a recent investigation, Nieminen et al. (2017) demonstrated that histopathological information relevant to OA can be reliably obtained from contrast-enhanced microcomputed tomography (CE mu CT images). This new grading system may be used as a reference for 3D imaging and analysis techniques intended for volumetric evaluation of OA pathology in research and clinical applications. Availability of new technologies and tools for improved morphological and pathophysiological understanding of OA-related changes in joints are an aid to early diagnosis and prognosis and in the monitoring of treatment (Boesen et al., 2016; Wyatt et al., 2017). Some important biomarkers of OA progression are discussed below.

Cartilage Oligomeric Matrix Protein (COMP)

COMP is a pentameric noncollagenous glycoprotein (435,000 Da) belonging to the heterogeneous family of thrombospondin, which can bind to collagen types I, II, and IX. It has been reported that COMP can bind up to five collagen molecules, thereby retaining them in close proximity. By this process, COMP facilitates the collagen−collagen interactions and microfibril formation. It is reported that COMP is mainly produced by articular chondrocytes, and COMP levels in serum

and synovial fluid might be related to cartilage degeneration (Clark et al., 1999; Williams and Spector, 2008; Benedetti et al., 2010). Das et al. (2015) identified COMP as a potential biomarker of OA, which has shown significant clinical promise as a tool for early detection, therapeutic monitoring, prognostication, and drug development. Increase in serum COMP level by > 1 unit increased the probability of radiographic progression by 15% (Sharif et al., 2004). The findings of Varma and Dalal (2013) and Shahi et al. (2013) suggested that serum COMP level, along with clinical profile including family history, joint injury and other visible symptoms, and radiographs, could be used as valuable biomarkers for early diagnosis, prognosis, and management of OA.

In a most recent investigation, Skiöldebrand et al. (2017) identified and quantified a unique COMP neoepitope in the synovial fluid from joints of healthy horses and those with different stages of OA. The findings revealed that the increase in the COMP neoepitope in the synovial fluid from horses with acute lameness suggests that this neoepitope has the potential to be a novel candidate biomarker for the early molecular changes in articular cartilage associated with OA.

Matrix Metalloproteinases (MMPs)

MMPs, also known as "Matrixins," are capable of degrading ECM proteins. It is well established that a number of MMPs (MMP-1, MMP-3, MMP-10, and MMP-13) are significantly involved in degeneration/loss of cartilage in OA (Pelletier et al., 2010; Koskinen et al., 2011). Increased levels of some of the MMPs in synovial fluid and serum have been correlated with cartilage degeneration and therefore have potential to serve as biomarkers of OA progression.

Hyaluronan

Hyaluronic acid (HA; hyaluronate, hyaluronan) is an anionic, nonsulfated glycosaminoglycan and is an important component of articular cartilage present as a coat around each chondrocyte. Molecular weight (MW) of HA can range from 5000 to 20,000,000 DA. The average MW of HA in human synovial fluid is 3−4 million DA. HA is synthesized by a class of integral membrane proteins called hyaluronan synthases (HAS), of which vertebrates have three types (HAS1, HAS2, and HAS3). HA is degraded by a family of enzymes called hyaluronidases. In a number of studies, HA has been recognized as a biomarker of OA (Venable et al., 2008; Plickert et al., 2013; Das et al., 2015; Singh et al., 2015). For further details on HA in relation to OA, readers can referred Gupta (2016).

Lubricin

The glycoprotein lubricin (also known as proteoglycan 4) is secreted by chondrocytes, synoviocytes, and

meniscus cells. It contributes to the boundary lubrication of the articular cartilage surface and is found in synovial fluid. As a boundary lubricant, lubricin reduces the coefficient of friction of the articular surface. Svala et al. (2017) demonstrated for the first time that the reduced sialation of lubricin in synovial fluid from OA joints may affect the boundary lubrication of the superficial layer of articular cartilage and could be one of the early events in the progression of OA. Reduced expression of lubricin in synovial synoviocytes and superficial zone chondrocytes with subsequent loss of joint lubrication are early events in the inflammation associated with OA. Using mass spectrometry, Ritter et al. (2014) identified several proteins (including clusterin and lubricin) in human plasma as predictors of OA progression.

Intra-articular injections of lubricin were reported to improve damaged cartilage and preserve viability of superficial zone chondrocytes (Swan et al., 2011; Elsaid et al., 2012).

Follistatin-Like Protein 1 (FSTL 1)

FSTL 1 is a glycoprotein implicated in OA pathogenesis, which secretes into synovial fluid and serum from OA articular cartilage. Wang et al. (2011) found that the FSTL 1 mRNA and protein levels were substantially elevated in the synovial tissues from OA patients. The FSTL 1 expression was strong in the cytoplasm of the synovial and capillary endothelial cells of the synovial tissues, but it was weak in the chondrocytes of the articular cartilage from OA patients. Interestingly, the serum and synovial fluid FSTL 1 levels were maximally higher in female OA patients than in male patients. The serum FSTL 1 levels of OA patients had significant correlations with K-L grade, JSN, WOMAC stiffness scale, and the WOMAC function subscale. The findings suggested that FSTL 1 could be a biomarker from synovium and might represent a biomarker of the burden of disease (severity of joint damage). However, FSTL 1 has two limitations: (1) it is not specific to OA, as it plays roles in kidney, heart, and other organs; and (2) it poorly correlates with chondrocytes of the articular cartilage. Furthermore, there are conflicting reports that FSTL 1 has potential preventive effects on joint destruction by inhibiting the production of MMPs and cytokines both in synovial cells in vitro and in mouse models in vivo (Tanaka et al., 2003; Kawabata et al., 2004).

Ghrelin

Ghrelin is a peptide hormone, which is involved in energy homeostasis, autoimmunity, inflammation, and many other physiological/pathophysiological processes. Wu et al. (2017) found that significant increases in serum levels of ghrelin were associated with increased knee symptoms, intrapatellar fat pad (IPFP)

signal intensity alteration, and serum levels of MMP-3, MMP-13, N-telopeptide of type I collagen (NTXI), and N-terminal procollagen III propeptide (PIIINP), suggesting that ghrelin may have a role in knee OA.

TSG-6

Tumor necrosis factor-stimulated gene-6 (TSG-6) is a member of the hyaluronan-binding proteins. TSG-6 plays a role in joint inflammation because of its inducible expression by the proinflammatory cytokines IL-1β and TNF-α in human synoviocytes and chondrocytes, and the presence of increased levels of this protein in the synovial fluids and cartilage of a majority of arthritis patients has been reported (Bayliss et al., 2001; Milner and Day, 2003; Wisniewski and Vilcek, 2004). TSG-6 serves as a biomarker of OA progression and is of particular interest for aiding development of disease modifying OA drug (DMOAD) and in identifying high-risk patients who would benefit mostly from the use of DMOAD (Kraus et al., 2011; Wisniewski et al., 2014). Potent antiinflammatory and chondroprotective activities of this protein have also been demonstrated in experimental arthritis models (Bardos et al., 2001).

Cartilage Damage and Imaging Biomarkers

Although many joint structures are affected in OA, articular cartilage is one of the main tissues involved in the OA disease process (Roemer et al., 2014). Articular damage or loss in OA is detected by radiography and measuring decreases in joint space width (JSW) on the radiograph, the so-called "gold standard." However, radiographic evidence is seen only after significant cartilage degradation has already taken place (Mobasheri, 2012). Radiographic measures are less than adequate for multiple reasons. First, radiographs indicate changes in bone and only indirectly measure alterations in cartilage (Bauer et al., 2006). Second, the measurement of articular cartilage change, namely JSN, is itself confounded by meniscal cartilage lesions and meniscal extrusion. Third, bone marrow perturbations and synovial abnormalities may go undetected. Fourth, radiographic features characteristic of OA appear only after significant deterioration has occurred in both the hard and soft tissues within and around the joint and changes may occur relatively slowly. Fifth, radiographic features are usually poorly correlated with joint function.

Bauer et al. (2006) stated that imaging techniques might themselves be considered as biomarkers for the pathologic joint abnormalities that define OA. Imaging measures should be accurate, precise (reliable), specific, sensitive to a longitudinal change, and acceptable to regulatory agencies (Eckstein et al., 2014). Recently, Palmer et al. (2017) reported that delayed gadolinium magnetic

resonance imaging of cartilage (dGEMRIC) could detect glycosaminoglycan loss in the cartilage of asymptomatic individuals with cam morphology. These investigators found a positive correlation between dGEMRIC and the magnitude of JSW narrowing. Baseline dGEMRIC is able to predict the development of radiographic OA. MRI offers the potential to identify patients who may benefit from early intervention to prevent the development of OA.

Recent studies demonstrated that articular cartilage thickness loss/cartilage degeneration score, and osteophyte formation, measured by MRI and µ-computed tomography were found to be associated with concurrent and subsequent radiographic progression and with concurrent symptomatic progression, and therefore they can be used as biomarkers of OA progression (Bagi et al., 2017; Wirth et al., 2017). Schaefert et al. (2017) validated a previously developed local-area cartilage segmentation software method to measure cartilage volume using MRI scans. Cartilage volume change was strongly correlated with radiographic and pain progressions. In canines, Ramírez-Flores et al. (2017) found a correlation between synovial fluid effusion and osteophytosis in the stifle joint, using the results of orthopedic, radiographic, ultrasonographic, and arthroscopic examinations. Inflammation, effusion, and capsular thickening can be clinically evident in some joints with OA and are more frequently observed using sensitive measures such as ultrasound and MRI (Hall et al., 2014).

Newly Identified Biomarkers

Currently, there is no universal biomarker for OA, and the available biomarkers lack specificity and sensitivity for early diagnosis and monitoring progression of OA. Therefore, new biomarkers are needed. New biomarkers are also needed to distinguish between catabolic and maintenance events because many existing biomarkers reflect normal cartilage turnover, tissue repair, or ECM remodeling. A new biomarker for diagnosing OA should be evaluated by comparison against an established gold standard in an appropriate spectrum of subjects. For OA, an accepted "gold standard" diagnostic test is the radiograph, and typically, K-L grade ≥ 2 is required for a diagnosis of OA (Altman et al., 1986).

De Senny et al. (2011) characterized four novel biomarkers in the serum of knee-OA patients (V65 vitronectin fragment, C3f peptide, CTAP-III, and m/z 3762 protein). Mobasheri (2012) and Mobasheri et al. (2017) recognized that enrichment of the deaminated epitope of D-COMP suggests that OA disease progression is associated with posttranslational modifications that may show specificity for particular joint sites. Fibulin-3 peptides (Fib3-1 and Fib3-2) have been proposed as

potential biomarkers of OA along with FSTL 1 (described above), a new serum biomarker with the capacity to reflect the severity of joint damage. The "membrane attack complex (MAC)" component of complement has also been implicated in OA.

Recently, Mobasheri et al. (2017) identified new biomarkers based on novel technologies, such as "omics." These authors referred to several new biomarkers, such as adipocytokines including leptin and adiponectin. ADAM metallopeptidase with thrombospondin type 1 motif 4 (ADAMTS-4), aggrecan ARGS neoepitope fragment (ARGS) in synovial fluid, and plasma chemokine (CeC motif) ligand 3 (CCL3) were reported as potential new biomarkers of knee OA. New and refined proteomic technologies and novel assays including a fluoro-microbead guiding chip for measuring C-telopeptide of type II collagen (CTX-II) in serum and urine and a novel magnetic nanoparticle-based technology (termed magnetic capture) for collecting and concentrating CTX-II also have great potential to be biomarkers of OA.

DNA-Methylation and MicroRNAs (miR)

Recently, Rogers et al. (2015) examined the role of inflammation-related genes in OA from the perspective of genetics, epigenetics, and gene expression. There is no compelling evidence that DNA variation in inflammatory genes is an OA risk factor. However, there is compelling evidence that epigenetic effects involving inflammatory genes are a component of OA and that alteration in the expression of these genes is also highly relevant to the disease process. van Meurs (2017) stated that current technological advances in the area of "omics" have elevated multiple molecular levels, from detailed sequencing of the genome, to epigenetic markers, such as DNA-methylation and microRNAs (miRNAs), transcriptomics, and metabolomics. The objective is to identify biomarkers that predict OA's early onset and progression. miRNAs have great promise as biomarkers because they are relatively stable in circulation. The exact role of miRNAs in OA is still under investigation, but as such, they could potentially be good biomarkers (van Meurs, 2017). Published studies have focused on one or two miRNAs, based on the hypothesis that they target a gene or metabolism that plays an important role in OA pathogenesis. For example, miR-33a, which is known to be important in cholesterol metabolism (Kostopoulou et al., 2015), was found to also regulate cholesterol metabolism in chondrocytes through the TGF-β1/Akt/SREBP-2 pathway, as well as cholesterol efflux-related genes ABCA1 and ApoA1. miR-370 and miRNA-373 were found to regulate expression of SHMT-2 and MECP-2 in chondrocytes (Song et al., 2015). miR-16-5p has been shown to

regulate SMAD5 expression in cartilage (Li et al., 2015) and miRNA-26a-5p was found to regulate iNOS expression in cartilage (Rasheed et al., 2016). miR-634 has been shown to target PIK3R1 in chondrocytes (Cui et al., 2016). Beyer et al. (2015) identified let-7e as a potential predictor for severe knee or hip OA, but an increase in circulating levels of let-7e could be due to other conditions, such as metabolic dysfunction or ischemic stroke.

miR-140 levels are significantly reduced in human OA cartilage—derived chondrocytes and synovial fluid. Overexpressing miR-140 in primary human chondrocytes promoted collagen II expression and inhibited MMP-13 and ADAMTS-5 expression (Si et al., 2017). These authors demonstrated that intra-articular injection of miR-140 can alleviate OA progression by modulating ECM homeostasis in rats and may have potential as a new therapy for OA. In an OA rat model, Wang et al. (2016) confirmed the effects of miR-98 on apoptosis in cartilage cells in vivo. MiR-98 expression is reduced in the cartilage cells of OA patients and the overexpression of miR-98 inhibits cartilage cell apoptosis, whereas inhibition of miR-98 leads to cartilage cell apoptosis.

Recently, Cong et al. (2017) identified 46 differentially expressed miRNAs involved in autophagy, inflammation, chondrocyte apoptosis, chondrocyte differentiation and homeostasis, chondrocyte metabolism, and degradation of the ECM. Additionally, these authors identified a wide range of miRNAs that have been shown to be differentially expressed in OA. The function of upregulated miRNAs primarily target transcription. These miRNAs may be useful as diagnostic biomarkers and/or may provide new therapeutic targets in OA.

CORRELATION OF CIRCULATORY BIOMARKERS WITH RADIOGRAPHIC/IMAGING BIOMARKERS AND SYMPTOMS OF OSTEOARTHRITIS

Although circulatory biomarkers, particularly of inflammation, are poorly correlated with radiographic or imaging evidence of OA, they are often used for early detection of this disease (Orita et al., 2011). Patra and Sandell (2011) reported that biochemical markers offer potential nonradiographic alternatives to detect early, nonsymptomatic OA. Accumulating evidence supports that COMP predicts MRI cartilage loss and appears as a useful biomarker of early OA (Williams and Spector, 2008). Combinations of cartilage-derived and bone-derived biomarkers have been used in the context of OA presence, severity, and bone turnover in cartilage integrity to assess the impact of treatment (Clark et al., 1999; Patra and Sandell, 2011). Circulatory

biomarkers of inflammation have been used to profile OA progression attesting to the inflammation of OA joints. Stannus et al. (2010) found that the circulating levels of IL-6 and TNF-α are associated with knee radiographic OA and knee cartilage loss in older adults. Berry et al. (2011) investigated the relationship of serum markers of cartilage metabolism to imaging and clinical outcome measures of knee joint structures. Pelletier et al. (2010) reported a decrease in serum levels of MMPs in prediction of the disease-modifying effects of OA drugs assessed by quantitative MRI in patients with knee OA. Of course, there are many other studies that have described correlation between body fluid biomarkers and joint inflammation and cartilage degeneration/loss.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

OA is a disease of the entire joint but primarily causes degeneration of articular cartilage. Currently, there are no reliable, quantifiable, and easily measured biomarkers that provide an earlier diagnosis, inform on the prognosis of disease, and monitor responses to therapeutic modalities. Available biomarkers also lack sensitivity and specificity. Biomarkers of both cartilage proteoglycan and noncollagenous, nonproteoglycan components of cartilage can be detected following their release as a result of turnover and disease. Therefore, continuing quests are underway to identify, test, validate, and qualify biomarkers of OA. Genetic and genomic biomarkers could be essential to stratify OA patients and assess their risk of developing OA later in life with different underlying driving etiologies (van Meurs, 2017). Many molecular "omic" advancements will be made in the near future to the genetic and epigenetic data. Imaging continues to play an important role in OA research, where several exciting new technologies and computer-aided analysis methods are emerging to complement the conventional imaging approaches. New biomarkers are needed to distinguish between catabolic and maintenance events because many existing biomarkers reflect normal cartilage turnover, tissue repair, or ECM remodeling. Circulatory microRNAs are not only offering early detection of disease but also providing basis for the development of novel targeted therapies for OA. There are still many challenges that we have yet to overcome in the near future.

INTRODUCTION

Simply defined, a biomarker is "a specific physical trait or measurable biologically produced change in the body connected with health or disease conditions" (Hunt, 2009). In toxicology practice, biomarkers are associated with some aspect of normal or abnormal biological function resulting from exposure to drugs, food additives, biopharmaceuticals, medical devices, environmental chemicals, and plants. From the three broad biomarker categories of exposure, effect, and susceptibility (Timbrell, 1998; Barr and Buckley, 2011), this chapter focuses on biomarkers of effect, limited to morphologic and clinicopathologic alterations in organs and tissues from which diagnoses are based. Brief descriptions of historical advancements are given, from the systematic practice of autopsies around 1346 and the invention of the light microscope in 1600 and its use in medicine beginning in the 1800s (Rosai, 1997). The 1800s to the recent past, considered to be the diagnostic era, was the period during which pathologists were principally involved in delivering diagnoses of disease conditions (Hunt, 2009). Pathologists arrived at their conclusions from the anamnesis, gross examination of specimens and later histopathologic examination after the light microscope was introduced into medical practice. From the 1960s to the 1990s, the inclusion of special pathology techniques, such as electron microscopy, confocal laser scanning microscopy, immunohistochemistry, and in situ hybridization, facilitated the transition of diagnostic pathology toward a prognostic and therapeutically oriented discipline (Rosai, 1997; Schnitt, 2003; Hunt, 2009). Now, sophisticated and novel technologies that relate to biomarkers of effect, exposure, and susceptibility to disease are becoming available, as

evidenced by the many chapters in this book. These biomarkers aid in disease diagnosis, understanding pathogenesis, defining prognosis, and helping to guide selections of the best options for therapy.

This chapter provides examples of pathological biomarkers, with emphasis on morphologic (gross and microscopic) and clinicopathologic changes. Biomarker examples of the effects of investigational drugs, biologicals, medical devices, environmental contaminants, and poisonous plants are given when the biomarker has been validated and applied in preclinical and clinical studies conducted in humans and animals. However, because of space limitations, not all information can be included; hence, apologies are extended to colleagues whose work has been omitted or inadvertently missed.

DIAGNOSTIC PATHOLOGY

Among the most significant historical advances in the evolution of medicine was the systematic practice of the autopsy/necropsy beginning in the 14th century, followed by the use of the light microscope in the 20th century. Restrictions against opening the human body after death were eased during the Black Death pandemic (1347–1350). Prior to this development, dissection (vivisection) had been carried out since ancient times for reasons related to animistic and naturalistic philosophies rather than to determine the cause of the disease. Hippocrates (468–377 BC), founder of a school of medicine in ancient Greece, taught that disease resulted not from divine or supernatural origin but from natural causes (King and Meehan, 1973). Hippocrates was the first great naturalistic physician and his concepts influenced the course of scientific medicine ever after. However, it

would be almost 1800 years after his death before the autopsy found its place in medicine.

Prior to these milestone events, diagnoses were based on clinical signs and symptoms. It has been reported that before the first histologic examination of colon cancer in humans, diagnosis was based on clinical observations of bowel symptoms, cachexia, and abdominal mass, which were deemed sufficient to confirm the diagnosis, as late as 1990 (cited by Hunt, 2009). Many years elapsed before autopsies became accepted practice; hence the medical practitioner had to have observed the cardinal signs of inflammation: *rubor, tumor, calor, dolor et functio laesa*, learned to recognize gross abnormalities from apparently normal organs and tissues, and applied knowledge of prevailing maladies at the time.

Gross findings were considered in disease diagnosis after physicians performed autopsies on dying patients "to know more clearly the illnesses of their bodies" (cited by Rosai, 1997). The systematic performance of the autopsy ushered the birth of the discipline of pathology in human medicine and, ipso facto, in veterinary medicine. Rosai (1997) reported that those who practiced the discipline of pathology employed morphological techniques to explain symptoms and signs, determine the cause of death, guide therapy, and predict the evolution of disease. With the introduction of the light microscope and other diagnostic techniques in the 20th century, pathology practice evolved to its present state. For the toxicologic pathologist, adequate training and ever-increasing improvements in processes and procedures have resulted in high-quality tissue specimens, proper identification of significant histopathologic findings, and accurate, correctly interpreted diagnoses (Crissman et al., 2004; Van Tongeren et al., 2011).

According to Buck et al. (1973), the accurate diagnosis of toxicosis is based on history, clinical signs, postmortem findings, chemical analysis, and laboratory animal tests. Depending on data availability, diagnoses rendered may vary from suspected (presumptive or preliminary) to definitive or confirmatory as in the following examples.

Enzootic Hematuria

Some cattle at a ranch in Cotabato province, Mindanao Island in the Philippines were clinically observed to have been excreting bloody urine by the farm veterinarian. Leptospirosis was diagnosed earlier following the isolation of *Leptospira pomona* by the Animal Disease Diagnostic Laboratory, University of the Philippines College of Veterinary Medicine (UPCVM), Diliman, Quezon City. However, hematuria persisted even after treatment; hence, a team consisting of a microbiologist, parasitologist, and pathologist from the UPCVM were invited to conduct field necropsies and collect samples for additional tests. During the inspection and tour of the ranch, lush growths of bracken fern were found alongside pasture fences and hillsides on the ranch; hence, bracken fern intoxication was suspected. Fenced cattle are known to be exposed to toxins, such as ptaquiloside and other toxins, mutagens, and carcinogens, from consumption of tips of crosiers and young fronds of the bracken fern along with pasture grasses during grazing (Panter et al., 2011; Panter et al., 2012).

At necropsy, the urinary bladder in three of five animals contained residual reddish urine and multiple red nodules on the bladder mucosa. The nodules correlated histologically with hemorrhagic and proliferative lesions, consistent with those described in bracken fern intoxication (Pamukcu et al., 1976; Jones and Hunt, 1983). The red nodular growths on the urinary bladder mucosa were gross pathological biomarkers. Maxie (1985) reported that more than 90% of cattle with enzootic hematuria had urinary bladder tumors. Being associated with the clinical signs of bloody urination and probable prolonged ingestion of bracken fern, the bladder tumors confirmed the suspected diagnosis of bracken fern—induced toxicity in the cattle herd.

Clinicopathological findings that might be encountered are anemia, leucopenia, monocytosis, thrombocytopenia, hypergammaglobulinemia, microhematuria, and proteinuria (Perez-Alenza et al., 2006). Regarding *L. pomona* infection, Chirathaworn and Kongpan (2014) reported that several inflammatory mediators were higher in susceptible animals versus resistant hosts. Immune responses with cytokines/chemokines and serum proteins (TNFα, IL-6, IL-8, and PTX3) that were induced following *Leptospira* infection may be correlated positively with mortality and were suggested to be biomarkers for disease severity in human with leptospirosis.

There are several studies on the expression of biomarkers in bovine enzootic hematuria (BEH) bladder lesions to detect molecular changes in the different stages of the disease. Up to 13% of the bladder lesions were found to be nonneoplastic and only half of the neoplastic lesions were malignant. The urothelial carcinoma was the most frequent tumor type (Carvalho et al., 2006; Peixoto et al., 2003). Cytokeratin is a protein found in the intracytoplasmic cytoskeleton of epithelial cells commonly used as an immunohistochemistry marker to identify epithelial cells in normal or malignant state. Cytokeratin 7 (CK7) is expressed in the urothelium, and this protein is frequently used to confirm the urothelial origin of tumors (Moll, 1998). There is a conserved transmembrane protein across species namely uroplakins (UPS) that is expressed in the superficial urothelial cells. The marker uroplakin III (UPIII) is also routinely

used to confirm the urothelial origin of tumors. However, in humans and domestic animals, a loss of expression can occur in high-grade urothelial tumors (Ambrosio et al., 2001; Ohtsuka et al., 2006; Ramos-Vara et al., 2003). An immunohistochemical study was performed on epithelial bladder tumor samples from 37 animals affected with BEH. In both high-grade and high-stage urothelial carcinomas, there was loss of UPIII and CK7 expression. Interestingly, there was immunoreactivity for p53 in high-grade and high-stage carcinomas (Cota et al., 2013).

Cyclopia

Consumption of another toxic plant, *Veratrum californicum*, has been associated with distinctive teratogenic abnormalities in ruminants (Burrows and Tyrl, 2001). Jervoline alkaloids in this plant such as cyclopamine, cycloposine, and jervine have been incriminated in producing teratogenic effects in the offspring of ewes and less commonly cows and goats (Panter et al., 2011). Pregnant ewes ingesting the plant from the 12th to the 14th day of gestation may have prolonged gestation due to the absence of the pituitary gland in the malformed offspring. The most striking malformation is partial or complete cyclopia in which one eye or two fused eyes are in a single orbit with a median skin protuberance above. Other abnormalities such as cleft palate and limb reductions have also been described. The gross findings and history of dietary exposure are presumptive diagnostic pathological biomarkers of the toxic plant's teratogenic effect.

Taxus (Yew) Poisoning

There are no characteristic gross or microscopic tissue alterations of Taxus (yew) toxicity. These evergreen plants are ornamental shrubs that contain toxic alkaloids (taxines) and irritant oils, which have been reported to cause sudden death in humans and a variety of animals. All parts of the plant except the aril are highly poisonous, with death attributed to the cardiotoxic effects of taxine alkaloids (Wilson and Hooser, 2018). In ruminants, nonspecific myocardial hemorrhages and focal nonsuppurative interstitial myocarditis have been reported, but diagnosis is usually based on a history of known or potential exposure to the yew plant. In the dairy cow ingesting trimmings of the plant, the presence of leaves, stems, twigs, and seeds or remnants thereof in the stomach contents is diagnostic and recognized as the gross pathological biomarker of yew toxicity. In horses where extensive mastication and digestion of the plant occur, stomach contents may be difficult to assess by the naked eye. Microscopic examination for plant parts and identification of taxine alkaloids in the stomach contents by the gas chromatography/mass spectrometry (GC/MS) method have been used to confirm diagnosis (Tiwary et al., 2005).

Cardiotoxic alkaloids from the yew leaves (*Taxus baccata*) have been identified and quantitated in perimortem samples of serum and gastric contents in human medicine (Musshoff et al., 1993; Stríbrný et al., 2010). The main substance identified by HPLC and GC-MS (gas chromatography/mass spectrometry) was 3,5-dimethoxyphenol, the aglycone of taxicatine. In cases of intoxication by yew, 3,5-dimethoxyphenol can be used as a marker.

Ergotism

Gross lesions occur on the extremities of cattle grazing on pastures infected with the fungi *Claviceps purpurea* and *Neotyphodium coenophialum* or fed grain contaminated with the ergot alkaloids, ergotamine, and ergovaline, respectively. One week after consumption of *C. purpurea*, swelling and redness of the extremities, particularly of the posterior limb, develop and the tips of the ear and tail have gangrene, which may slough off about 2 weeks following ingestion of the ergovaline-producing fungus; necrosis (dry gangrene) of the distal extremities is observed (Jones and Hunt, 1983). The gross observations are indicative of peripheral vasoconstriction induced by the ergot alkaloids produced by the fungal organisms.

Interestingly, an ELISA test to detect ergot alkaloids is available and offered by Randox Food Diagnostics. The Ergot Alkaloid ELISA kit is validated for flour and seed. The ELISA test offers excellent limits of detection for the toxin ergotamine at 1 ppb. GC/MS is routinely used for identification and confirmation of ergot alkaloids. For further details on toxicity and biomarkers of ergot alkaloids poisoning refer to Gupta et al. (2018).

Morphologic (Gross and Microscopic) and Clinical Pathology

Until the light microscope was incorporated into medical practice, gross pathology was the primary means to establish a diagnosis (Hunt, 2009). However, 200 years elapsed from the invention of the very first microscope in 1600 until it was incorporated into medical practice (Hagdu, 2002). Although Anton Van Leeuwenhoek (1632−1723) was the first to use the light microscope to study organisms and Robert Hooke (1635−1703) was the first to use the microscope in the practice of medicine, integration of microscopy into medical practice did not occur until Rudolf Virchow (1821−1902) introduced the light microscope in pathology, allowing the study of cellular and later subcellular events for a better understanding of disease. The use

of the microscope by pathologists enhanced their skills and diagnostic acumen. With the microscope, identification of causative agents and pathognomonic lesions facilitated diagnosis. For instance, light microscopic identification of Negri bodies in neurons of a dog is pathognomonic for rabies. However, few pathognomonic lesions are encountered by the toxicologic pathologist in preclinical safety and toxicity studies.

Solar Injuries

Damage to the skin by ultraviolet (UV) light has resulted in sunburn, solar dermatitis, and neoplasia (Hargis and Ginn, 2006). Solar injuries begin clinically with the cardinal signs of inflammation: *rubor, tumor, calor, dolor et functio laesa*. Gross lesions of erythema, scaling, and crusting occur where there is little or no pigment or hair in the affected skin, whereas the haired or pigmented areas of the skin are unaffected. Microscopically, epidermal acanthosis and follicular hyperkeratosis (comedones) develop. Multiple layers of compacted stratum corneum may form cutaneous horns and the comedones can rupture (furunculosis), releasing follicular contents into the dermis. The endogenous foreign materials, including follicular stratum corneum, hair shafts, and sebum may get infected and cause an inflammatory response with secondary bacterial infection. The gross and microscopic findings and distribution pattern support the diagnosis of solar dermatitis.

Skin Photosensitization

In primary skin photosensitization, gross lesions occur in nonpigmented and lightly pigmented skin and poorly haired areas of the body that include erythema and edema, followed by blisters, exudation, and necrosis and sloughing of necrotic tissue (Hargis and Ginn, 2006). Histologically, there is coagulative epidermal necrosis, which may extend to the superficial dermis, follicular epithelium, and adnexal glands. Fibrinoid degeneration and thrombosis of dermal vessels result in infarction and sloughing of necrotic tissues and secondary bacterial infection. Skin damage occurs as a result of ingestion of preformed photodynamic substances (e.g., helianthrone, furocoumarin, psoralens, phytoalexins) contained in a variety of poisonous plants, or the administration of phenothiazine, which is converted to photoreactive metabolite in the intestinal tract. The photodynamic substances are absorbed into the skin where they react with UV light, releasing energy that produces reactive oxygen molecules, degranulation of mast cells, production of inflammatory mediators, and cell damage. The gross findings on the skin associated with exposure to photoreactive substances are considered to be the pathological biomarkers of primary photosensitization. The results of one research group suggest that changes of cell surface thiols and/or amines may be useful biomarkers to predict photosensitization potential of chemicals (Oeda et al., 2016). Further research is needed to find useful biomarkers for skin photosensitization.

Secondary (hepatogenous) photosensitization occurs primarily in herbivorous animals, but any animal with massive hepatic disorder given a chlorophyll-rich ration can be affected (Hargis and Ginn, 2006). The liver fails to excrete phylloerythrin, a chlorophyll breakdown product formed in the intestinal tract due to inherited hepatic defects, primary hepatocellular damage, or bile duct obstruction from toxic plants, pyrrolizidine alkaloids, or mycotoxins. For example, gross findings associated with the mycotoxin sporidesmin, produced by the fungus *Pithomyces chartarum*, included bile-stained liver with prominent bile ducts, dilated with bile and surrounded by periductal edema. In addition, cholestasis and facial eczema were also observed in affected sheep.

Skin Neoplasia

Chronic exposure to sunlight has been stipulated by Madewell (1981) as the best-known etiologic factor for many skin tumors in animals. After chronic exposure, the skin becomes wrinkled and thickened due to epidermal hyperplasia, fibrosis, and elastosis, which could progress to neoplasia, such as hemangiomas, hemangiosarcomas, and squamous cell carcinomas. The most frequently diagnosed malignant tumor in cattle is ocular squamous cell carcinoma. Although the cause is thought to be multifactorial, cattle with nonpigmented eyelids and conjunctiva are predominantly affected. Premalignant stages including plaques, keratomas, papillomas, and the squamous cell carcinomas are found in the junction of the cornea and sclera, the third eyelid, and on the margins of upper and lower eyelids.

Scrotal hemangioma in boars is rarely reported in North America but common in tropical countries. According to Szcech et al. (1973), the probable index case in the United States was a Chester White boar from a swine-breeding establishment in Indiana. Grossly, a hemorrhagic, 1.0×1.5 cm, dark blue and pedunculated wartlike mass was located at the junction of the scrotum and perineum. Following surgical excision and histopathology, the mass was diagnosed as a capillary hemangioma. Novilla (1989) reported a high number of scrotal capillary hemangiomas, 317 (31% of 1027 boars were affected) from 17 farms in the Philippines (Fig. 53.1). Light-skinned purebred boars had more and larger scrotal tumors than dark-skinned boars had. Two- or three-way crossbred boars tended to have growths in nonpigmented areas of the scrotal skin. Grossly, the

FIGURE 53.1 Scrotal capillary hemangiomas in Landrace Crossbred boars from the Philippines. *Courtesy of Dr. D. A. Novilla, USDA, FSIS Morristown, Tennessee.*

lesions varied from tiny reddish blotches or blebs to pedunculated warty and cauliflower-like masses.

Histologically, the dermis contained lobules of capillary-like vascular spaces lined by mostly endothelial-type cells supported by delicate connective tissue stroma. Gross and microscopic features were consistent with previous descriptions of scrotal hemangioma (Munro et al., 1982) and presumed to be due to exposure to sunlight.

According to Kycko and Reichert (2014), many candidate biomarkers were identified and proven to be not specific enough to be further investigated and developed as a diagnostic tool for skin cancer. Reports concerning proteomic biomarkers of spontaneously occurring tumors in animals provided preliminary results up to this point. Most studies resulted in protein changes involving a small number of cases, which limits the significance of the findings. The candidate biomarkers are usually nonspecific for a particular type of cancer and, in most cases, components of the acute phase response, which is not necessarily associated with cancer.

Iatrogenic Acromegaly in Dogs

Dogs administered progestogens indirectly develop a syndrome of growth hormone excess (La Perle and Capen, 2012). Injection of medroxyprogesterone acetate to prevent estrus in dogs has been shown to produce off-target adverse effects. There is expression of the growth hormone gene in the mammary gland, elevated circulating levels of growth hormone, and clinical manifestations of acromegaly. Affected animals have coarse facial features with markedly folded and thickened skin of the face, enlarged abdomen, and expansion of interdigital spaces.

According to Kooistra (2006), diagnosis of GH excess is established by measuring basal plasma GH levels. The basal plasma GH level in acromegalic animals in many instances exceeds the upper limit of the reference range. The diagnosis may be supported by the measurement of elevated plasma IGF-I levels. IGF-I is bound to proteins and for this reason its level is more stable versus GH. However, there is some overlap in plasma IGF-I levels between healthy animals and individuals with acromegaly.

Endocrine Alopecia

Endocrine alopecia may occur from iatrogenic hyperadrenocorticism or hyperestrogenism in dogs from administration of glucocorticoids or estrogens, respectively. Other reported causes are bilateral adrenocortical hyperplasia secondary to a pituitary tumor, functional adrenocortical hyperplastic nodule, or neoplasm inducing hyperadrenocorticism. Dogs with hyperadrenocorticism have truncal alopecia, sparing the head and limbs, distended abdomen, calcinosis cutis, and thin skin. Histologically, the epidermis, dermis, and hair follicles are atrophic with follicular hyperkeratosis and calcinosis cutis in hyperadrenocorticism.

Hyperestrogenism associated with ovarian cysts in females and functional Sertoli cell tumor of the testis in males also induces endocrine alopecia (Hargis and Ginn, 2006). In hypestrogenism, gross findings include symmetrical alopecia and hyperpigmentation over the posterior trunk and limbs (Fig. 53.2). In addition, male dogs may develop pendulous prepuce and enlargement of the nipples and prostate, whereas female dogs have enlarged vulva and abnormal estrus cycle. Epidermal and follicular hyperkeratosis and follicular atrophy are observed in hyperestrogenism. A history of iatrogenic exposure to glucocorticoids or estrogen together with clinical and morphologic findings supports a diagnosis of endocrine alopecia.
FIGURE 53.2 Hyperestrogenism, iatrogenic diethylstilbestrol, dog. *Reproduced from Pathologic Basis of Veterinary Disease (Fig. 17–69), fourth ed. p. 1223. Academic Press/Elsevier.*

Alopecia and Inhibition of Hair Growth (Mimosine Toxicity)

Fariñas (1951) reported the utilization of the legume *Leucaena glauca*, also known as *ipil-ipil*, Koa haole, or Santa Elena tree, as a fodder and pasture crop in the tropics. However, loss of hair has been reported after ingestion of seeds in native women and seeds and foliage in animals. The toxic nonprotein free amino acid, identified as mimosine or leucenol, was shown to act as a tyrosine analog capable of competitive inhibition of tyrosinase and inhibition of thyroxine decarboxylase (Crounce et al., 1962). Dietary administration of the purified toxic principle and ground seeds to mice produced hair growth inhibition and loss of hair, probably from inhibition of mitosis of hair follicles, especially in the matrix (Montagna and Yun, 1963). Growing (anagen) hairs were affected, and there was complete recovery following withdrawal from treatment. Grossly, the skin appeared thin and atrophic. Histologic findings of absent mitosis, destruction of matrix cells of the hair follicles, and extracellular melanin were observed. Morphologic findings together with a history of exposure to ipil-ipil seeds and foliage are suggestive of mimosine-induced alopecia.

Acute Bovine Pulmonary Edema and Emphysema

Acute bovine pulmonary edema and emphysema (*ABPE* or "fog fever") occurs in adult beef-type cattle grazing fall pastures on changing from sparse dry range to lush green pastures (Dungworth, 1985). Gross findings are observed primarily in the dorsocaudal lobes of the lungs, which are pale, soft, and rubbery in texture and moist on cut section. Microscopically, diffuse interstitial pneumonia with severe alveolar and interstitial edema and interlobular emphysema are observed. There is hyaline membrane formation within alveoli and hyperplasia of type II alveolar epithelial cells in animals that survive for several days.

ABPE is related to increased amounts of L-tryptophan in the ingested pasture grasses, which are metabolized to 3-methyl indole (3MI) in the rumen, absorbed into the bloodstream, and carried to the lung. In the lung, 3MI is converted by mixed function oxidases (MFOs) in Clara cells to a pneumotoxic compound that produces extensive necrosis of bronchiolar epithelial cells and type I pneumocytes and increases alveolar permeability leading to edema, interstitial pneumonia, and emphysema. Experimentally reducing the ruminal conversion of L-tryptophan to 3MI prevents the development of the condition. The history and morphologic findings support the presumptive diagnosis of ABPE.

Toxic Myopathy—Ionophore Toxic Syndrome

Ionophore toxic syndromes have resulted from overdosage, misuse, and drug interactions of feed additives, including formulations with monensin, lasalocid, salinomycin, narasin, maduramicin, laidlomycin, or semduramicin. Target organs damaged by toxic doses of ionophores include the heart and skeletal muscles in all species studied (reviewed by Novilla, 2012). The most important change is a toxic myopathy characterized by focal areas of degeneration, necrosis, and repair in cardiac and skeletal muscles with a variable inflammatory component (Novilla and Folkerts, 1986; Van Vleet et al., 1991). The development of muscle lesions varies among domestic species. The heart is primarily affected in horses, skeletal muscle in pigs and dogs, and there is about equal tissue predilection in rats,

chickens, and cattle. In addition, neurotoxic effects have been reported for lasalocid (Shlosberg et al., 1985; Safran et al., 1993), narasin (Novilla et al., 1994), and salinomycin (Van der Linde-Sipman et al., 1999). Neuropathic changes occurred in peripheral nerves and the spinal cord. Focal swelling, fragmentation, loss of axons, and formation of digestion chambers filled with macrophages were observed in both sensory and motor nerves, and there was vacuolation with swelling, degeneration, and fragmentation of myelin sheaths and axons in the spinal cord.

It is not easy to diagnose ionophore toxicoses. Clinical signs and muscle lesions of monensin toxicoses are not pathognomonic. In the absence of proof of a gross feed mixing error with monensin (usually >5×), the diagnostic pathologist must go through a process of exclusion of potential causes of the lesion. Confirmatory diagnosis requires laboratory assays to determine the identity and amounts of the ionophore involved or concurrent use of an incompatible drug.

In humans, there are three publications of intentional exposure to monensin. According to Kouyoumdjian et al. (2001), a 17-year-old Brazilian male admitted ingesting monensin premix (Rumensin, exact amount unknown), probably to develop muscle. Instead he fell ill, was hospitalized, and died from acute rhabdomyolysis with renal failure. Although the amount of monensin ingested in this case was not estimated, in another case cited by the authors, two deaths among six people who consumed baked goods made with premix were attributed to monensin exposure of at least 10 times the optimum daily dose fed to cattle. In another report from Brazil, a 16-year-old farmworker who ingested approximately 500 mg of monensin (5 g of Rumensin 100 premix) "to become stronger" developed an early and severe rhabdomyolysis followed by acute renal failure, heart failure, and death (Caldeira et al., 2001). More recently, a 58-year-old man after ingesting 300 mg monensin (self-treatment) for suspected brain toxoplasmosis presented with 8 days of vomiting and abdominal pain had severe rhabdomyolysis without renal toxicity and survived (Blain et al., 2017). Echocardiography revealed decreased ejection fraction from 69% to 56% on his echocardiogram. Clinical pathology findings included decreased total CK (from peak above 100,000 to 5192 U/L) following 15 days of aggressive hydration and sodium bicarbonate therapy.

Consequent to ionophore-induced muscle damage, significant increases in enzymes of muscle origin occur (Amend et al., 1981); Van Vleet et al., 1983). Levels of aspartate transaminase, creatine phosphokinase, lactic dehydrogenase, alkaline phosphatase (ALP), blood urea nitrogen (BUN), and total bilirubin (TB) are elevated; calcium (Ca) and potassium (K) levels transiently decrease, whereas sodium (Na) levels are within normal limits. Cardiac troponins (both cTnI and cTnT) were reported to be highly sensitive and specific biomarker of myocardial injury in humans (O'Brien, 2008) and animals. The published range of cardiac troponin I (cTnI) in clinically normal horses was 0.0−0.06 ng/mL compared to that of 0.08−3.68 ng/mL found in six horses gavaged with a single dose of 1.0−1.5 mg monensin/kg body weight (Divers et al., 2009; Kraus et al., 2010). Because these monensin doses are close to the LD50 of 1.38 mg/kg body weight (Matsuoka et al., 1996), it was not surprising that the biomarker revealed the presence of the myocardial injury caused by toxic doses of monensin, as it would for any significant injury to heart muscle. However, the presence of heart injury is insufficient to confirm a diagnosis of monensin toxicity, so toxic exposure must be demonstrated.

Ionophore toxicoses may be suspected when there is a history of a feed-related problem in a group of animals; clinical signs of anorexia, diarrhea, labored breathing, depression, locomotor disorder, *colic*, recumbency, and death; lesions affecting heart and skeletal muscles; or congestive heart failure. The clinical signs and lesions induced by toxic levels of ionophores are not pathognomonic. However, a history of recent introduction of newly formulated feed or supplement to a herd or flock in which signs and lesions are present may cause one to suspect that acute intoxication has occurred. Dose and time factors influence the severity and distribution of lesions. Animals that die soon after exposure may not have muscle lesions discernible by light microscopy. Lesions are likely to be found in animals that survived longer than a week. Although a presumptive diagnosis of ionophore toxicosis can be made based on history, clinical signs, lesions, and considerations of the differential diagnosis, specific assays are needed for confirmatory diagnosis. Confirmatory diagnosis requires efficient laboratory assays to determine the identity and amounts of the ionophore involved and a thorough consideration of differential diagnoses. For suspected cases of monensin toxicity in horses, the exertional myopathies, such as equine rhabdomyolysis (Monday morning disease) and hyperkalemic periodic paralysis, plant poisoning from coffee senna and white snakeroot, blister beetle intoxication, colic, and laminitis (Whitlock et al., 1978; Amend et al. , 1981), should be ruled out as differential diagnoses. Complete herd history, clinical examination, successful supportive treatment, and necropsy may help differentiate these conditions from monensin and other ionophore toxicoses (Tables 53.1 and 53.2).

TABLE 53.1 Clinical Pathology Biomarkers of Ionophore Toxicoses

Drug-Eluting Stents

Stents are commonly used to treat diseased or partially occluded coronary or peripheral arteries by acting as a scaffold to hold open the dilated segment of artery following balloon angioplasty. Early problems associated with use of bare metal stents included restenosis of the artery due to thrombosis and neointimal proliferation. Drug-eluting stents (DESs), first available in the United States in 2003, were developed to decrease restenosis and improve patient outcomes (Fig. 53.3).

DESs are polymer-coated stents impregnated with antiproliferative or antiinflammatory drugs. These stents release drug (eluate) following direct contact with the arterial wall. Common drugs used with DES include sirolimus and paclitaxel, both members of the taxine family used as immunosuppressive or oncologic chemotherapeutic agents. Specific biomarkers of toxicity include evaluation of vessel injury, inflammation, endothelialization, neointimal proliferation, coverage of stent struts, and stent apposition to the artery wall, which can be characterized microscopically with hemotoxylin and eosin, elastin, and trichrome stains. Standardized scoring systems are commonly used to evaluate these parameters. Neointimal proliferation can also be estimated with standard immunohistochemical methods for cell proliferation such as Brdu (bromodeoxyuridine), proliferating cell nuclear antigen (PCNA), or Ki-67.

TABLE 53.2 Summary of Cardiac and Skeletal Muscle Biomarkers

Biomarkers	Sources	Interpretation
LEAKAGE MARKERS		
Cardiac troponin 1 (cTn1)	Cardiac muscle	Cell injury/necrosis
Cardiac troponin 1 (cTnT)	Cardiac muscle	Cell injury/necrosis
Heart-type fatty acid binding protein (H-FABP or FABP3)	Cardiac muscle and skeletal muscle	Cell injury/necrosis
Myoglobin	Cardiac muscle and skeletal muscle	Cell injury/necrosis
Myosin light chains (Mlc)	Cardiac muscle and skeletal muscle	Cell injury/necrosis
Creatine kinase (CK)	Cardiac muscle and skeletal muscle, brain, GI tract	Cell injury/necrosis
CK-MM	Cardiac muscle and skeletal muscle	Cell injury/necrosis
CK-MB	Cardiac muscle and skeletal muscle	Cell injury/necrosis
Lactate dehydrogenase (LD)	All muscle types, liver, RBCs	Cell injury/necrosis
Aspartate aminotransferase (AST)	All muscle types, liver, RBCs	Cell injury/necrosis
Skeletal muscle troponin I (sTnI)	Skeletal muscle	Cell injury/necrosis
FUNCTIONAL MARKERS		
Atrial natriuretic peptide (ANP)	Primarily cardiac atria	Atrial wall stretch
Brain natriuretic peptide (BNP, proBNP, NT-proBNP)	Primarily cardiac ventricles	Ventricular wall stretch

One study has indicated an association of restenosis occurrence after DES implantation with diabetes mellitus, circulating CD45-positive platelets, and neutrophil to lymphocyte ratio (Melnikov et al., 2017).

HEPATOPATHIES

Glycogen Hepatopathy

Glycogen accumulates in hepatocytes secondary to xenobiotics that increase glycogen synthesis or decrease glycogenolysis. Glucocorticoid analog, such as dexamethasone, are potent stimulators of glycogen synthesis, especially in dogs, causing centrilobular hepatocellular hypertrophy secondary to glycogen accumulation (Fig. 53.4). Glycogen accumulation extends into midzonal regions when the effect has greater magnitude. Liver size and weight are increased because of the increased hepatocellular glycogen accumulation. Ultrastructurally, hepatocytes have large accumulations of
FIGURE 53.4 Glycogen hepatopathy caused by corticosteroid administration to a dog. *Courtesy of Dr. V. Meador, Covance Laboratories Global Pathology.*

glycogen free in the cytosol that displaces cytoplasmic components to the cell periphery. Interspersed in glycogen are lipid droplets.

Hepatotoxicity Secondary to Enzyme Induction

Proliferation of smooth endoplasmic reticulum (SER) is a well-documented change seen secondary to administration of xenobiotics that induce cytochrome P450 enzymes (Guengrich, 2007). Hepatocytes have a full complement of cytochrome P450s (CYP) because one of the liver's main functions is metabolism of foreign substances. Induction most commonly occurs in centrilobular hepatocytes. Not all xenobiotics that induce CYP cause proliferation of SER. Proliferation is dependent on the subset of CYP that are induced, as no single agent induces all CYPs. Cytochrome P450 enzymes are grouped into families (e.g., CYP1, CYP2, CYP3) with capital letters designating subfamilies (e.g., CYP1A, CYP1B, CYP1C) and numerals further identifying individual enzymes (e.g., CYP1A1). Not all CYP inducers cause SER proliferation and liver enlargement (Barka and Popper, 1967); however, SER proliferation is nearly pathognomonic for CYP induction.

Classic inducers of SER proliferation are phenobarbital and its analog. Phenobarbital is metabolized by, and induces, cytochrome P4502B, the major membrane protein of SER (2d). Proliferation can be rapid and dramatic, with morphologic changes occurring within 4 days. Liver weight and size are increased. By light microscopy in Hematoxylin and Eosin (HE) sections, centrilobular hepatocytes are hypertrophied because of increased amounts of homogeneous eosinophilic cytoplasm. SER proliferation begins in centrilobular hepatocytes (Fig. 53.5). With increasing magnitude, proliferation will extend into midzonal regions and rarely to periportal hepatocytes. Withdrawal of the inciting xenobiotic is accompanied by a rapid regression of changes (Cheville, 1994). Effete SER forms aggregates that are removed from the cell by autophagocytosis (Feldman et al., 1980).

Hepatotoxicity secondary to hepatocellular enzyme induction can occur through increased activation of xenobiotics to hepatotoxins (Zimmerman, 1999). Subsets of CYP inactivate xenobiotics while others can activate creating reactive electrophiles (Greaves, 2007). Aflatoxin B1, a mycotoxin, is activated to a number of metabolites, including exo-8,9-epoxide, a hepatocarcinogen. Acetaminophen, an analgesic, is activated to a reactive iminoquinone. Trichloroethylene (TCE), an industrial toxicant and previously used anesthetic, is activated to TCE oxide, which forms unstable protein adducts. Troglitazone, an antidiabetes drug, is metabolized to electrophilic reactive metabolites.

Peroxisome Proliferator-Activated Receptor Hepatopathy (Characteristic Lesion by Light and Electron Microscopy) in Rodents

Peroxisomes are identified primarily in liver and kidneys, and they are located in cytoplasm often adjacent to mitochondria. Drug-induced effects on peroxisomes have been reported to increase numbers and cause qualitative changes in appearance, but decrease in numbers has not been reported. Stimulation of the hepatocytes with peroxisome proliferator-activated receptor (PPAR) α causes proliferation of peroxisomes (Fig. 53.6). Drugs that induce CYP4A, e.g., PPARα, cause proliferation of hepatic peroxisomes. The PPARα receptor is the transcription factor that activates CYP4A. In general, the change is quantitative causing an increase in numbers, which is appreciable in the liver, but has also been reported in the kidney. By light microscopy, liver has centrilobular hepatocellular hypertrophy, with enlarged hepatocytes having a finely stippled eosinophilic granular appearance. Liver weight can be increased. Changes in appearance of peroxisomes have been reported, but apart from disappearance of the crystalline core, qualitative changes are seldom detected. There is species susceptibility to peroxisome proliferation: rodents are most susceptible, with dogs, nonhuman primates, humans, and guinea pigs being poorly susceptible.

For the purpose of this discussion, "disorder" is considered as any morphologic change of peroxisomes as evidenced by a quantitative and/or qualitative change compared to control. Compromise of
FIGURE 53.6 Peroxisome proliferation in a rat given peroxisome proliferator-activated receptor alpha. *Courtesy of Dr. V. Meador, Covance Laboratories Global Pathology.*

FIGURE 53.7 Icterus, hemolytic anemia, dog. *Reproduced from Pathologic Basis of Veterinary Disease (Fig. 1–72), fourth ed. p. 58. Academic Press/Elsevier.*

hepatocellular integrity or function is generally minimal, until the magnitude of peroxisome proliferation change is marked, at which point direct effects of peroxisome proliferation may be related to the massive cellular enlargement physically leading to compromised cellular integrity and/or pressure-induced collapse of vascular and canalicular spaces. Diagnosis of peroxisome proliferation is by electron microscopy and staining of tissues with diaminobenzidine.

The demonstration of lysosomal lamellar bodies by TEM might be considered as a pathologic biomarker of phospholipidosis. A readily accessible, reliable, and noninvasive clinical biomarker of phospholipidosis need to be found. Phospholipidosis results from a multiplicity of different molecules involving different tissues. One impediment is that each phospholipidosis-producing chemical must be evaluated independently (Chatman et al., 2009).

Iron Toxicosis

Iron-containing products can increase iron pigment in hepatocytes and/or Kupffer cells. Excessive iron supplementation in dogs and cats has resulted in hemochromatosis due to iron overload in the liver. Cases of iron poisoning have occurred in suckling pigs administered iron dextran intramuscularly and in newborn foals administered ferrous fumarate to prevent anemia (Cullen, 2006). In severe toxicosis, there is significant mortality due to massive hepatic necrosis and affected piglets die soon after injection. There is yellowish brown discoloration (icterus) of tissues, notably those near the injection site. Although the yellowish brown discoloration is considered a gross pathological biomarker in the case of iron dextran poisoning, icterus has been reported in other diseases and conditions with extensive liver damage; see Fig. 53.7.

Copper Poisoning in Sheep

In ruminants, especially sheep, accumulation of copper in the liver may occur over time because of poor regulation of copper storage. Copper toxicity in sheep results from: (1) dietary excess from contamination of pastures from sprays or fertilizer or access to copper-containing mineral blocks intended for cattle; (2) grazing on pasture grasses containing normal copper but inadequate levels of molybdenum, which antagonizes copper uptake by the liver; and (3) grazing on pastures with hepatotoxic plants such as *Heliotropium*, *Crotalaria*, and *Senecio*, which produce pyrrolizidine alkaloids (Cullen, 2006). Sudden release of the copper results in severe hemolytic anemia and extensive hepatic necrosis. The breakdown of erythrocytes results in release of hemoglobin, which stains the plasma pink and discolors the kidney dark blue and the urine dark red. Gross findings are usually characteristic and include generalized icterus, greatly enlarged "gunmetal blue" kidneys with hemorrhagic mottling, mildly enlarged, friable and yellowish liver, distended gall bladder with thick greenish bile, and enlarged brown to black spleen. Microscopically, there are multifocal areas of hepatocellular vacuolation and necrosis in the liver, and the kidney tubules have hyaline and coarsely granular hemoglobin casts resulting from intravascular hemolysis with glomerular filtration of hemoglobin into the uriniferous space.

NEPHROPATHIES

Polycystic Kidney Disease in Rats

Dietary administration of diphenylthiazole to rats for 4—8 weeks resulted in three- to fivefold bilateral and symmetrical enlargement of the kidneys due to marked cystic changes (Carone, 1986). The most prominent enlargement occurs in the outer medulla with radially arranged dilated collecting tubules and occasional dilation of cortical collecting and distal tubules. The histologic correlates include focal degeneration and necrosis and mild tubular dilation of collecting ducts at 2 weeks of feeding and marked cystic change at 4—8 weeks. Recovery from the distinctive morphologic changes occurred after diphenylthiazole treatment withdrawal of 4—8 weeks.

Urinary neutrophil gelatinase-associated lipocalin (NGAL) and IL-18 excretion have been shown to be slightly elevated in ADPKD. However, the increased level does not correlate with alterations in total kidney volume or kidney function. A potential explanation could be the discontinuity between individual cysts and the urinary collecting system in this pathology (Parikh et al., 2012).

Alpha 2-Microglobulin Nephropathy

Abnormal accumulation of alpha 2-microglobulin (alpha-2 mu-globulin) in kidney lysosomes of male rats has been described in nephropathy resulting from exposure to a variety of chemicals, including D-limonene, a constituent of orange juice. The nephropathy is characterized by distinctive cytoplasmic hyaline droplets in epithelial lining cells of proximal convoluted tubules and granular casts at the junction of the inner and outer stripe of the outer medulla and linear mineral deposits in the descending limb of the loop of Henle. Accumulation of hyaline droplets leads to tubular apoptosis followed later by regeneration, exacerbation of spontaneous renal disease, and tumor formation.

Tubulointerstitial Nephritis

A considerable number of xenobiotics can induce kidney injury. Most nephrotoxicants damage the renal tubules with many toxicants affecting specific segments. Microscopic findings include interstitial inflammation, edema, fibrosis, and atrophy. Acute kidney injury has been proposed to encompass the full spectrum of renal injury from minor elevations of serum chemistry values to anuric renal failure (Gwaltney-Brant, 2012). In drug-induced tubulointerstitial nephritis (DTIN) microscopic findings include interstitial inflammation, edema, fibrosis, and atrophy (Wu et al., 2010). Lack of correlation has limited the usefulness of established noninvasive diagnostic biomarkers in defining severity and progression of kidney injury. For instance, renal azotemia (increased BUN) occurs only after approximately 75% of the nephrons have lost function (Turk et al., 1997). According to Wu et al. (2010), a renal biopsy is the gold standard for diagnosis, prognosis, and selection of therapies for DTIN. Urinary monocyte chemotactic peptide-1 (MCP-1) levels correlated with the degree of severity of acute lesions in DTIN. The roles of **NGAL** and α1-microglobulin in chronic lesions need further evaluation (Wu et al., 2010), and to monitor the progression rate of drug-induced chronic DTIN, urinary N-acetyl-β-D-glucosaminidase (NAG) and matrix metalloproteinases (MMPs) 2 and 9 are two possible candidates to consider (Shi et al., 2013).

Ethylene Glycol (Oxalate) Poisoning

Toxic amounts of ethylene glycol, which is commonly used as antifreeze, get metabolized in the liver via alcohol dehydrogenase resulting in formation of oxalates and development of hypocalcemia. The latter occur from the formation of insoluble calcium oxalates that are widely deposited but most severely in the kidney, resulting in crystalluria, which is used as a biomarker for this toxicity. The precipitated calcium oxalates, seen better under polarized light as numerous pale yellow, birefringent (rosette-shaped) crystals in proximal convoluted tubules are consistent and characteristic in animals that die from ethylene glycol toxicity (Thrall et al., 1985; Stice et al., 2018). In addition to ethylene glycol, oxalate poisoning can result from ingestion of oxalate salts, plants with toxic levels of oxalates, and plants infected with fungi that produce oxalates. Grossly, the kidneys are pale, swollen, and feel gritty when cut. Microscopically, degeneration and necrosis of proximal convoluted tubules associated with pale yellow variable-shaped crystals forming sheaves, rosettes, or prisms within proximal tubular lumens, and cytoplasm of the lining of epithelial cells and interstitial spaces confirm the diagnosis of oxalate poisoning.

Melamine Poisoning

Melamine cyanurate crystals (MCA) precipitate in the kidney of dogs and cats ingesting commercial pet food contaminated with melamine and cyanuric acid (Bischoff, 2018). Grossly, there is hemorrhage and interstitial edema primarily of the medullary region and histologic correlates of tubular degeneration and necrosis of distal straight tubules associated with pale yellow to brown crystals that were fan to starburst to globular in appearance within the lumen of the distal straight and collecting tubules. The more downstream location and different morphology of the crystals is diagnostic of MCA poisoning.
FIGURE 53.8 Lead-acid fast inclusion bodies in rat. *Reproduced from Pathologic Basis of Veterinary Disease (Fig. 11—41), fourth ed. p. 654. Academic Press/Elsevier.*

Lead Toxicity

In the kidney, toxic tubular necrosis is caused by several classes of naturally occurring and synthetic compounds, including heavy metals such as lead, cadmium, thallium, and inorganic mercury. The nephrotoxic heavy metal cannot be identified by renal lesions alone, except for lead. Exposure to old paints and batteries may result in lead toxicity in which renal tubular epithelial cells have irregularly shaped intranuclear inclusion bodies that are acid fast (Myers and McGavin, 2006; Fig. 53.8). The inclusion bodies, composed of lead protein complexes, are considered to be a diagnostic pathological biomarker for lead toxicosis.

Nephrotoxicity and Acute Renal Injury

One major factor that explains the distinct susceptibility of the kidney to injury is the exposure to a variety of exogenous compounds (e.g., aminoglycosides, cisplatin, radiocontrast agents) and endogenous compounds (e.g., free hemoglobin after hemolysis, free myoglobin after rhabdomyolysis) via the blood flow. Both kidneys receive roughly 25% of cardiac output. Heavy metals (e.g., chromium, lead, and mercury), analgesics (including acetaminophen and nonsteroidal antiinflammatory drugs), aminoglycoside antibiotics (e.g., neomycin, gentamicin), immunosuppressive agents (e.g., cyclosporine, tacrolimus), and chemotherapeutic agents (e.g., cisplatin, carboplatin) are known common nephrotoxic drugs that cause kidney damage (Schnellman, 2008; Pazhayattil and Shirali, 2014). For drug-induced renal dysfunction, the potential mechanisms underlying their toxicity include alterations in renal perfusion and glomerular filtration, tubular cell damage, and tubular obstructions.

To detect and monitor renal dysfunction, clinical pathology end points such as BUN, serum creatinine (sCr), phosphorus, and urine-specific gravity has been established and used over the past decades. However, these parameters are relatively insensitive indicators in chronic injury and exhibit alteration only when more than two-thirds nephrons have functional deficit (Stockham and Scott, 2008). In addition to BUN and sCr, there are seven renal injury biomarkers with improved sensitivity that was qualified by the FDA to monitor drug-induced renal injury in rats (Dieterle et al., 2010a,b). These seven renal injury biomarkers are kidney injury molecule-1, albumin, total protein, β2-microglobulin, cystatin C, clusterin, and trefoil factor-3 (Rosenberg and Paller, 1991; Witzgall et al., 1994; Ichimura et al., 1998; Han et al., 2002; Davis et al., 2004; Filler et al., 2005; Vaidya et al., 2006; Perez-Rojas et al., 2007; Bonventre et al., 2010; Dieterle et al., 2010a,b; Yu et al., 2010; Vlasakova et al., 2014). Clusterin and renal papillary antigen-1 have been used to detect acute drug-induced renal tubule alterations in rats. Several biomarkers such as NGAL (lipocalin-2) have been used in drug development settings (Ennulat and Adler, 2015; Mishra et al., 2003). For several decades, more traditional biomarkers employing enzymes that are released from damaged renal tubular cells such as ALP, lysosomal enzymes N-acetyl-β-glucosaminidase (NAG), and gamma glutamyltransferase (GGT) have been used as markers of renal injury in animal studies (Clemo (1998); Emeigh (2005); D'Amico and Bazzi (2003).

It is important to understand the relationship between biomarkers and microscopic pathologic changes on the kidney as assessed by light microscopy. Because of renal cell injury, enzymes such as BUN are elevated prerenal, renal, or post renal; but, BUN can also increase with diet, without renal injury. For the kidneys, histopathologic findings remain the gold standard by which biomarkers are validated for use (Table 53.3).

Polioencephalomalacia

Polioencephalomalacia is diagnosed at necropsy of cattle, sheep, and, less commonly, goats observed with clinical signs including depression, stupor, ataxia, head pressing, apparent cortical blindness, opisthotonos, convulsions, and recumbency with paddling of the limbs. Although primarily associated with thiamine deficiency, this may be a multifactorial metabolic disorder. Multiple dietary factors have been proposed, such as feeding high carbohydrate rations with little roughage (Zachary, 2006). In cattle, microcavitation of the deep cortical lamina adjacent to subcortical white matter is characteristic of chronic polioencephalomalacia.

TABLE 53.3	Summary of Renal Injury Biomarkers

Biomarkers	Sources	Interpretation
Kidney injury molecule 1 (KIM-1, TIM-1, HAVCR-1)[a]	Proximal tubules	Toxic, ischemic, septic renal tubular injury
Neutrophil gelatinase-associated lipocalin (NGAL/Lipocalin-2)[b]	Proximal and distal tubules, neutrophils, bone marrow	Renal tubular injury (urinary), inflammatory (blood)
Clusterin	Proximal and distal tubules	Toxic, ischemic, septic renal tubular injury
Cystatin C	All nucleated cells, renal tubules	Plasma levels inversely related to GFR; renal tubular injury (urine)
Alkaline phosphatase (ALP)	Renal tubules	Renal tubular injury
N-Acetyl-β-glucosaminidase (NAG)	Renal tubules	Renal tubular injury
Gamma glutamyltransferase (GGT)	Renal tubules	Renal tubular injury
Total protein	Plasma protein	Glomerular injury
Albumin (microalbumin)	Plasma protein	Glomerular injury
α1/β2-microglobulin	Plasma protein	Glomerular injury and/or proximal tubular injury

[a]May not be useful in canines.
[b]False-positive increases can be induced in neutrophils by various stimuli (inflammation, infections, neoplasia).
Reproduced from A Comprehensive Guide to Toxicology in Nonclinical Drug Development (Table 17.1), first ed. Academic Press/Elsevier, p. 457.

Results from a previous study suggest that gut fill, Cu status, and cytochrome *c* oxidase activity in brain tissue might be influenced and compromised by wet distillers grains with solubles when fed at 60% of diet dry matter in diets based on steam-flaked corn. It might imply a greater susceptibility to polioencephalomalacia (Ponce et al., 2014).

Sodium Chloride Toxicity

Sodium chloride toxicity or salt poisoning has been reported primarily in pigs, poultry, and occasionally in ruminants, horses, and dogs following increased intake of sodium chloride from feed rations or supplements with limited access to drinking water. Gross lesions include inconsistent meningeal congestion and edema, and transverse slices of fixed brain have shown subgross evidence of laminar necrosis. Histologically, laminar cerebrocortical necrosis accompanied by astrocytic swelling and infiltration of meningeal and cerebral blood vessels by eosinophils were observed in pigs. The latter was considered the microscopic pathology biomarker of salt poisoning.

Nigropallidal Encephalomalacia in Horses

Sharply demarcated foci of pale yellowish discoloration to buff-colored foci of softening or cavitation of the substantia nigra and the globus pallidus have been reported in horses grazing on yellow star thistle (*Centaurea solstitialis*) or Russian knapweed (*Acroptilon*

repens) for long periods of time (Cordy, 1978). The gross lesions, which were usually bilateral, correlated histologically with necrosis and loss of neurons as well as necrosis of axons, glia, and blood vessels in the anterior regions of the globus pallidus and substantia nigra. In addition, localized encephalomalacia (necrosis) of the nucleus of the inferior colliculus (Fig. 53.9), the mesencephalic nucleus of the trigeminal nerve, and the dentate nucleus was also reported in horses fed dried Russian knapweed (Young et al., 1960). Morphologic findings
FIGURE 53.9 Equine nigropallidal encephalomalacia. *Reproduced from Pathologic Basis of Veterinary Disease (Fig. 11−79), fourth ed. p. 921. Academic Press/Elsevier.*

are distinctive for the neurotoxicity that develops in horses. A potential biomarker of nigropallidal encephalomalacia in horses would be in relation to oxidative stress. Results from a previous study suggest that glutathione (GSH) depletion by the sesquiterpene lactone repin may increase the susceptibility to oxidative damage in equine nigropallidal encephalomalacia (Tukov et al., 2004).

Phospholipidosis

Cationic amphophilic drugs (CADs) from different pharmacologic classes are known to induce accumulation of phospholipids and drugs within a variety of cells (Reasor, 1989). When taken up by the lysosomal system the CADs, such as chlorphentermine, amiodarone, and chloroquine, may raise intracellular pH and form complexes with polar lipids or mucopolysaccharides, which interfere with lysosomal enzyme activity, resulting in accumulation of polar lipids (Hein et al., 1990). By light microscopy, affected cells are foamy because of presence of lamellar inclusion bodies.

Wünschmann et al. (2006) reported that captive Humboldt penguins found dead after treatment for avian malaria with higher than usual doses of chloroquine had neuronal storage disease. Affected birds were found histologically to have moderate to marked vacuolation of Purkinje cells, neurons of the brainstem, and motor neurons of the spinal cord. By electron microscopy, the cytoplasmic vacuoles were multilayered lamellar structures by electron microscopy, characteristic of drug-induced lysosomal storage disease (Fig. 53.10). For chloroquine toxicity, gangliosides rather than phospholipids are primarily stored (Klinghardt et al., 1981). A tentative
FIGURE 53.10 Chloroquine toxicity in penguin. Electron micrograph of a spinal cord motoneuron with distended perikaryon due to the presence of numerous multilayered concentric lamellar structures. Bar = 300 nm. *Courtesy of Dr. A. Wünschmann, College of Veterinary Medicine, University of Minnesota.*

histopathologic diagnosis may be enhanced by Immunohistochemistry (IHC) with antibodies for autosomal membrane associated protein-2 (LAMP-2) and anti-ADRP for adipophilin. However, the widely accepted standard for a diagnosis of lysosomal storage disease is electron microscopic identification of concentric lamellar inclusion bodies in secondary lysosomes (Monteith et al., 2006).

The central nervous system that contains numerous cell bodies with specific functions is protected from xenobiotics by the blood–brain barrier (BBB); but, some molecules can cross BBB by nature of their physico-chemical properties or design. As of this writing, "there are no routinely used molecular/chemical validated biomarkers to assess xenobiotic related injury to the nervous system."

CONCLUDING REMARKS AND FUTURE DIRECTIONS

This chapter focused on morphologic (gross and microscopic) and clinical pathology findings as pathological biomarkers of adverse effects of drugs, food additives, biopharmaceuticals, medical devices, environmental chemicals, and plants. Introduction of the autopsy/necropsy and the use of the light microscope to investigate diseases were important milestones that provided recognizable postmortem morphologic end points—the gross and microscopic pathological biomarkers. Later, integration of special morphologic pathology techniques resulted in increased accuracy of diagnoses reported accurately and interpreted correctly in a timely manner. Now there are validated biomarkers being used to fine tune diagnosis, prognosis, and therapy with more being discovered through "omics" technologies (Milburn et al., 2013). Because morphologic techniques remain typically the gold standard against which specificity and sensitivity of novel biomarkers are being validated, the toxicologic pathologist should be aware of and adapt to his/her expanding role. As per *Best Practices Guideline: Toxicologic Histopathology* (Crissman et al., 2004), the toxicologic pathologist must be qualified and possess credentials that document a high level of education, training, experience, and expertise and shall be provided well-prepared slides, laboratory test results, and other study information necessary to conduct an accurate pathologic evaluation. A draft guidance regarding the use of histopathology for biomarker qualification studies has been issued (Food and Drug Administration, 2011). Continued improvements in pathology processes and procedures will come from the alignment with *Best Practices Guidelines*. Taken together with the personal integrity of the toxicologic pathologist, this assures a high-quality pathology

report, contributing to the final reports of R&D safety, toxicity, and efficacy studies for the benefit of man and animals.

Oral Pathology Biomarkers

Anupama Mukherjee

Oral Pathology, Microbiology and Forensic Odontology, Goa Dental College and Hospital, Panaji, India

INTRODUCTION

The oral cavity is regarded as a window to the human body. The stomatognathic system plays a critical role in numerous physiological processes such as digestion, respiration, and speech. Subtle and early signs of various diseases often manifest in the oral tissues. This necessitates a detailed study of the oral cavity and its associated structures to identify and understand local and systemic disease processes.

Oral and maxillofacial pathology is a specialty of dentistry and pathology, which deals with the nature, identification, and management of diseases affecting the oral and maxillofacial regions. It is a science that investigates the causes, processes, and effects of these diseases. The practice of oral and maxillofacial pathology includes research along with diagnosis of diseases using clinical, radiographic, microscopic, biochemical, or other examinations and the subsequent management of patients.

Numerous developmental disturbances/disorders often involve the orofacial regions. These may be as a result of hereditary factors, administration of drugs, or even exposure to radiation during dental development. Additionally, the use of tobacco in a smoked or smokeless form or betel quid chewing in synergy with alcohol consumption, predispose an individual to oral potentially malignant disorders (OPMDs) and subsequently oral cancer (George et al., 2011; Sarode et al., 2012). A continuous and excessive exposure to inorganic substances such as fluoride, silica, asbestos, and heavy metals (lead, mercury, etc.) may manifest in the oral mucosa, as a sign of toxicity.

Various biomolecules (growth factors, enzymes, and interleukins) and the presence of toxicants can be assessed in oral samples. Saliva, a biofluid, exclusive to the oral cavity has emerged as a significant diagnostic tool (Langie et al., 2017). The altered concentrations or unusual presence of certain biomolecules in saliva are now being utilized as biomarkers for diagnosis and prognosis. Biomarkers of oral diseases are more routinely evaluated using tissue biopsies. The application of special techniques such as histochemistry and immunohistochemistry allow a more detailed evaluation of the proteomic and molecular profile of diseases. This chapter describes oral pathology biomarkers of select toxicants and diseases.

ANATOMICAL AND HISTOLOGICAL CONSIDERATIONS OF THE ORAL CAVITY

The stomatognathic system displays a harmonious coexistence of functional hard and soft tissues. The hard tissue components include the teeth, temporomandibular joint, mandible, and maxilla, whereas the soft tissue components include the oral mucosa (including tongue) and the salivary glands (Nanci, 2017). (Fig. 54.1).

Teeth

The teeth represent the exposed mineralized structures of the oral cavity. They play a vital role in mastication along with aesthetics and provide support to facial tissues such as the lips and cheeks. Teeth are composed of enamel, dentine, and cementum, which are mineralized, whereas the pulp accounts for the vital, soft, connective tissue enclosed within the tooth.

The oral mucosa refers to the soft tissue lining the oral cavity. Mucosal organization at the various anatomic sites of the oral cavity is categorized as (1) lining mucosa, (2) masticatory mucosa, and (3) specialized mucosa based on its regional variation in structure and function (Table 54.1).

The salivary glands produce a multifunctional fluid, saliva, which moistens the oral cavity. The predominant
FIGURE 54.1 Shows the various anatomical regions of the oral cavity. *Image courtesy: Seeley—Stephens—Tate: Anatomy and Physiology, sixth ed., Part 4-Regulations and Maintenance, Chapter: 24 Digestive System, The McGraw—Hill Companies, 2004.*

functions of saliva include lubrication, mastication, gustation (taste) and digestion. It also plays an important role in speech, oral pH maintenance, and ion exchange between tooth surfaces, along with providing defense against early microbial invasions. Saliva also acts as a vehicle for numerous substances, such as vitamins, drugs, glucose and salts, facilitating their dispersion and rapid absorption by the oral mucosa.

HISTOLOGY OF ORAL MUCOSA

The oral mucosa comprises the oral epithelium and connective tissue. (Fig. 54.2). The epithelium is stratified squamous in nature and may be keratinized or nonkeratinized in different areas. It forms a physical barrier to the external environment. The epithelium is supported by the connective tissue, designated as the lamina propria and submucosa. The connective tissue comprises the vascular, muscular, and neural components. The submucosa in the oral cavity also shows the presence of specialized glandular structures. These are the serous or

seromucous minor salivary gland acini. The organizational relations of the various tissue elements when viewed under a microscope are shown in Fig. 54.3. The basement membrane is a specialized zone that maintains the structural integrity of the epithelium, along with its intimate association with the underlying connective tissue. Histologically, it is observed as an interface between the basal layer of epithelial cells and the lamina propria (Nanci, 2017).

Thus the variable histomorphological features confer each oral site with a specialized function. The areas covered by the masticatory mucosa protect the underlying tissues from microtrauma and abrasions during mastication. The specialized mucosa on the dorsum of the tongue allows for taste perception. Based on the variable keratinization of the oral mucosa, some sites (sublingual, floor of the mouth) are more permeable as compared to others (palate). (Fig. 54.4). The presence of minor salivary gland acini, in conjunction with the major salivary glands, maintains a moistened mucosa. The water content of these secretions acts as a vehicle to facilitate intercellular transport and absorption (Nanci, 2017).

TABLE 54.1 A Comparative Overview of the Numerous Regional Variations of the Oral Mucosa

Region	Overlying Epithelium	Lamina Propria	Submucosa
LINING MUCOSA			
Soft palate	Thin (150 μm), nonkeratinized stratified squamous epithelium; few taste bud present.	Thick with numerous short papillae; elastic fibers forming an elastic lamina; highly vascular with well-developed capillary network	Diffuse tissue containing numerous minor salivary gland acini
Ventral surface of the tongue	Thin, nonkeratinized, stratified squamous epithelium.	Thin with numerous short papillae and some elastic fibers; a few minor salivary gland acini; capillary network in subpapillary layer.	Thin and irregular, where absent, mucosa is bound to connective tissue surrounding tongue musculature.
Floor of the mouth	Very thin (100 μm), nonkeratinized stratified squamous epithelium.	Short papillae; some elastic fibers; extensive vascular supply with short anastomosing capillary loops.	Loose fibrous connective tissue, containing fat and minor salivary glands.
Alveolar mucosa	Thin, nonkeratinized stratified squamous epithelium.	Short papillae, connective tissue containing many elastic fibers; capillary loops close to the surface.	Loose connective tissue containing thick elastic fibers attaching it to the periosteum of alveolar process; minor salivary gland acini.
Labial and Buccal mucosa	Very thick (500 μ), nonkeratinized stratified squamous epithelium.	Long, slender papillae; dense fibrous connective tissue containing collagen and some elastic fibers; rich vascular supply giving off anastomosing capillary loops into papillae.	Mucosa firmly attached to underlying muscle by collagen and elastin; dense collagenous connective tissue with fat, minor salivary glands, some sebaceous glands.
Lips: Vermilion zone	Thin, orthokeratinized, stratified squamous epithelium.	Numerous narrow papillae; capillary loops close to surface in papillary layer.	Mucosa firmly attached to underlying muscle; some sebaceous glands in vermilion border, minor salivary glands and fat in intermediate zone.
Lips: Intermediate zone	Thin, parakeratinized, stratified squamous epithelium.	Long irregular papillae; elastic and collagen fibers in connective tissue.	
MASTICATORY MUCOSA			
Gingiva	Thick (250 μm), orthokeratinized or parakeratinized, stratified squamous epithelium often showing stippled surface.	Long, narrow papillae, dense collagenous connective tissue; long capillary loops with numerous anastomoses.	No distinct layer, mucosa firmly attached by collagen fibers to cementum and periosteum of alveolar process.
Hard palate	Thick, orthokeratinized (parakeratinized in some parts), stratified squamous epithelium thrown into transverse palatine ridges (rugae).	Long papillae; thick, dense collagenous tissue, especially under rugae; moderate vascular supply with short capillary loops.	Dense collagenous connective tissue attaching mucosa to periosteum ("mucoperiosteum"), fat and minor salivary gland acini are packed into connective tissue in regions where mucosa overlies lateral palatine neurovascular bundles.
SPECIALIZED MUCOSA			
Dorsal surface of the tongue	Thick, keratinized, and nonkeratinized stratified squamous epithelium forming various types of papillae, some bearing taste buds.	Long papillae, minor salivary gland acini in posterior region; rich innervation, particularly near taste buds; capillary plexus in papillary layer, large vessels lying deeper.	No distinct layer; mucosa is bound to connective tissue surrounding musculature of tongue.

Cellular permeability is attributed to cell structure and concentrations of substances in the cytoplasm. The lipid bilayer configuration of the cell membrane allows trafficking of lipid soluble substances. Special protein channels and transport proteins help carry water-soluble substances across the cell membrane. These structural characteristics allow for selective permeability across the membrane. The mechanisms by which substances travel across the cell membrane include (1) active transport, (2) passive diffusion, and
FIGURE 54.2 Schematic representation of the various components of the oral mucosa. *Image courtesy: Antonio Nanci, 2017. Ten Cate's Oral Histology-Development, Structure and Function, ninth ed.*

(3) facilitated diffusion. Occasionally, endocytosis may be demonstrated by a cell. However, this is not common in oral epithelial cells.

The stratified squamous epithelium lining the oral mucosa, like all epithelial cells, shows the presence of membrane surface specializations called cell junctions, which allow cell-to-cell communication along with the passage of substances through and between cells. Thus, epithelial cells can allow and promote the diffusion of gases, liquids, and nutrients. Epithelial cells demonstrate four major types of cell-cell junctions. The **tight junction** (zonula occludens) and the **adherent junction** (zonula adherens) are typically close together and each forms a continuous ribbon around the cell's apical end. Multiple ridges of the tight, occluding junctions prevent passive flow of material between the cells. The adhering junctions, usually located immediately below the tight junctions, serve to stabilize and strengthen circular bands around the cells and help hold the layer of cells together (Fig. 54.5).

Both desmosomes and gap junctions make spot-like plaques between two cells. Bound to intermediate filaments inside the cells, **desmosomes** form very strong attachment points and play a major role in maintaining the integrity of the epithelium. **Gap junctions**, which are patches of many **connexons** in the adjacent cell membranes, have little strength but serve as intercellular channels for the flow of molecules. The specific
FIGURE 54.3 A pictomicrograph showing the tissue organization of the oral mucosa. *MSG*, minor salivary glands; *P*, connective tissue papillae; *R*, reticular lamina propria; *SM*, submucosa. *Image courtesy: Ellen Eisenberg, Easwar Natarajan, Bradley K. Formaker, 2018. Oral Mucosa and Mucosal Sensation, Department of Oral Health and Diagnostic Sciences, School of Dental Medicine, University of Connecticut, Storrs, CT, USA.*

arrangement of these junctions forms a "junctional complex" and defines the basolateral surface of a cell (Nanci, 2017).

ORAL PHYSIOLOGY AND PHARMACODYNAMICS

The oral cavity allows for two major routes of administration of drugs, oral (as when ingested) and mucosal. Saliva constantly bathes the oral mucosa and acts as a vehicle allowing dissolution of substances to pass across. Mucosal absorption bypasses first pass metabolism in the liver and directly delivers the drug/substance into the vascular system. Absorption by the oral mucosa occurs predominantly via passive diffusion into the lipid membrane.

Numerous studies have been initiated to understand the process of mucosal absorption, particularly for various drugs. A rapid absorption of drugs/substances via the mouth into the mucosal membranes does not imply that they are immediately transported to the systemic circulation. This is because the rate-limiting step could be the transport of molecules through the mucosal membranes into the systemic circulation. Mucosal absorption is usually rapid and short, depending largely on duration of contact and permeability of the mucosa. The sublingual area/floor of the mouth is most permeable followed by the buccal mucosa and palate. Mucosal permeability is attributed to relative thickness of epithelium, keratinization, and vascularity. The floor of the mouth is mostly vascular and thinly epithelialized. Thus, it demonstrates a rate of absorption about 3–10 times greater than that seen via other routes of administration (Narang and Sharma, 2011).

A key role, in mucosal absorption, is played by the secretory glands of the oral cavity—the major and minor salivary glands. Saliva comprises water, mucin, enzymes, and salts. The anatomical location of the sublingual salivary glands also contributes to maintaining a moist environment that can act as a vehicle for the dissolution and distribution of substances (Nanci, 2017). Certain factors that influence oral mucosal absorption include lipid solubility and permeability of solution (osmosis), molecular weight of substances, and the ionization state (pH).

The cells of the oral epithelium and epidermis are also capable of absorbing by endocytosis. These engulfed particles are usually too large to diffuse through its wall. It is unlikely that this mechanism is used across the entire stratified epithelium. It is also unlikely that active transport processes operate within the oral mucosa. Occasionally large inert substances (heavy metals/pigments) may accumulate in the fine capillaries and tissues present as clinical signs of toxicity or pigmentation.

BIOMARKERS IN THE ORAL CAVITY

Biomarkers have been defined as a biological characteristic that is objectively measured and evaluated as an indicator of normal biological/pathological processes or a response to a therapeutic intervention (Mayeux, 2004). The WHO has defined biomarkers as "almost any measurement reflecting an interaction between a biological system and a potential hazard, which may be chemical, physical, or biological. The measured response may be functional and physiological, biochemical at the cellular level, or a molecular interaction."
FIGURE 54.4 Schematic representation comparing the variable epithelial and connective tissue thickness at various oral sites. The buccal mucosa and floor of the mouth are richly vascular area. *Images courtesy: Niki M. Moutsopoulos, Joanne E. Konkel, 2018. Tissue-specific immunity at the oral mucosal barrier. Trends Immunol. 39 (4), 276—287.*

Biomarkers can be broadly categorized as biomarkers of exposure, which are used in risk prediction, and biomarkers of disease, which are used in screening, diagnosis, and monitoring of disease progression (Mayeux, 2004). Although drug and metal toxicity may manifest as clinically and histologically observable features, these are predominantly biomarkers of exposure/risk. For other oral diseases such as periodontitis, oral squamous cell carcinoma, pemphigus, pemphigoid, oral lichen planus (Sultan et al., 2014; Gopalakrishnan et al., 2016), etc., the evaluation of distinct histological features, proteomic profiles, and gene expression have been used as biomarkers for screening to assess disease progression and aggressiveness (Fernández-González et al., 2011; Mehdipour et al., 2018).

To simplify and categorize the various biomarkers observed in the oral cavity, a three-tier approach may be adopted. This would include a) clinical biomarkers, observable clinical features that reflect the risk/presence of a disease either systemically or locally in the oral cavity (brownish mottled teeth suggestive of fluorosis), and b) tissue biomarkers, the histopathological characteristics that are informative of the degree of variation from normal. They aid in providing a definitive diagnosis and help ascertain the severity or aggressiveness of the disease (keratin pearls as dyskeratosis as seen in squamous cell carcinoma (Gopalakrishnan et al., 2016)). c) Molecular biomarkers include molecular profiles or the expression of specific protein(s), the presence of which may be increased/decreased or be abnormal in a diseased state. These markers may also be used to monitor disease progression or for the evaluation of therapy (antibodies directed against DSG-3 and/or DSG-1 in pemphigus).

COMMON DRUGS AND TOXICANTS SHOWING ORAL MANIFESTATIONS

1. Drugs
   a. Tetracycline/Minocycline
   b. Bisphosphonates
   c. Hydantoin
2. Heavy Metals
   a. Mercury
   b. Silver
   c. Lead
   d. Arsenic
   e. Bismuth
3. Poisonings
   a. Cyanide
   b. Organophosphates
   c. Aluminum phosphide

SELECT DISEASES OF THE ORAL CAVITY

1. Periodontal disease
2. Immunologically mediated oral diseases/ Autoimmune diseases
  a. Pemphigus
  b. Pemphigoid
  c. Oral Lichen Planus
3. Oral squamous cell carcinoma

ORAL BIOMARKERS OF EXPOSURE AND EFFECTS OF SELECT DRUGS/TOXICANTS

Tetracycline/Minocycline

Tetracycline is a broad-spectrum antibiotic introduced in 1948. It was routinely administered to children and adults for the treatment of common infections caused by Gram-positive bacteria. A few Gram-negative bacteria also showed sensitivity to the drug. Minocycline, a semisynthetic derivative of tetracycline, is commonly administered to treat acne. A prominent side effect of long-term administration of tetracycline is its incorporation into various mineralizing sites. This occurs because of the select affinity of tetracycline for calcium ions. The drug forms a chelate with the calcium hydroxyapatite crystals and is deposited into teeth and bones during mineralization. Minocycline causes staining via different mechanisms. The drug assumes a highly protein-bound state and preferentially binds to collagen-rich tissues such as teeth and bones. Alternatively, the chelation of a minocycline breakdown product similar to hemosiderin forms an insoluble complex with teeth (Raymond and Cook, 2015). The excretion of minocycline in the gingival cervical fluid and its subsequent oxidation when incorporated into enamel could also cause staining, which appears as a blackish discoloration. The administration of tetracycline and its derivatives to pregnant mothers (second and third trimester) or children (up to 7 years of age) results in staining of teeth and bones. The distribution and intensity of color vary based on the specific form of the drug along with the duration of exposure.

The occurrence of staining is noted in 3%–6% of minocycline-treated patients. Clinical biomarkers of tetracycline administration include the following:

- Yellowish or brownish-gray staining of deciduous and permanent teeth. Discoloration is more intense at the time of tooth eruption and gradually becomes browner. Occasionally a bluish discoloration has also been reported (Johnston, 2013).
- Chlortetracycline administration leads to brownish-gray color. Oxytetracycline leads to a yellowish color.
- Bright yellow fluorescence under ultraviolet light.
- Minocycline administration causes "black bones," "black or green roots," and a blue-gray to gray hue, darkening the crowns of permanent teeth.

Such teeth usually pose an esthetic challenge and are not functionally compromised. Various techniques such

as composite restorations or dental veneers are often employed to improve patient aesthetics.

Mercury and Silver

Mercury is a glistening, odorless liquid that becomes a colorless and odorless gas when heated. Mercury is very toxic and exceedingly bioaccumulative. It is a major cause of acute heavy metal poisoning. Because mercury is ubiquitous in the environment, individuals are routinely exposed to it via air, water, and food. According to WHO, the maximum allowable environmental level of mercury is 50 μg/day in the workplace. Three major forms of mercury in descending order of toxicity are organomercury, mercury vapor, and inorganic mercury. Organomercury (methyl-, ethyl-forms) is well absorbed or may even be formed because of the interaction of gut flora with inorganic mercury.

The toxic effects of mercury are noted at a cellular level and eventually manifest clinically. Mercury affects cellular integrity and disrupts intracellular calcium homeostasis. Excessive mercury also interferes with transcription and translation, resulting in the disappearance of ribosomes and endoplasmic reticulum activity. These cell organelles are vital for cell functions (Jaishankar et al., 2014). Mercury is largely neurotoxic as it depletes glutathione and thiols. It also leads to the generation of reactive oxygen species (ROS) and oxidative stress. High levels of mercury in the blood can be nephrotoxic and neurotoxic. Severe mercury toxicity, particularly from methyl mercury is termed as the "Minamata disease". It is a severe neurological syndrome characterized by headache, loss of peripheral vision, numbness in hands and feet, general muscle weakness, and damage to hearing and speech. The disease was first noted in Japanese residents of the city of Minamata in 1956 (Yorifuji et al., 2017).

Silver is a heavy metal occurring naturally as a soft, glistening metal. It occurs as a powdery white (silver nitrate and silver chloride) or dark gray to black compound (silver sulfide and silver oxide). Exposure to silver occurs via jewelry, silverware, medication, printed photographic material, electronic equipment, and dental fillings with silver in its metallic form. Excessive exposure to silver results in argyria. A clinical biomarker would be a gray to blue-gray discoloration of the skin and body tissues. This phenomenon is also referred to as "ashen-Gray" discoloration.

Dental amalgam is an alloy of silver and mercury. It contains about 50% mercury, along with other toxic metals such as tin, copper, nickel, palladium, etc. Amalgam restorations continuously leak mercury due to its low vapor pressure and loss due to the galvanic action of mercury with dissimilar metals in the mouth. It has been reported that an amalgam filling releases about 0.8—0.10 μg of mercury vapor each day. Often, residual amalgam from a restoration may be lodged into the gingiva. This can result in a grayish-black discoloration of the localized area referred to as an "Amalgam tattoo." This poses no significant health hazard (Sivapathasundharam, 2016).

A key microscopic biomarker is the appearance of black, granular deposits of silver salt in the submucosa. This is a key feature to rule out localized pigmentation. The measurement of urinary mercury levels in adults and children has been used as a parameter in various studies aimed at understanding the toxic effects of dental amalgam. Results remain elusive because age of the patient, time of sampling, duration since filling, and even masticatory habits have shown to play a role.

Dental practitioners and dental assistants are at a high risk to develop mercury toxicity because of the use of amalgam in dental practice. Handling of mercury during restorative procedures, removal of old amalgam restorations, and mercury spills/open disposal jars pose a long-term health risk. Numerous studies have evaluated mercury levels in the blood, urine, hair, and nails of dental practitioners and reported higher values as compared with patients and nondental professionals.

Lead

Lead is a bluish-gray metallic element that is soft, ductile, durable, and heavy. It is used in a variety of products such as batteries, paint, solders, and ceramics. More recently the use of lead in pipes, gasoline, and cosmetics has been curbed owing to the propensity to cause toxicity. Exposure to lead can occur via ingestion, absorption (from skin), or inhalation. Lead poisoning (plumbism, saturnism, painter's colic) may manifest as acute or chronic poisoning. The severity of presentation depends on the amount of lead in the blood and tissues, as well as duration and amount of exposure. Organic forms of lead are more toxic than inorganic forms. The excess lead binds to the sulfhydryl groups of proteins. It also causes an inhibition in the synthesis of heme, an essential component of hemoglobin, myoglobin, and various cytochromes.

Plumbism can present in an acute or chronic form based on duration of exposure. Nausea, vomiting, diarrhea, muscle pain, abdominal pain, and weakness are noted in clinically acute lead poisoning. Headaches, fatigue, stupor, and anemia are noted due to chronic lead poisoning. Additionally, oral signs would include astringency, metallic taste in the mouth, and the appearance of "lead hue," a biomarker of chronic lead exposure. It appears as a characteristic bluish-gray line along the free gingiva around the tooth.

A tissue biomarker of plumbism is the perivascular deposit of lead sulfide in the submucosa and basement

membrane zone. In tissue samples, lead can be demonstrated histochemically using the rhodizonate method. Blood levels of lead have often been used to aid in the diagnosis of lead toxicity/poisoning, which is a clinicopathological correlation. It is suggested that cognitive impairment occurs at blood lead levels of 5 μg/dL, particularly in children. At highly elevated blood lead levels of 70 μg/dL, encephalopathy, seizures, and even death may occur (Jaishankar et al., 2014; Ihmed, 2016).

In a study by Gardner et al. (2016), saliva has been reported as a reliable sample for lead evaluation when screening children for toxicity. Based on their study, saliva was reliable for lead concentrations of less than 5 μg/dL. Salivary samples with a concentration of lead greater than 1.40 μg/dL should be confirmed using blood evaluation.

The oral cavity provides subtle indications of toxicities and poisonings. Data regarding the correlation between the clinical biomarkers and serum and/or salivary levels of metals remain unexplored. Often in case of acute toxicity or poisoning, the systemic manifestations are overwhelming, and diagnosis based solely on oral biomarkers is not necessitated. In the case of inert metals, such as silver or exposure to amalgam, oral findings are often suggestive and diagnostic when correlated with history and examination.

BIOMARKERS OF SELECT DISEASES

Biomarkers have assumed a forefront in the assessment of numerous oral diseases. This approach allows them to be categorized as screening, diagnostic, and prognostic biomarkers. Biomarkers are evaluated using techniques ranging from routine histopathology to specialized techniques, such as immunohistochemistry, ELISA, immunofluorescence, and even fluorescence in situ hybridization (to detect gene fusions and characterize soft tissue tumors).

PERIODONTAL DISEASE

Periodontal disease refers to a microbial infection affecting the supporting structures of the tooth, that is, the gingiva, periodontal ligament, and alveolar bone. It predominantly affects the connective tissue structures and is clinically preceded by gingivitis. If not intercepted, periodontal disease progressively leads to loss of tooth support and eventually tooth loss. Periodontal disease affects almost 50% of the adult population in the United States. The clinically observable biomarkers of gingivitis include bleeding on probing the gingival

crevice, along with redness and edema of gingival tissues (Taba et al., 2005).

The clinically evaluated diagnostic biomarkers for periodontitis include pocket formation due to loss of attachment at the dentogingival unit and gingival recession, which is the apical migration of the gingiva. These features are often accompanied by tooth mobility. A diagnostic radiographic finding of loss of alveolar bone is significant. Aggressive forms of periodontal disease can lead to early tooth loss resulting in masticatory difficulties and poor aesthetics. Over a long period, it may also render the jawbones unsupportive to rehabilitation techniques such as dental implants or prosthesis. Hence, methods for early detection and assessment of disease progression could decrease morbidity. Tools to measure periodontal disease at the clinical, cellular, and molecular level have been devised. Studies evaluating saliva and gingival crevicular fluid (GCF), a fluid found in the space between the tooth and gingiva, for potential biomarkers of periodontal disease have been carried out. Considering that periodontitis is characterized by connective tissue destruction, the levels of matrix metalloproteinases (MMP) in GCF have been evaluated. In particular, MMP-8 has demonstrated an 83% sensitivity and 96% specificity in differentiating periodontitis from gingivitis and other disease sites. A study by Holmlund et al. (2004) reported an increase in IL-1α, IL-1β, and IL-1 receptor antagonist, which are associated with bone resorption, particularly in samples from diseased sites.

It has been established that an increase in prostaglandins (PGE2), IL-1β, and TNF-α is associated with the severity of periodontal disease. A review by Loos and Tjoa (2000) identified GCF-related probable diagnostic biomarkers of periodontitis. This included alkaline phosphatase, β glucuronidase, cathepsin B, collagenase-2 matrix metalloproteinase (MMP-8), gelatinase (MMP-9), dipeptidyl peptidase (DPP) II and III, and elastase. Early detection could help address and arrest the disease in its initial stage, using suitable therapeutic regimens of antibiotics, oral prophylaxis, and root planning procedures.

IMMUNOLOGICALLY MEDIATED ORAL DISEASES

Autoimmune diseases encompass a group of diseases where an immunological dysfunction results in failure of the host to recognize and distinguish self- from non—self-tissues. Some conditions which present as mucocutaneous diseases, may manifest solely in the oral cavity, at a given time and pose a diagnostic challenge. In such a situation, the use of specific biomarkers can help eliminate other differential diagnoses and allow effective

treatment planning. Some of the immunologically mediated oral diseases are listed below:

- Hypersensitive Reaction
- Pemphigus vulgaris
- Paraneoplastic pemphigus
- Cicatricial or mucocutaneous pemphigoid
- Cutaneous, bullous pemphigoid
- Lichen planus
- Scleroderma
- Bechet's syndrome

- Reiter's Syndrome
- Linear IgA
- Epidermolysis bullosa
- Erythema multiforme

- Lupus erythematosus

- Systemic drug reaction
- Crest syndrome

PEMPHIGUS

Pemphigus is classified as a vesiculobullous lesion with an autoimmune pathogenesis. Pemphigus is a broad term that encompasses a number of mucocutaneous presentations. The term "Pemphigus" is derived from the Greek word "Pemphix" implying blister or bubble (Mignogna et al., 2009). Some cases that involve the skin and mucous membranes extensively may pose to be life threatening (Azizi and Lawaf, 2008).There are various subtypes of pemphigus, each of which are characterized by the loss of normal cell-to-cell adhesion secondary to the binding of autoantibodies. This results in the formation of an intraepithelial vesicle with acantholysis (loss of cellular cohesion) (Mignogna et al., 2009; Zunt, 1996).

The three major subsets of pemphigus are (1) pemphigus vulgaris, (2) pemphigus foliaceus, and (3) paraneoplastic pemphigus. Pemphigus vulgaris is a relatively rare disease with an onset around 50—60 years of age. It commonly affects the oral mucosa. Oral lesions precede cutaneous lesions and are often the first sign of disease. They are described as "first to show and last to go" because they are the most challenging to address with therapy.

Clinically, lesions are noted on the soft palate, buccal mucosa, lower lip, and ventral surface of the tongue. They appear as oral vesicles and bullae that readily rupture to give rise to multiple eroded ulcers that may bleed.

The condition is attributed to the abnormal production of autoantibodies directed toward the specific molecules desmoglein-3 (DSG-3) and desmoglein-1 (DSG-1). Both molecules are structural components of desmosomes which are a type of cell junction. (Azizi and Lawaf, 2008). The disruption of cell adhesion leads to blister formation. The expression of DSG-3 is seen in the parabasal cells of the oral epithelium and epidermis. DSG-1 is noted in the superficial layers of the epidermis and minimally expressed in the oral epithelium. Thus, patients with autoantibodies directed only toward DSG-1 shall exclusively demonstrate dermal lesions, whereas those with autoantibodies directed toward DSG-3 alone, or DSG-1 and DGS-3, shall demonstrate oral lesions (Mignogna et al., 2009).

PEMPHIGOID

Pemphigoid is also classified as a vesiculobullous lesion with an autoimmune pathogenesis. The term pemphigoid represents the similarity in its clinical presentation with pemphigus. Yet its histopathological features, immunological findings, and prognosis differ. Two distinct lesions, mucous membrane pemphigoid, and bullous pemphigoid are observed (Neville et al., 2015; Sivapathasundharam, 2016).

Mucous membrane pemphigoid or cicatricial pemphigoid refers to a heterogeneous group of blistering lesions caused by autoantibodies that are directed toward any of the numerous components of the basement membrane (Xu et al., 2013). It is usually seen in females 50—60 years of age. Intraoral lesions are seen more commonly as compared to bullous pemphigoid. Clinically, the appearance of bullae or vesicles is noted. They rupture to form ulcerated, denuded surfaces on the mucosa and may persist for weeks to months if left untreated. Other mucosal surfaces in addition to the oral cavity, such as the conjunctival, nasal, laryngeal, esophageal, and vaginal mucosa, may also be involved (Petruzzi, 2012; Xu et al., 2013). In some cases, dermal involvement is also seen. The clinical course in patients is usually progressive and protracted as compared to bullous pemphigoid (Zunt, 1996).

The appearance of denuded gingiva termed as "desquamated gingivitis" is often used as a clinical biomarker to differentiate this lesion from bullous pemphigoid, though it may also be seen in erosive lichen planus or pemphigus vulgaris. Bullous pemphigoid is described as the most commonly occurring autoimmune condition (Xu et al., 2013). It is characterized by the production of autoantibodies toward the components of the hemidesmosome cell surface specializations that attach the basal cells to the basement membrane.

Clinically, it is noted in older adults usually 60—80 years of age with no gender predilection. Involvement of the oral mucosa is not a very common finding. If present, oral mucosal lesions are usually noted as shallow erythematous ulcers with smooth and distinct margins. This is due to the rupture of the intraoral vesicle/bullae as a result of constant low-grade trauma

TABLE 54.2 Clinical and Tissue Biomarkers That Aid in Eliminating Some Confounding Vesiculobullous/Autoimmune Lesions

Condition	Mean Age	Sex Predilection	Clinical Features	Histopathology
Pemphigus vulgaris	40–60 years	Equal	Vesicles, erosions, and ulcerations on any oral mucosal site or skin surface	Intraepithelial clefting
Paraneoplastic pemphigus	60–70 years	Equal	Vesicles, erosions, or ulceration on any mucosa or skin surface	Subepithelial and intraepithelial clefting
Mucous membrane pemphigoid	60–70 years	Female	Primarily mucosal lesions	Subepithelial clefting
Bullous Pemphigoid	70–80 years	Equal	Primarily skin lesions	Subepithelial clefting

Based on Xu, H.-H., Werth, V.P., Parisi, E., et al., 2013. Mucous membrane pemphigoid. Dent. Clin. North Am. 57 (4), 611–630; Neville, B., Damm, D.D., Allen, C. et al., 2015. Oral and Maxillofacial Pathology, fourth ed. Elsevier, Amsterdam; Sivapathasundharam, B., 2016. Shafer's Textbook of Oral Pathology. Elsevier, India.

within the oral cavity. Even though numerous clinical findings can be enlisted to differentiate pemphigus and pemphigoid, histopathological and immunological evaluations provide a more definitive diagnosis, particularly in cases that do not show a classical presentation. Clinical and tissue biomarkers that distinguish and aid in eliminating some confounding vesiculobullous/autoimmune lesions are summarized in Table 54.2.

ORAL LICHEN PLANUS

Lichen planus is a chronic inflammatory mucocutaneous condition. Oral lichen planus (OLP) refers to the oral presentation of the disease, and it may/may not be accompanied by skin lesions. Females in the fifth to sixth decade of life are more commonly affected (Fernández-González et al., 2011). A vast spectrum of clinical presentations are noted, such as unilateral or bilateral white striations, papules, or plaques on the buccal mucosa, labial mucosa, or tongue. The appearance of "striae of Wickham" is a pathognomic clinical feature of oral lichen planus. Lesions involving the gingiva cause inflammation and denudation of the surface epithelium (Kamath et al., 2015). This phenomenon is also referred to as desquamative gingivitis. Erythema, erosion, and blisters may or may not be present.

Numerous theories have been cited to understand the pathogenesis. OLP is regarded as a dysregulated T cell-mediated disorder to exogenous triggers or a dysregulated response to autologous keratinocyte antigens (autoimmune) (Fernández-González et al., 2011). A number of etiological agents have been proposed, such as:

1. local and systemic inducers of cell-mediated hypersensitivity,
2. stress,
3. autoimmune response to epithelial antigens or a dysregulated response to external antigens, and
4. viral infections.

Histopathologically, the pathognomonic features of lichen planus include liquefactive degeneration of basal cell layer, saw tooth rete pegs, a band of chronic inflammation in the sub-basilar region, along with supplementary findings such as hyaline/colloidal bodies and Max–Joseph cleft (Fernández-González et al., 2011; Kamath et al., 2015; Mehdipour et al., 2018).

Lichen planus is not a life-threatening disease, but it continues to be listed as a potentially malignant disorder (OPMD) (Sarode et al., 2012). This has been attributed to mixed reports of malignant transformation of OLP to oral squamous cell carcinoma (Fitzpatrick et al., 2014). The presence of chronic inflammation, as seen with OLP, has been recognized as a potential cause of malignant transformation.

Diagnosing OLP is a clinicopathological correlation and may pose a challenge because similar clinical features may also be noted in oral lichenoid reaction (an allergic response to drugs, restorative materials, betel quid chewing, etc.), pemphigus, pemphigoid, and leukoedema. In such cases, evaluation of biomarkers using immunofluorescence can help eliminate other possibilities.

Immunofluorescence is based on the principle of antigen–antibody reaction. The resulting complex is tagged with a fluorescent compound to allow visualization. Two major techniques are utilized, direct immunofluorescence (aims at detecting the presence of the antigen in the patient's biopsy sample) and indirect immunofluorescence (aims at detecting the presence of antigen-directed antibodies in the patient's serum). Because autoimmunity is a dysregulation of the immune system, antigen and antibody evaluations, along with the distribution of the immune complex, can be utilized as a specific diagnostic biomarker. The application of immunofluorescence in the diagnosis of immune-related

TABLE 54.3 Application of Immunofluorescence for the Diagnosis of Immune-Mediated Lesions

Lesion	Direct Immunofluorescence	Indirect Immunofluorescence
Pemphigus vulgaris	Intercellular deposition of IgG (IgG 1 and 4) throughout epidermis—chicken wire/fish net appearance	Intercellular circulating IgG autoantibodies that bind to epidermis in 80%—90% cases
Paraneoplastic pemphigus	IgG with or without C3 in an intercellular pattern. Granular or linear deposition of C3, IgG, and/or IgM along dermal—epidermal junction in minor cases	Both intercellular intraepidermal antibody deposition and along dermal—epidermal junction
Cicatricial pemphigoid	Linear deposits of C3, IgG, IgA at dermal epidermal junction—"shoreline pattern"	Circulating IgG autoantibodies directed against basement membrane one in 20% cases + circulating autoantibodies to laminin 5
Bullous pemphigoid	IgG (70%) and C3 (90%—100%) deposition at dermal—epidermal junction	Circulating autoantibodies against basement membrane zone
Erythema multiforme	Granular deposits of IgG, C3, IgM, and fibrinogen around dermal vessels or at dermal—epidermal junction	—
Lichen planus	Shaggy deposit at dermal—epidermal junction of IgM (within scattered cytoid bodies), C3 and IgG with fibrin deposition at basement membrane zone	—
Systemic lupus erythematosus	Deposition of IgG, IgM, or C3 in a shaggy band at basement membrane (positive Lupus band test)	—

conditions has gained universal acceptance (Anuradha et al., 2011; Rastogi et al., 2014) (Table 54.3).

ORAL SQUAMOUS CELL CARCINOMA

A tumor is defined as an abnormal mass of tissue, the growth of which exceeds and is uncoordinated with that of the normal tissues and persists in the same excessive manner after the cessation of the stimuli that evoked the change. Tumors can be benign or malignant based on their proliferation characteristics, local tissue invasion, and behavior. The head and neck region is afflicted by distinct tumor entities that may affect the face, oral cavity, nasal and paranasal structures, pharynx, and salivary glands. Oral squamous cell carcinoma (OSCC) accounts for almost 90% of all oral cancers, with over 300,000 new cases reported annually worldwide. OSCC is a malignant epithelial neoplasm affecting the mucosal lining of the oral cavity and oropharynx. Despite attempts aimed at early diagnosis and improving treatment and prognosis, OSCC continues to have a dismal 5-year survival rate of 55%. OSCC can affect the tongue, buccal mucosa, gingiva, palate, floor of the mouth, and lips in decreasing incidence. Most cases are detected at an advanced stage and therapeutic alternatives are expensive and disfiguring. OSCC was reported to be a "disease of the elderly" because it commonly affected males over the age of 50. More

recently, a bimodal distribution of cases has been reported, some as early as in 27—30 year old individuals.

The use of tobacco in a smoked/smokeless form with or without the synergistic effects of alcohol consumption is a major risk factor to develop the disease. The malignant transformation of OPMDs (leukoplakia, oral submucous fibrosis, and oral lichen planus) (George et al., 2011; Sarode et al., 2012) continues to bewilder clinicians and researchers because of the unpredictable course of these diseases culminating into OSCC. Recently, the role of chronic inflammation due to microtrauma, chronic mucosal irritation, sharp tooth, or denture clasps has also been recognized as leading to nonhabit-associated OSCC.

The molecular aspects of OSCC reveal the derangement of basic cellular processes that govern DNA repair, cell proliferation, and cell survival. This is led by genetic alterations and mutations that dysregulate normal functions. Mutation in tumor suppressor genes-p53 and/or oncogenes such as epidermal growth factor receptor (EGFR), Bmi (B lymphoma Mo-MLV insertion region 1 homolog), c-myc, RAS result in uncontrolled proliferation and cell survival (Lavanya et al., 2016). The tumor also establishes a microenvironment conducive for its proliferative and metabolic needs. As the tumor thrives, the increase in vascular and lymphatic channels provides routes for metastasis to lymph nodes and distant organs. Thus, OSCC cannot be viewed solely as an epithelial pathology but more like a rouge organ.

Attempts to grade (degree of disorganization of epithelium) and stage (disease severity) the disease have been made so as to facilitate treatment planning and prognostication. Often, cases within the same stage/grade demonstrate a variable outcome. Hence, the accurate evaluation of tumor aggressiveness and behavior remains a challenge.

Biomarkers for tumors include histopathological characteristics (tissue markers) and tumor markers.

Routine histopathology remains the gold standard for diagnosis and can be regarded as a definitive diagnostic tissue biomarker. Other specialized techniques such as immunohistochemistry, ELISA, and immunofluorescence have been proposed to actively evaluate the various phases of tumor development from initiation, promotion, and progression (Lavanya et al., 2016). A tumor marker is a substance present in or produced by a tumor or the tumor's host in response to the presence of the tumor and can be used to differentiate a tumor from normal tissues or to determine the presence of a tumor based on its measurement in blood or secretions (Rivera et al., 2017).

Scully and Burkhardt (1993) proposed that tumor markers can be categorized based on (1) tissue and cell site specificity, (2) their interaction with tissues, and (3) their association with tumoral processes such as invasion and metastasis. The role of tumor markers as an aid for early diagnosis, disease prognostication, and for treatment evaluation has steadily evolved.

The application of tumor markers for OSCC attempts to address two major challenges:

- to predict the transformation of oral potentially malignant disorders (leukoplakia, erythroplakia, discoid lupus erythematosus, oral submucous fibrosis) to frank malignancy (OSCC), and
- to predict metastasis and understand tumor behavior and aggressiveness.

The evaluation of tumor tissue, patient blood, and salivary samples has been carried out in an attempt to unravel efficient biomarkers. Because a universally accepted panel of markers is yet to be proposed, we regard the listed markers as "potential tumor biomarkers." An enhanced expression of Bmi and survivin in OPMDs, which transformed to OSCC, has been demonstrated. Increased expression of transforming growth factor alpha (TGF-α), epidermal growth factor receptor (EGFR), and fibroblast growth factor receptor (FGFR) have been suggested as early markers for head and neck carcinogenesis (Feng et al., 2013).

The expression of cytokeratin (AE-1/3) can aid in characterizing the epithelial cell of origin in tumors, which are atypical or dedifferentiated. Cytokeratin-19 (CK-19) is associated with high-grade dysplasia and early OSCC, whereas cytokeratin-13 (CK-13) has been proposed as a prognostic marker to reveal metastasis and tumor progression (Frohwitter et al., 2016). The decrease in expression of cell adhesion molecule E-cadherin and an increase in N-cadherin is indicative of an invasive aggressive tumor.

To understand the stromal response, expression of vascular endothelial growth factor (VEGF), matrix metalloproteinases (MMP-2,-9,-13), alpha smooth muscle actin (α-SMA), interleukin-8 (IL-8), CD-163, and CD-44 have been evaluated in addition to over 35 other markers with promising results. Although studies have been carried out on tumor tissues, the salivary biomarkers that are significantly altered in OSCC patients are inhibitors of apoptosis (IAP), squamous cell carcinoma associated antigen (SCC−Ag), carcinoembryonic antigen (CEA), carcino-antigen (CA19-9), CA128, serum tumor marker (CA125), tissue polypeptide specific antigen (TPS), reactive nitrogen species (RNS) (Radhika et al., 2016) and 8-Oxo-2′-deoxyguanosine (8-OHdG), which are critical markers of DNA damage, lactate dehydrogenase (LDH), and salivary IgA(s-IgA), to name a few.

SALIVA: A HIDDEN PLETHORA OF BIOMARKERS

Saliva is the exclusive omnipresent biofluid of the oral cavity. It is the result of synthesis and secretion of products from the major and minor salivary glands. Saliva is attributed with distinct functions, as previously stated, and contributes toward maintaining oral health. In the event of oral disease infection, inflammatory or neoplastic, alterations in salivary constituents have been demonstrated. Over 100 potential salivary biomarkers have been reported. A variety of techniques such as liquid chromatography, gel and capillary electrophoresis, mass spectrometry, microbial cultures, immunoassays, and magnetic bead immunoprecipitation have been used to evaluate the proteomic, metabolomic, and microbiomic classes of salivary biomarkers (Wang et al., 2016).

Saliva is considered as the best diagnostic tool for periodontitis. A salivary sample can help ascertain the number and taxa of bacteria and help categorize the disease (Aimetti et al., 2012). A diagnosis of Leishmaniasis in asymptomatic patients can be established by detecting the *Leishmania siamensis* DNA in salivary samples via polymerase chain reaction (PCR) even before its appearance in blood (Siriyasatien et al., 2016). The detection of HIV antibodies in saliva has paved the way for rapid diagnostic kits allowing self-testing, prior to

laboratory confirmation (Wang et al., 2016). OraQuick is an in-home oral swab-based testing kit, approved by the FDA for use in the United States (US Food and Drug Administration, 2017).

Dental caries is a microbial disease of the teeth, characterized by the irreversible loss of tooth structure due to demineralization of the inorganic component along with dissolution of the organic matrix constituting a tooth. Salivary samples from patients can be evaluated using specific tests referred to as caries activity tests. The *Lactobacillus* colony count test provides information regarding the microbial load of the cariogenic bacteria *Lactobacillus*. The Snyder test evaluates the ability of salivary microbes to form organic acids from a carbohydrate substrate, which eventually leads to demineralization of the tooth. Enamel solubility test and saliva flow rate are a few other saliva-based investigations that are employed as predictive biomarkers for dental caries (Wang et al., 2016). As a result of the evaluation, preventive measures may be adopted for highly susceptible individuals or the caries vaccine may be advised.

Antibodies (IgG) directed against dengue virus antigen, Ebola virus antigen, and *Plasmodium falciparum* antigens have also been detected in saliva. The application of these markers in a clinical setting warrants further investigation and validation. Numerous studies have investigated the correlation of serum and salivary glucose levels in diabetics (Gupta et al., 2015). An ongoing challenge of this correlation is to establish a noninvasive, rapid investigation to monitor the glycemic status of patients.

In an attempt to facilitate early diagnosis of OSCC, the evaluation of potential biomarkers such as cytokines, i.e., interleukin-6, interleukin-8, matrix metalloproteinases MMP1, MMP3, MMP9, TNF-α, vascular endothelial growth factor A (VEGF-A), fibroblast growth factors, and transferrin in salivary samples has revealed promising results (Radhika et al., 2016). The assessment of CD-59, profilin, and Mac-2–binding protein (M2BP) have demonstrated an 83% specificity and 90% sensitivity for OSCC detection (Wang et al., 2016). SaliMark OSCC is a recently developed noninvasive saliva-based evaluation to detect OSCC. An introduction of these evaluation techniques, as part of a routine work-up, needs further validation.

Investigating the role of saliva in the detection of distant malignancies is still under way. A study by Bigler et al. (2002) suggests that the response to chemotherapy in breast cancer could be measured by the expression of an oncogenic protein c-erbB-2 in saliva. It is evident that saliva holds numerous biomarkers that are yet to be assayed and correlated. (Fig. 54.6). The major challenges for investigations and research

using saliva include (1) inherent variability of the sample due to dehydration, use of medication or salivary gland disorders, and (2) inconsistent sample collection techniques along with the confounding effects of diet, oral hygiene status, and contamination with oropharyngeal secretions with the samples collected. Yet, salivary diagnostics and investigations remain a promising avenue to be explored owing to the ease of sample collection, patient compliance, and substantial availability of sample, with minimal risks of collection site complications or infections. Thus, the assay of salivary biomarkers could be applied as predictive and diagnostic biomarkers, contributing toward disease prevention, early diagnosis, disease monitoring, and evaluation of treatment.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The exposure to any substance, organic or inorganic, of intrinsic or extrinsic origin, in an excessive amount, can pose to be a threat to normal vital functions. Often individuals may remain oblivious of the risk factors they are exposed to until the disease manifests. The advancements in laboratory techniques have facilitated the early diagnosis of hereditary and acquired pathologies, which would have otherwise presented only at an advanced stage of the disease. Thus health care services now focus not only on treatment but also on prevention and screening.

The use of biomarkers has been the key to detection and diagnosis since early medical practice, wherein clinical features of a disease were the only accessible and assessable biomarkers. Over the years, study of the biological response and involvement of organs and organ systems in various diseases has unfurled countless biomarkers ranging from tissue characteristics to the molecular signature of diseases.

The oral cavity provides a general impression of an individual's health status. This view is substantiated by the early and subtle hints of disease, which are often observable at this site. Although not many studies have focused on the oral signs of toxicity, it remains an intriguing area to be investigated because oral signs may precede the actual systemic manifestation of toxicity, thus allowing early intervention.

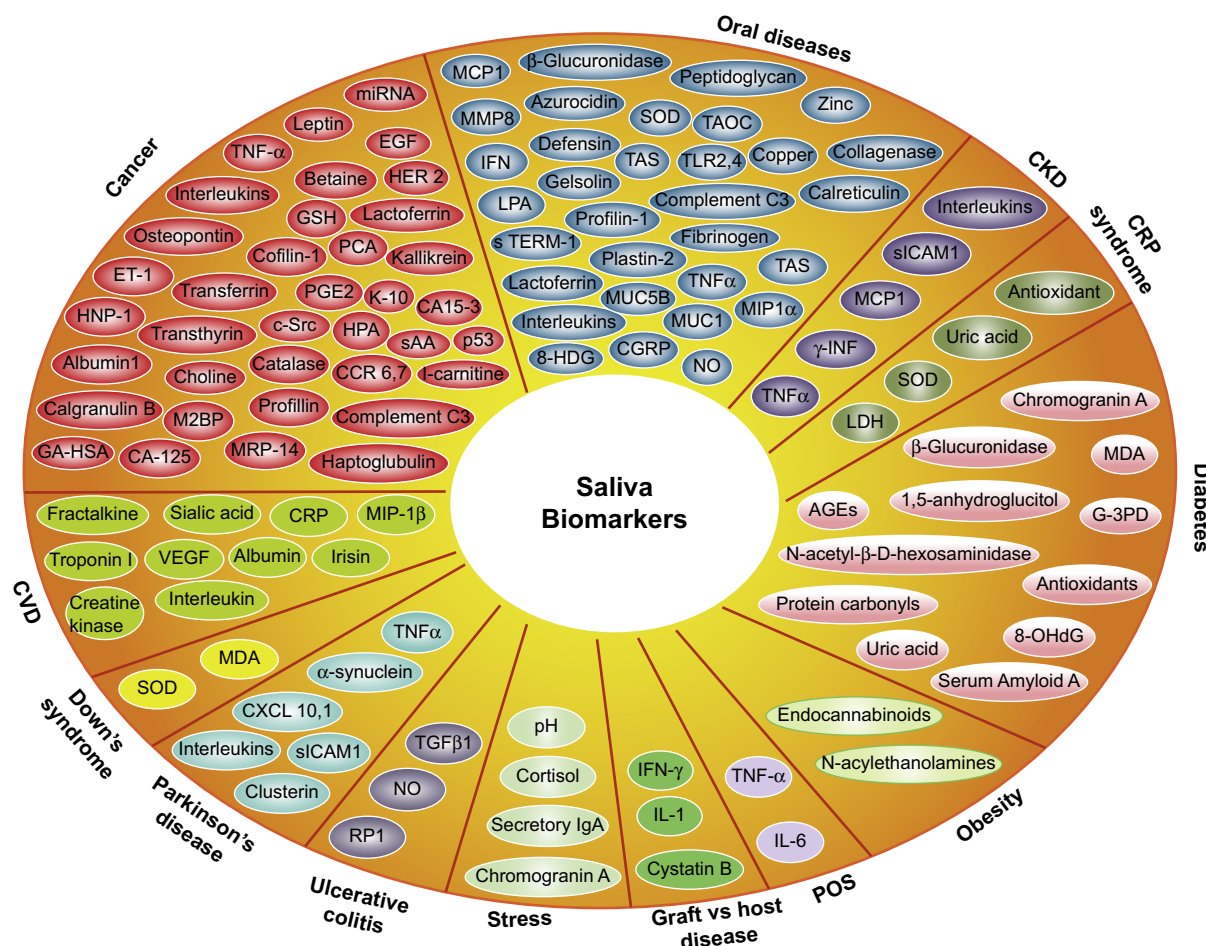
Oral diseases encompass conditions as basic as dental caries and as lethal as oral cancer. A spectrum of other pathologies ranging from hereditary conditions such as amelogenesis imperfecta and regional odontodysplasia to orofacial cysts such as dentigerous cysts, radicular cysts, odontogenic keratocyst, and even tumors such as


FIGURE 54.6 An overview of the various biomarkers that have been detected in saliva along with their association with specific disease processes. *Image courtesy: Prasad, S., Tyagi, A.K., Aggarwal, B.B., 2016. Detection of inflammatory biomarkers in saliva and urine: potential in diagnosis, prevention, and treatment for chronic diseases. Exp. Biol. Med. 241, 783−799.*

ameloblastoma, pleomorphic adenomas and calcifying epithelial odontogenic tumors are also encountered. The use of specific clinical (radiographic) and tissue biomarkers is often employed for diagnosis. Molecular biomarkers in oral diseases continue to be an evolving arena. The discussion of each pathology and its biomarkers is extensive and external to this chapter.

The sublingual route of drug administration has garnered much attention as an efficient means of systemic drug delivery. Various pharmaceuticals have developed drug preparations such as lozenges, oral sprays, gels, and dispersible tablets to best use this route.

What remains to be achieved is the proposal and acceptance of a standardized universal panel of biomarkers, which can be used to detect, diagnose, and evaluate efficacy of treatment for a particular disease. As newer facts regarding etiopathogenesis and pathophysiology are unfurled, novel biomarkers continue to emerge while many go on to become obsolete. Further

studies to quantify the various organic and inorganic constituents of saliva, as affected by various diseases, could aid in devising a quick, noninvasive and simple screening test.

Biomarkers of Mitochondrial Dysfunction and Toxicity

Carlos M. Palmeira, João S. Teodoro, Rui Silva, Anabela P. Rolo

Center for Neurosciences and Cell Biology of the University of Coimbra and Department of Life Sciences of the University of Coimbra Largo Marquês de Pombal, Coimbra, Portugal

INTRODUCTION

Mitochondria play a central role in the life and death of cells. They are not only the mere center for energy metabolism and ATP generation but are also the prime location for different catabolic and anabolic processes, calcium fluxes, and various signaling pathways, while also playing major role in cell life-defining processes such as apoptosis. Mitochondria maintain cellular homeostasis by interacting with reactive oxygen—nitrogen species and responding adequately to different stimuli. In this context, the interaction of pharmacological agents with mitochondria is an aspect of molecular biology that is too often disregarded, not only in terms of toxicology but also from a pharmaceutical point of view, especially when considering the potential therapeutic applications related to the modulation of mitochondrial activity.

Numerous works have shown that mitochondria are a major toxicological target, with their dysfunction being a major mechanism of drug-induced injury. The aim of this chapter is to highlight the role of mitochondria and the modulation of mitochondrial activities in pharmacology and toxicology and also to stress some of the potential therapeutic approaches.

In recent years, there has been extraordinary progress in mitochondrial science that has further outlined the critical role of these organelles in cell biology, pathophysiology, and the diagnosis and therapeutic treatment of different human diseases, such as ischemic diseases, diabetes, some forms of neurodegeneration, and cancer (Duchen, 2004b; Scatena et al., 2007; Giorgi et al., 2012). Mitochondrial physiology and pathophysiology is notably complex, and the role of mitochondria in bioenergetics is also linked, as mentioned earlier, to other essential functions, such as anabolic metabolism,

the balance of redox potential, cell death and differentiation, and mitosis. In addition to these basic functions, mitochondria are associated with more specialized cell activities, including calcium homeostasis and thermogenesis, reactive oxygen species (ROS) and reactive nitrogen species signaling, maintenance of ion channels, and the transport of metabolites. Consequently, the basis of different congenital mitochondrial diseases on a molecular level is equally complex and heterogeneous, making mitochondrial pathophysiology difficult to investigate (Hamm-Alvarez and Cadenas, 2009; Cardoso et al., 2010).

This field is made even more challenging by recent evidence that suggests mitochondrial structure and function is dynamic. Specifically, mitochondria possess many interesting properties, such as the ability to fuse or divide, move along microtubules and microfilaments, or undergo turnover (Westermann, 2010; Michel et al., 2012), and these unique properties are often overlooked in research. Undoubtedly, much is still unknown about the mutual interactions between mitochondrial energetics, biogenesis, dynamics, and degradation (Detmer and Chan, 2007), and the contribution of these interactions to mitochondrial toxicology and pharmacology.

MITOCHONDRIAL FUNCTION: GENERAL OVERVIEW

The mitochondrion consists of four main structures or compartments: two membranes, the intermembrane space, and the matrix within the inner membrane. The mitochondrial outer membrane (MOM) separates the cytosol from the intermembrane space. The MOM is responsible for interfacing with the cytosol and its interactions with cytoskeletal elements, which are important for

the movement of mitochondria within a cell. This mobility is essential for the distribution of mitochondria during cell division and differentiation. The mitochondrial inner membrane (MIM) separates the intermembrane space from the matrix. The foldings of the MIM toward the matrix (cristae) serve to increase the surface area of this membrane. Mitochondria also move along intermediate actin filaments, using kinesin and dynein proteins. The MIM hosts the most important redox reactions converting the energy of nutrients into ATP. These reactions are catalyzed by the mitochondrial electron transport chain (ETC), which transports electrons from several substrates to oxygen, in the complex multistep process termed as *mitochondrial respiration*. According to the chemiosmotic theory, mitochondrial respiration generates a transmembrane potential ($\Delta\Psi_m$) across the inner membrane, which is used by ATP synthase to phosphorylate ADP. The MIM is normally virtually impermeable to protons and other ions, and this solute barrier function of the MIM is critical for energy transduction. Permeabilization of the MIM dissipates the $\Delta\Psi_m$ and thereby uncouples the process of respiration from the ATP synthase, halting mitochondrial ATP production (Kushnareva and Newmeyer, 2010). Hence, the free energy of respiration is used to pump protons from the matrix to the intermembrane space (IMS), establishing an electrochemical gradient. Because the MIM displays an extremely low passive permeability to protons, an electrochemical gradient ($\Delta\mu H^+$) is built across the membrane. The electrochemical gradient is the sum of two components: the proton concentration difference and the electrical potential difference across the membrane. The estimated magnitude of the proton electrochemical gradient is about $-220\,\mathrm{mV}$ (negative inside), and under physiological conditions most of the gradient is in the form of electrical potential difference. The proton gradient is converted in ATP by the F_1F_0-ATP synthase. F_1F_0-ATP synthase couples the transport of the protons back to the matrix with the phosphorylation of ADP to ATP.

Inefficient electron transfer through complexes I–IV causes human diseases in part not only because of loss of energy generation capacity but also of insults to the various enzymes (particularly complexes I, II, and III) induce production of toxic ROS. Defects of complex V are also a cause of mitochondrial dysfunction (Schapira, 2006; Wu et al., 2010a; Abramov et al., 2011). It has also been reported that the deterioration of mitochondrial function underlies common metabolic-related diseases (Rolo and Palmeira, 2006; Palmeira et al., 2007; Turner and Heilbronn, 2008), and several studies have identified compromised oxidative metabolism, altered mitochondrial structure and dynamics, and impaired biogenesis and gene expression in insulin resistance or type 2 diabetes (T2DM) models (Cheng et al., 2010; Rolo et al., 2011; Gomes et al., 2012; Dela and Helge, 2013; Teodoro et al., 2013).

In addition to the process of ATP formation, mitochondria are highly dynamic organelles that have been implicated in the regulation of a great and increasing number of physiological processes. Cells need energy not only to support their vital functions but also to die gracefully, through programmed cell death, or apoptosis (Kushnareva and Newmeyer, 2010). Execution of an apoptotic program includes energy-dependent steps, including kinase signaling, formation of the apoptosome, and effector caspase activation. Furthermore, mitochondrial regulation is also present beyond cell death mechanisms. Indeed, besides oxidative ATP production, mitochondria assume other functions such as heme synthesis, β-oxidation of free fatty acids, metabolism of certain amino acids, production of free radical species, formation and export of Fe/S clusters, and iron metabolism and play a crucial role in calcium homeostasis (Duchen, 2004a; Michel et al., 2012). In addition, initially described as a key checkpoint of intrinsic programmed cell death, accumulating data point to mitochondria as a central platform involved in many cellular pathways, such as those recently highlighted participating in the innate immune response (West et al., 2011) or its lipidic contribution to autophagosomal membrane genesis during starvation-induced autophagy (Hailey et al., 2010). Still, the regulatory roles of mitochondria over normal physiology include the transduction pathway that underlies the secretion of insulin in response to glucose by pancreatic β-cells and in the evaluation of oxygen tension necessary for sensing oxygen in the carotid body and the pulmonary vasculature. Mitochondria also house key enzyme systems quite distinct from those required for intermediary metabolism—the rate-limiting enzymes in steroid biosynthesis and even the carbonic anhydrase required for acid secretion in the stomach (Duchen, 2004b). By accumulating calcium when cytosolic calcium levels are high, mitochondria play subtle roles in coordinating the complexities of intracellular calcium-signaling pathways, at least in some cell types, in which their contribution may be extremely important in the finer aspects of cell regulation. The physiological "uncoupling" of mitochondria plays a central role as a heat-generating mechanism in nonshivering thermogenesis in young and small mammals. It has also been suggested that the production of free radical species by mitochondria might play a key role as a signaling mechanism—for example, in the regulation of ion-channel activities and also in initiating cytoprotective mechanisms in stressed cells (Michel et al., 2012).

MITOCHONDRIAL TOXICITY

Mitochondrial dysfunction is a fundamental mechanism in the pathogenesis of several significant toxic effects in mammals, especially those associated with the liver, skeletal and cardiac muscle, and the central nervous system. These changes can also occur as part

of the natural aging process and have been linked to cellular mechanisms in several human disease states including Parkinson's and Alzheimer's diseases, as well as ischemic perfusion injury and the effects of hyperglycemia in diabetes mellitus (Amacher, 2005).

Knowledge of the effects of xenobiotics on mitochondrial function has expanded to the point that chemical structure and properties can guide the pharmaceutical scientist in anticipating mitochondrial toxicity. Recognition that maintenance of the mitochondrial membrane potential is essential for normal mitochondrial function has resulted in the development of predictive cell-based or isolated mitochondrial assay systems for detecting these effects with new chemical entities. The homeostatic role of some uncoupling proteins, differences in mitochondrial sensitivity to toxicity, and the pivotal role of mitochondrial permeability transition (MPT) as the determinant of apoptotic cell death are factors that underlie the adverse effects of some drugs in mammalian systems. To preserve mitochondrial integrity in potential target organs during therapeutic regimens, a basic understanding of mitochondrial function and its monitoring in the drug development program are essential.

At the mitochondrial level, there are several potential drug targets that can lead to toxicity, but a real clinical counterpart has been demonstrated only for a few of them. Recently, antiviral nucleoside analog have shown mitochondrial toxicity through the inhibition of DNA polymerase gamma. Other drugs targeted to different components of the mitochondrial channels can disrupt ion homeostasis or affect the MPT pore. Many molecules are known as inhibitors of the mitochondrial ETC, interfering with one or more of the complexes in the respiratory chain. Some drugs, including nonsteroidal antiinflammatory drugs (NSAIDs), may lead to uncoupling of oxidative phosphorylation, whereas the mitochondrial toxicity of other drugs seems to depend on the production of free radicals, although this mechanism has yet to be clearly defined. Besides toxicity, other drugs have been targeted toward mitochondria to treat mitochondrial dysfunctions. A clear example is the recent development of drugs that target the mitochondria of cancer cells to trigger apoptosis or necrosis, thus promoting cell death and fighting cancer (Rohlena et al., 2011).

XENOBIOTICS AND MITOCHONDRIAL DYSFUNCTION

Mitochondria, because of their central role in metabolism and cell function, have been often used to assess chemical-induced toxicity. Organophosphorus (OPs) pesticides are a class of widely used pesticides in agriculture and in domestic uses. Mitochondria as a site of cellular oxygen consumption and energy production can be a target for OP poisoning as a noncholinergic mechanism of OPs toxicity (Gupta et al., 2001a,b; Karami-Mohajeri and Abdollahi, 2013). Some toxic effects of OPs arise from the dysfunction of mitochondrial oxidative phosphorylation through alteration of the activities of all respiratory complexes and disruption of the mitochondrial membrane. Reduction of ATP synthesis or induction of its hydrolysis can impair the cellular metabolism. The OPs perturb cellular and mitochondrial antioxidant defenses, ROS generation, and calcium uptake and promote oxidative and genotoxic damage triggering cell death via cytochrome c released from mitochondria and consequent activation of caspases. Mitochondrial dysfunction induced by OPs can be restored by use of antioxidants such as vitamin E and C, alpha-tocopherol, and electron donors and increasing the cytosolic ATP level. Moreover, other organophosphates have been reported to induce neuron apoptosis in hen spinal cords, which might be mediated by the activation of the mitochondrial apoptotic pathway, causing neuropathy (Zou et al., 2013).

Some compounds used as food additives for growth promotion, such as olaquindox, induce DNA damage and oxidative stress, causing apoptosis in liver cells through the mitochondrial pathway (Zou et al., 2011). More recently, there have been reports of an increase in the frequency of mitochondrial DNA (mtDNA) somatic mutations in lung tissues of fruit growers that had been exposed to pesticides multiple times via inhalation (Wang and Zhao, 2012). The mitochondrial genome is particularly prone to DNA damage, because of its limited DNA repair capabilities, lack of protective histone proteins, and the low tolerance of damaged DNA. Moreover, mitochondria are known to be the major source of reactive oxygen in most mammalian cell types, as well as a major target organelle for oxidative damage (Chomyn and Attardi, 2003). Mitochondrial superoxide and H_2O_2 can cause direct damage to mitochondrial proteins, resulting in nuclear and mitochondrial genotoxicity (Shen et al., 2005), and initiation of apoptosis.

It has been reported that dioxins cause sustained oxidative stress and damage in liver mitochondria from mice exposed to TCDD and in hepatocytes (Senft et al., 2002; Aly and Domènech, 2009); thus, mitochondria are also a direct target for dioxin-induced toxicity. In both hepatic mitochondria isolated from TCDD-treated mice and mitochondria incubated in vitro with TCDD, a number of functional alterations have been observed, including a defect in ATP synthesis and increased ROS production (Senft et al., 2002; Shen et al., 2005; Shertzer et al., 2006; Kopf and Walker, 2010). TCDD decreases hepatic ATP levels through changes in mitochondrial F_0F_1-ATP synthase and

ubiquinone and generates mitochondrial oxidative DNA damage, which is exacerbated by decreasing mitochondrial reduced (active) glutathione and by inner membrane hyperpolarization. These mitochondrial effects of TCDD are also associated with altered expression of nuclearly encoded mitochondrial genes (Forgacs et al., 2010; Dere et al., 2011), as well as apoptosis induction involving calcium/calmodulin signaling (Kobayashi et al., 2009). In primary hepatocytes, TCDD has been shown to induce an oxidative stress response involving mitochondrial dysfunction (Aly and Domènech, 2009) and, in mice, exposure to TCDD causes a loss in mitochondrial membrane potential mediated by AhR-dependent production of ROS (Fisher et al., 2005).

Furthermore, previous studies have identified mitochondrial targets of environmental pollutants, namely ROS production and decreased ATP content (Shertzer et al., 2006). Consequently, maintenance of cellular function is strictly dependent on the existence of a healthy population of mitochondria, given that alterations of mitochondrial bioenergetic features by toxicants reduce energetic charge and may ultimately result in cell death. Some detrimental effects of dibenzofuran (DBF), a ubiquitous dioxin-like compound considered to be an environmental pollutant, have already been reported in lung mitochondria (Duarte et al., 2011) and lung cells (Duarte et al., 2012); in addition, some previous studies reported that environmental toxicants induce mitochondrial damage (Palmeira and Madeira, 1997), proving that some pollutants injure mitochondria directly. More recently, siRNA-mediated knockdown of the AhR in lung epithelial cells and fibroblasts was shown to increase sensitivity to smoke-induced apoptosis (Souza et al., 2013), and these effects involved mitochondrial dysfunction, decreased antioxidant enzymes, and oxidative stress.

MITOCHONDRIA AND DISEASE

In a clinical setting, research has shown a significant relationship between mitochondrial metabolic abnormalities and tumors found in renal carcinomas, glioblastomas, paragangliomas, or skin leiomyoma, which has led to the discovery of new genes, oncogenes, and oncometabolites involved in the regulation of cellular and mitochondrial energy production with a particular focus on reevaluating the Warburg effect (Fulda et al., 2010; Ralph et al., 2010; Solaini et al., 2011). Furthermore, the examination of rare neurological diseases, such as Charcot-Marie Tooth type 2a, autosomal dominant optic 53 atrophy, lethal mitochondrial and peroxisomal fission, and spastic paraplegia, has suggested the involvement of MFN2, OPA1, DRP1, or paraplegin in

the auxiliary control of mitochondrial energy production (Benard et al., 2010; Du and Yan, 2010; Zhu, 2010). Advances in the understanding of mitochondrial apoptosis have suggested a supplementary role for Bcl-2 or Bax in the regulation of mitochondrial respiration and dynamics, which has led to the investigation of alternative mechanisms of energy regulation (Benard et al., 2010). In addition, different metabolic diseases, such as diabetes, obesity, and nonalcoholic fatty liver disease (NAFLD), and the more general metabolic syndrome underline the role of dysfunctional mitochondria in pathogenesis (Dalgaard, 2011; Rolo et al., 2011).

MITOCHONDRIAL DYSFUNCTION IN DIABETES

In a situation of excess nutrients, mitochondrial membrane potential ($\Delta\Psi_m$) can rise to abnormally high levels, with concomitant excessive reduction of the mitochondrial respiratory chain complexes. This occurs because of elevated levels of ATP and low levels of ADP, meaning that the membrane potential generated by the oxidation of substrates is not totally utilized and begins to build up. Although there is a normal buildup of membrane potential, when it reaches high enough values it can lead to extremely dangerous situations. Overreduction means that the electrons obtained from substrate oxidation can no longer reach molecular O_2 at complex IV or cytochrome c oxidase to generate H_2O. As the vectorial ejection of protons against their gradient is a requirement for electronic transport across the respiratory chain, given a high enough membrane potential, the electronic leap between each complex no longer carries enough energy to transport protons against their enlarged gradient, and for that reason electrons get "stuck" inside the respiratory chain. This is most dangerous, for these proteic complexes are in an altered, unstable conformational state, which they must abandon by getting rid of the electrons to anything that will take them. That turns out to be molecular O_2, resulting in the heightened generation of ROS. Given enough time, the abnormal ROS generation overwhelms natural antioxidant defenses and creates mitochondrial damage, further increasing their generation and leading ultimately to cellular and tissue dysfunctions (Fig. 55.1).

The increase in nutrients offered without elevated demand for ATP leads to the abnormal augment of membrane potential ($\Delta\Psi_m$). This, in turn, leads to increased ROS generation that, if prolonged enough, causes cellular and mitochondrial damage. By activating PGC-1α (by phosphorylation—AMPK and deacetylation—sirtuins), one can induce the activation of the mitochondrial biogenic program, leading to the generation of more mitochondria. More mitochondria allows for better
FIGURE 55.1 Role of mitochondria in diabetes and obesity. *AMPK,* AMP-activated protein kinase; *PGC1α,* peroxisome proliferator-activated receptor γ coactivator 1α; *ROS,./* reactive oxygen species; *UCP1,* uncoupling protein 1.

handling of the excess nutrients, thus reducing ROS generation. Another way to reduce $\Delta\Psi_m$ is by mildly uncoupling the oxidative phosphorylation. UCP1 (and other members of the uncoupling protein family) accomplishes this by reducing $\Delta\Psi_m$ and generating heat, thus preventing ROS generation.

It was found that mitochondria from high-fat fed (HFD) rats were morphologically and structurally altered (Lieber et al., 2004; Kim et al., 2008). These studies demonstrate that there appears to exist a direct correlation between altered mitochondrial functionality and insulin resistance, obesity, and diabetes (Vial et al., 2010). As such, correct mitochondrial structure and function correction could lead to the unveiling of therapeutic strategies to treat obesity and diabetes.

The master regulator of mitochondrial biogenesis, the peroxisome proliferator—activated receptor γ (PPARγ) coactivator 1α (PGC1α), is of great necessity for the correct number, structure, and function of mitochondria. The regulation of PGC1α can occur by several means: its expression, phosphorylation, and acetylation status (Fernandez-Marcos and Auwerx, 2011), for example. The ones highlighted are particularly important, for they appear to be dependent on the cell's energetic status.

In fact, it has been shown that sirtuin 1 (SirT1) regulates PGC1α. Sirtuins are a class of NAD^+-dependent deacetylases and, as such, their activity on gene

transcription can be classified as a nutrient-sensitive action. Sirtuins' activity as gene transcription modulators has been explored in various fields of investigation, from aging to obesity, diabetes, and Alzheimer's, to name a few (Yamamoto et al., 2007). SirT1 effects on metabolic regulation were found on SirT1-*null* mice, which have decreased insulin release, whereas overexpression of SirT1 has increased insulin response to glucose (Moynihan et al., 2005). Also, SirT1 deacetylates and thus activates PGC1α, correlating directly to improved metabolic status (Nemoto et al., 2005). Curiously, SirT1 decreases uncoupling protein 2 (UCP2) expression, resulting in increased mitochondrial coupling and thus reducing substrate utilization (Moynihan et al., 2005), which makes some sense because elevated NAD^+ levels activate SirT1 and, as such, the cell has energetic needs and should not waste $\Delta\Psi_m$. Conversely, PPARγ's expression is downregulated by SirT1, resulting in decreased adipogenesis and increased lipolysis (Picard and Auwerx, 2002). SirT1 activation of PGC1α in brown adipocytes leads to increased mitochondrial biogenesis and thus increased thermogenic dissipation of excess nutrients (Lagouge et al., 2006). For further reading on SirT1, readers are encouraged to read the excellent work by Yamamoto et al. (2007). These works are sometimes conflicting and make it difficult to understand the effects of SirT1

on metabolism. In fact, until very recently, the role of resveratrol (the most famous natural SirT1 activator) was still questioned and not fully understood (Hubbard et al., 2013). SirT1 is the most famous and most studied sirtuin, but it is not the only one. Another extremely important sirtuin is the normally mitochondrial native SirT3. Expression of SirT3, in white and brown adipose tissue (WAT and BAT, respectively), is induced by calorie restriction and cold exposure. One of the most interesting facts about SirT3 is that its constitutive expression causes increased levels of PGC1α and UCP1 expression, and as such it is a very attractive target for obesity reduction. Because it is a mitochondrial sirtuin, SirT3's activity leads to decreased acetylation of mitochondrial proteins, which invariably results in increased activity (Shi et al., 2005). We have recently shown that the isoquinoline alkaloid berberine is a potent inducer of SirT3's activity in high fat—fed rats, which at least partially explains this compound's potent anti-obesity effects (Teodoro et al., 2013). Because SirT1 is a NAD$^+$-dependent deacetylase, its activity is dependent on the cell's reductive status, and a high nutrient ambient leads to decreased SirT1 activity, where PGC1α remains acetylated and its activity diminished (Cantó and Auwerx, 2009). Another metabolic sensor, the AMP-activated protein kinase (AMPK), is activated in the presence of low energy levels, i.e., when the ATP levels are low (or, more appropriately, when AMP levels are high). It phosphorylates PGC1α, activating it to produce more mitochondria to try to elevate ATP levels (Cantó and Auwerx, 2009). As such, these sensors' activities on PGC1α were designed to counter situations of low energy stress and are completely shut down in obesity and diabetes. Consequently, the artificial induction of their activation can be considered a potential and extremely attractive therapeutic strategy, especially considering that oxidative phosphorylation inhibition is a hallmark of HFD and diabetic animals.

AMPK is an important metabolic sensor and regulator, being involved in, among other effects, glucose uptake, lipidic β-oxidation, and mitochondrial biogenesis. Its effects are present on several organs, from the liver to the brain, from WAT and BAT to skeletal muscle, i.e., all metabolic-relevant tissues (Winder et al., 2000). Because AMP activates AMPK, a rise in this adenosine nucleotide (with concomitant decrease in ATP) signals the cell to begin substrate oxidation processes to generate ATP. As paralleled by NAD$^+$ and SirT1, this (and subsequent downstream effects) can be explored (and has been extensively studied) for obesity management. Although SirT1 deacetylates proteins and histones, AMPK phosphorylates and alters proteins' activity (either increasing or decreasing) (Hardie et al., 2012). AMPK induces GluT1 activation and GluT4 migration to the cellular membrane and thus increased

glucose uptake and oxidation (Barnes et al., 2002; Pehmøller et al., 2009). AMPK also mediates fatty acid uptake in cardiac cells (Habets et al., 2009), while improving their uptake and oxidation mainly by the inhibition of acetyl-CoA carboxylase and thus increasing mitochondrial import of fatty acids (Merrill et al., 1997) and by increasing the glycolytic rate (Marsin et al., 2002). Another key effect of AMPK is on mitochondrial biogenesis for, unsurprisingly, AMPK phosphorylates and activates PGC1α, thus increasing mitochondrial content, particularly in skeletal muscle (Winder et al., 2000). Finally, AMPK can also activate (and be activated by) SirT1, by increasing cellular NAD$^+$ levels (Cantó et al., 2010). As with sirtuins, these are just some effects of AMPK on metabolism, for it is also involved in many other biological functions. For further reading, we refer the reader to Hardie et al. (2012).

Oxidative stress also plays a major role in mitochondrial dysfunction in high-energy situations. In fact, as noted before, increased ROS generation is common in high-energy situations. The increased ROS generation, along with mitochondrial damage, also causes the activation of inflammatory pathways (as the c-Jun N-terminal kinase [JNK] and mitogen-activated protein kinase [MAPK]). These cause the inactivation of the insulin signaling pathway and loss of GluT4 (the insulin-sensitive glucose transporter) translocation to the cellular membrane (Qatanani and Lazar, 2007), increasing insulin resistance and thus exacerbating the problem. Also, because of the high energy levels, it comes as no surprise that the expression of proteins involved in lipid handling and mitochondrial lipid β-oxidation is diminished (Schreurs et al., 2010). Furthermore, ROS contribute to diminish glycolytic rates, as it is known that ROS inhibit the key glycolytic enzyme GAPDH (Du et al., 2000), which appears to be a self-defense mechanism against glucose damage (Rolo and Palmeira, 2006). Also, the persistent excess of nutrients leads to the maintenance of said inhibition and worsening of the situation. All of this contributes to increased lipid deposition inside cells, which affects not just mitochondrial function, but also the entire cell. Increasing the number of mitochondria is an attractive strategy for it leads to more units to carry the load of more nutrients, because not only would ROS generation be attenuated but also more antioxidant defenses would also be present. On the other hand, mildly uncoupling mitochondria leads to decreased ROS generation by the caloric dissipation of the electrochemical protonic gradient (Korshunov et al., 1997; Skulachev, 1998). There is already much work being conducted on both perspectives, both yielding very promising results (for further reading, please refer to Ren et al., 2010; Wu et al., 2013).

In terms of increasing mitochondrial numbers, there has been an enormous push toward research on brown adipose tissue since its recent discovery in human adults. Brown adipose tissue (BAT) evolved into the main source of heat generation in small mammals by having a high content of UCP1-expressing mitochondria (UCP1 can be and is considered a hallmark of BAT) (Cannon and Nedergaard, 2004). When activated, BAT generates a high metabolic rate, sustained by a rather large rate of substrate oxidation, which is obtained both from its lipid droplets and from circulation (Bartelt et al., 2011). As such, overactivation of BAT is, theoretically, a highly effective therapeutic strategy for obesity. In fact, we have recently shown just that, with the use of the bile acid chenodeoxycholic acid (CDCA) an obese phenotype can be normalized by elevating BAT UCP1 activity (Teodoro et al., 2014). It was thought that BAT was not present in adult humans, voiding such therapeutic approaches, but, as noticed before, it has been shown otherwise (Whittle, 2012). However, Vosselman et al. (2012) demonstrated that overstimulation of BAT in adult humans was hardly a valid strategy. As such, thermogenic therapy for obesity in adult humans could only be a failed idea, if not for the fact that adipocytes are highly plastic cells. This means that, given the right stimuli, white adipocytes can be, to some extent, converted into brown-like cells, the so-called "brite" or beige adipocytes (the opposite, i.e., the conversion of brown into white is also possible). As such, the next "big thing" in metabolic research is the conversion of white into brown adipocytes thus creating elevated basal metabolic rates, burning more fuel, and decreasing obesity. Most therapeutic strategies already studied and reported, which reduce adiposity in white adipocytes, produce metabolic alterations that are common to what is described to happen in "brite" induction—i.e., the activation of PPARα and induction of lipolysis, increased leptin release, and induction of mitochondrial biogenesis (Flachs et al., 2013). These alterations are usually associated with UCP1 induction and nonshivering thermogenesis. Curiously, UCP1-*null* mice are obesity-resistant when exposed to cold, but not at thermoneutrality (Anunciado-Koza et al., 2008). To make matters worse, the work by Nedergaard and Cannon (2013) skillfully argues that, despite the huge increase in UCP1 expression in WAT (arising from virtually zero), the overall contribution of these newly formed "brite" cells to the body's basal metabolic rate is negligible at best. As such, the authors propose that some other mechanism is responsible for the effects demonstrated in other works. Flachs et al. (2011) suggest that n-3 PUFA anti-obesogenic effects are not UCP1-dependent, which is also the case when combined with calorie restriction, but they are caused by increased cycling of triglyceride/free fatty acid cycle (TG/FFA cycle), a so-called

metabolic futile cycle, for it consumes energy while not causing the generation of products. This cycle could be behind many anti-obesogenic effects of countless compounds, whose effects are clear, but whose mechanisms are not. Research into these metabolic pathways will probably become a hot topic for obesity research in the near future. We have shed some light into this matter, by demonstrating once more using CDCA that there is more than just thermogenic dissipation behind bile acids' anti-obesity effects, in particular, an acceleration of metabolic functions (Teodoro et al., 2016).

MITOCHONDRIAL DYSFUNCTION IN ISCHEMIA/REPERFUSION

Ischemia/reperfusion (I/R) injury is a phenomenon whereby damage to a hypoxic organ is accentuated following the return of the oxygen supply, and it has been recognized as a clinically important pathological disorder. I/R may occur in many clinical situations such as transplantation, resection, trauma, shock, hemorrhage, and thermal injury.

The mitochondrial function is impaired in I/R settings, leading to an alteration of energy metabolism. Ischemia leads to the cessation of oxidative phosphorylation, which causes tissue ATP and creatine phosphate concentrations to decrease with a simultaneous increase in ADP, AMP, and inorganic phosphate (Pi) concentrations. During ischemia, anaerobic glycolysis and ATP degradation produce H^+-maintaining mitochondrial membrane potential. As maintenance of ion gradients across the plasma membrane and between cellular compartments depends on ATP-driven reactions, metabolic disruption by injurious stresses may rapidly perturb cellular ion homeostasis.

During oxygen deprivation the intracellular H^+, Na^+, and Ca^{2+} levels are elevated, inducing osmotic stress and causing mitochondrial damage. Intracellular H^+ accumulation activates the Na^+/H^+ exchanger, leading to Na^+ influx. Na^+ efflux is attenuated because the Na^+/K^+-ATPase is inhibited during ischemia. Therefore, Na^+/H^+ exchange activity leads to increasing intracellular Na^+ (Inserte et al., 2002, 2006; Murphy and Steenbergen, 2008). This augmentation of intracellular Na^+ during ischemia is accompanied by an increase in intracellular Ca^{2+} through reverse mode of the Na^+/Ca^{2+} exchanger. Although Na^+ overload stimulates Ca^{2+} influx by the Na^+/Ca^{2+} exchanger and depletion of ATP reduces Ca^{2+} uptake by the endoplasmic reticulum, the Ca^{2+} level is maintained as modest during ischemia because acidosis inhibits the Na^+/Ca^{2+} exchanger, and cytosolic Ca^{2+} is taken up by the mitochondria as long as its membrane potential is maintained. Influx of extracellular Ca^{2+} is responsible

for irreversible cell injury as shown by studies in which removal of extracellular Ca^{2+} protects against various hepatotoxicants (Schanne et al., 1979; Farber, 1982).

ROS generation plays a major role in damaging the organ during ischemia and sensitizing it to reperfusion. The source of the ROS is uncertain, perhaps involving complexes I and III of the ETC of mitochondria, or perhaps xanthine/xanthine oxidase (X/XOD) acting on xanthine formed from the degradation of adenosine (AMP is slowly converted into adenosine and then inosine and xanthine through a purine degradation pathway). There is a gradual decline in cellular integrity as a consequence of combinative action of ATP depletion, elevated intracellular Ca^{2+}, and ROS. Thus, the ATP-dependent repair processes are incapable of operating. Maintenance of mitochondrial integrity is a critical determinant of cell outcome. As such, if mitochondria remain sufficiently intact to generate ATP after short periods of ischemia, tissue damage is reversible and can be repaired. But if the ischemia is more aggressive then recovery is not possible. The ATP restored during reperfusion will exacerbate the damage to the organ due to metabolic disorders that accumulate during ischemia leading to cell death. The increased Ca^{2+} and bursts of ROS generation are characteristics of reperfusion.

Probably the majority of ROS is formed by uncoupled mitochondria, mainly from mitochondrial complexes I and III of the ETC (Jaeschke and Mitchell, 1989; Turrens, 2003). When the respiratory chain is inhibited by absence of oxygen and then reexposed to oxygen, ubiquinone can become partially reduced to ubisemiquinone. It can then react with oxygen to generate superoxide that is reduced to hydrogen peroxide by superoxide dismutase. Hydrogen peroxide is removed by glutathione peroxidase or catalase, but if ferrous ions (or other transition metals such as copper) are present it will form the highly reactive hydroxyl radical through a Fenton reaction (Becker, 2004). In fact, mitochondrial lipids and proteins that are damaged during ischemia favor ROS generation during reperfusion (Inserte et al., 2002). ROS cause peroxidation of cardiolipin of the inner mitochondrial membrane, impairing electron flow through the ETC (Petrosillo et al., 2003; Paradies et al., 2004). Moreover, lipid peroxidation causes the release of reactive aldehydes such as 4-hydroxynonenal that alters membrane proteins (Echtay et al., 2003). ROS also have direct effects on several respiratory chain components and can cause inhibition of the ATP synthase and ANT (adenine nucleotide translocase). There is depletion in superoxide dismutase, glutathione peroxidase, and glutathione during reperfusion that enhances oxidative stress.

Mitochondria are the major target of ROS and Ca^{2+} overload. These agents are potent inducers of the MPT,

resulting in mitochondrial-initiated cell death. A major consequence of MPT induction is inhibition of oxidative phosphorylation, which when unrestrained will lead to necrotic cell death. The permeability transition has also been pointed to as being involved in apoptosis, through the release of proapoptotic factors, such as cytochrome c, and other apoptosis-inducing factors into the cytosol (Forbes et al., 2001; Murata et al., 2001). In response to proapoptotic signals, Bax, a proapoptotic member of the Bcl-2 family, is translocated to the mitochondria and can form channels that allow the release of cytochrome c from the mitochondrial intermembrane space (Borutaite and Brown, 2003). In conditions of ATP depletion, apoptosis can deviate to necrosis (necroapoptosis). Changes in mitochondrial morphology achieved by fission and fusion may play an important role as a determinant of cell viability. It is important to understand the molecular mechanisms of mitochondrial dynamics and their relationship with ischemia-reperfusion injury.

Given the role of mitochondria in ischemia/reperfusion injury, strategies have been developed that focus on maintaining mitochondrial function and consequently reducing the damage. Perfusion with GSK-3β inhibitors reduces cell death induced by I/R (Tong et al., 2002; Gross et al., 2004; Pagel et al., 2006; Gomez et al., 2008). It is thought that the mechanism of protection elicited by GSK-3β inhibition is related to modulation of MPT, by interaction between GSK-3β and components of the MPT process (Juhaszova et al., 2008). Phospho-GSK-3β can bind to the ANT, voltage-dependent anion channel (VDAC), or Cyclophilin D (CypD) (Pastorino et al., 2005; Nishihara et al., 2007). Pretreatment with indirubin-3′-oxime (an inhibitor of GSK-3β) in conditions of hepatic I/R protects the liver by maintaining mitochondrial calcium homeostasis, thus preserving mitochondrial function and hepatic energetic balance (Varela et al., 2010). GSK-3β inactivation by indirubin-3′-oxime acts as pharmacological preconditioning, modulating the susceptibility to MPT induction and preserving mitochondrial function after I/R.

The suppression of the ANT-CypD interaction may contribute to the elevation of the threshold for MPT induction. CypD null mice mitochondria have been demonstrated to have higher Ca^{2+} buffering capacity, demonstrating a desensitization of these mitochondria to Ca^{2+}-induced MPT (Baines et al., 2005). Recently, a relationship was established between SirT3 and CypD: SirT3 deacetylates and inactivates CypD causing its dissociation from the ANT (Shulga et al., 2010). The decrease in SirT3 activity leads to increased activation of the MPT in response to Ca^{2+} increases, cardiac stress, and aging, resulting in a decline in cardiac function (Hafner et al., 2010). This ability to suppress MPT formation indicates SirT3 as a potential target for new drugs that protect against I/R.

Mitochondrial K-ATP channels are normally closed in vivo because of the inhibitory concentrations of ATP and ADP. Mitochondrial K-ATP–dependent matrix alkalization, preservation of mitochondrial volume, and the structure of the intermembrane space, as well as MPT inhibition, are involved in a preconditioning protective action (Andrukhiv et al., 2006; Costa et al., 2006; Costa and Garlid, 2008). Diazoxide is a selective mitochondrial K-ATP channel agonist that was previously shown to decrease I/R injury induced by orthotopic liver transplantation (Huet et al., 2004). The protective effects of diazoxide against hepatic I/R were dependent on Bcl-2 expression and also with the inhibition of mitochondrial cytochrome c release, being abolished by siRNA knockdown of Bcl-2 (Wu et al., 2010b). We have recently contributed to the demonstration of the essential role of mitochondrial function preservation in an I/R setting (Alexandrino et al., 2016) (Fig. 55.2).

The events of ischemia/reperfusion lead to a number of cellular alterations, with particular relevance for mitochondrial function. During ischemia, restriction of blood flow limits access to nutrients, ions and, most relevantly, oxygen. Because ATP requirements are maintained (and, in some cases, elevated), ATP generation drains the mitochondrial membrane potential. Eventually, the cell has to resort to anaerobic generation

of ATP through glycolysis, which results in the accumulation of lactate and concomitant decrease in pH. Furthermore, ion exchanges are altered leading to intracellular Na^+ accumulation and Ca^{2+} overload (see full text for further details). Accompanying the decrease in mitochondrial function, there is a mild increase in ROS generation. If the ischemic event is prolonged and if the cell was not prepared for it (for example, by preconditioning it with pharmacological agents or with short, repetitive ischemia/reperfusion events), during reperfusion, the restoration of blood flow and particularly of oxygen restores mitochondrial activity but in a totally different setting. Mitochondrial environment and function are compromised because of alterations suffered during ischemia, and ROS generation is highly exacerbated, with resulting damage to mitochondrial components such as the members of the respiratory chain and cardiolipin, heightening the problem. All this leads to the induction of the mitochondrial permeability pore, with concomitant release of cytochrome c and other proapoptotic factors, which might lead to cell death. Various therapeutic agents have already been shown to be modulators of mitochondrial function and normalizers during ischemia/reperfusion. Of note, berberine leads to an overactivation of SirT3 and GSK-3β inhibitors such as indirubin-3′-oxime (see text for further details).

MITOCHONDRIAL DYSFUNCTION IN CANCER

As noted before, mitochondria are responsible for a wide array of reactions and phenomena in the cell. Energy (ATP) production, redox status maintenance, ROS generation, Ca^{2+} storage, and apoptosis control, to name a few, are all dependent on and/or take place in mitochondria. As such, it comes as no surprise to find that mitochondrial alterations and/or deregulation are involved in cancer development. In fact, alterations in biosynthetic pathways, cell signaling, or DNA replication can shift a cell from a quiescent to a proliferative status (Wallace, 2012). The idea of mitochondrial dysfunction in cancer is rather ancient, dating back to the description of the Warburg effect, meaning the realization that cancerous cells have increased lactic acid production in the presence of oxygen, the so-called aerobic glycolysis. This led to the idea that cancer cells have damaged mitochondria because pyruvate is converted into lactate, and glycolysis is the main source of ATP for the cancerous cell. This is further supported by the notion that the interior of tumors is a highly anoxic area, elevating the need for glycolytic-derived ATP and downplaying the need for a functional mitochondrial population. All these factors would come into play in creating a highly proliferative, malignant cell. As discussed below, a healthy mitochondrial population is as vital to a normal cell as it is to a cancerous one. It is noteworthy, however, that it is true that mtDNA is highly mutated in cancer cells and these cells have a higher glycolytic rate than do normal cells. It is the fact that mitochondria are not essential to the cancerous cell that is in dispute.

One way by which we can demonstrate that mitochondria are essential to cancerous cells comes from studies where the mtDNA was removed by ethidium bromide exposure, generating the so-called ρ^0 cells. These cells present a lower metabolic rate, resulting in decreased growth and tumor formation (Cavalli et al., 1997; Weinberg et al., 2010). In his seminal review, Wallace (2012) points to Tasmanian devils' and dogs' transmissible tumors, which cause mtDNA decay and which would have disappeared long ago, if not for periodic uptake of normal mtDNA from host cells.

Both somatic and germline mtDNA mutations have been reported in almost all cases of tumors and cancers. Despite the fact that some of these alterations could be considered normal heterogeny of the population, there are no doubts about the direct correlation of some of these mutations with a cancerous phenotype. Consequently, almost all cancerous cells demonstrate impaired OXPHOS activity, when compared with normal cells. As such, these alterations can be beneficial to the cancer cell, by promoting neoplastic alterations and allowing the cancer cell to adapt to a wide array of metabolic environments (Brandon et al., 2006). In fact, several mtDNA mutations have been demonstrated to be positively selected in cancer cells, in contrast to normal cells (Gasparre et al., 2008). But the presence of a mutation that will affect mtDNA and thus lead to a cancerous phenotype appears to not even be necessary, for it has been shown that the nuclear-encoded SUV3 RNA helicase is required for correct mitochondrial function and biogenesis. In fact, $SUV3^{+/+}$ can present the same altered mitochondrial phenotype of a heterozygous or double recessive individual, because of maternal inheritance of altered mitochondria (Chen et al., 2012). But if cancerous cells do indeed present mitochondrial alterations and impaired OXPHOS activity, then how is it possible that functional mitochondria are needed for the viability of said cells?

For one, mitochondrial activity can be altered by more than just mtDNA mutations. In fact, various nDNA mutations for mitochondrial proteins have been reported in various types of cancers. For example, mutations in the complex II proteins have been shown to lead to increased ROS generation, decreased succinate consumption, and decreased respiratory rates and thus a shift toward glycolysis, in a mechanism that appears to involve the stabilization of the hypoxia-inducible factor 1α, HIF1α (Wallace and Fan, 2010; Kurelac et al., 2011). In the same fashion, fumarate hydratase, an enzyme of the Krebs cycle, has also been shown to be mutated in various cancers, leading to increased succinate levels and thus the shift toward increased glycolytic metabolism but, apparently, without the involvement of HIF4α (Adam et al., 2011; Frezza et al., 2011). There are many other reported mutations in other mitochondrial proteins, for example isocitrate dehydrogenase (Ward et al., 2012), and complexes I, III, IV, and V of the respiratory chain (Wallace, 2012).

Mitochondria produce ROS as a by-product of their activity. It is estimated that roughly 5% of all oxygen consumed in a cell is not converted into water but rather into a reactive species. Although a by-product, it has been recently shown that ROS have a signaling activity (Lander, 1997; Devasagayam et al., 2004), resulting in their production being not only required but also needed (within certain limits). As such, a complex (and, for most cases, effective) antioxidant system is in place to reduce them and thus neutralize their activity. However, mitochondrial defects, metabolic imbalances, mutations, and lack of mtDNA histones all lead to increased mtDNA mutations and thus increased cancerous potential. ROS can be one of the most important causal factors for said mutations. In fact, it has been demonstrated that ROS generation is augmented by

inhibition of the OXPHOS, in particular of the ATP synthase (Sánchez-Cenizo et al., 2010). In addition to contributing to increased ROS generation, this blockade of OXPHOS also leads to the already discussed metabolic shift toward glycolysis.

We have previously mentioned that the shift toward a greater dependence on glycolytic-derived ATP is a standard condition in the progression from a normal to a cancerous cell. This shift typically involves the overactivation of the PI3K—Akt signaling pathway (Jones and Thompson, 2009), which leads to increased expression of glucose transporters, glycolytic and lipogenic enzymes, and activation of the mechanistic target of rapamycin, mTOR (DeBerardinis et al., 2008), resulting in elevated rates of glycolysis and lactate generation. This pathway also inhibits fatty acid oxidation and prevents carbon flow toward the Krebs cycle (Gatenby and Gillies, 2004; DeBerardinis et al., 2008). Furthermore, by inhibition of the master regulator of mitochondrial biogenesis, PGC1α, this pathway leads to decreased mitochondrial respiratory activity and content, of both respiratory chain units and antioxidant defenses (Daitoku et al., 2003). As mentioned before, HIF1α stabilization is a recurring phenomenon in cancer cells, so it comes as no surprise to realize that HIF1α can impair mitochondrial biogenesis (Zhang et al., 2007). But why does the cancerous cell go to such an extent as to possibly limit its own ATP production? The answer is rather simple: the downplay of mitochondrial bioenergetics is a side effect of the need for the activation of glycolysis-parallel anabolic pathways. By increasing glycolysis, more carbon is shunted toward, for example, the pentose phosphate pathway for nucleotide synthesis and NADPH generation to combat oxidative stress (Grüning et al., 2011). Also, the increased generation of glycerol-3-phosphate in glycolysis leads to heightened lipogenesis (Esechie and Du, 2009), which requires mitochondrial-derived acetyl-CoA, supplied by a complex process that involves the aggressive oncogene Myc, in an anaplerotic refill of Krebs cycle intermediaries (DeBerardinis et al., 2007), making cancer cells dependent on glutamine for their survival (Wise et al., 2008). The antitumor p53 protein provides another proof of mitochondrial dependence of cancer cells. p53 inhibits glycolysis and diverts carbon toward the pentose phosphate pathway, leading to increased NADPH generation; in addition, its activation by telomere shortening prevents PGC1α-mediated mitochondrial biogenesis, thus leading to increased ROS generation and cellular senescence (Sahin and Depinho, 2010). As such, it is clear that, for a cancerous cell, a viable, efficient mitochondrial population is a vital requirement (Vander Heiden et al., 2009).

There are many other ways by which mitochondrial function is linked with cancer (masterfully reviewed in Wallace, 2012). If mitochondria are so vital for the cancer cell, then it is only reasonable to assume that targeting mitochondria to try to treat cancer is a viable therapeutic strategy. In fact, various works (Fulda et al., 2010; Hockenbery, 2010; Wenner, 2012) have focused on the subject. Therefore, we will briefly approach the thematic in these works.

Cancer trademarks, such as immortal potential, unresponsiveness to growth arrest signaling, increased anabolic metabolism, and decreased apoptosis and autophagy, have already been linked to mitochondria (Galluzzi et al., 2010). Despite the already discussed dependence on mitochondrial activity, cancer cells have structurally and functionally different mitochondria when compared with normal cells (Modica-Napolitano and Singh, 2004). One way to target mitochondria is by targeting its membrane potential ($\Delta\Psi_m$). Specific ANT ligands can lead to the induction of the MPT (Lehenkari et al., 2002; Don et al., 2003; Oudard et al., 2003) and could be a valid strategy because cancer cells should be more susceptible owing to having higher metabolic rates and higher Ca^{2+} loads. Also, the peripheral benzodiazepine receptor (PBR) is thought to be a component of the MPT (as well as ANT) and binds to the voltage-dependent anion channel (VDAC) and prevents MPT induction. Thus, it comes as no surprise that PBR is typically overexpressed in various cancers, as it blocks the antiapoptotic effect of the Bcl-2 protein family. As such, PBR ligands have shown antitumor activity (Decaudin et al., 2002). These are but a few examples of how reducing $\Delta\Psi_m$ and inducing apoptosis can be considered a valid and promising anticancer strategy. In fact, various compounds are already in test that target these described mechanisms.

It is evident that a compound or therapeutic strategy that would increase ROS generation or inhibit antioxidant defenses in cancer cells could be immensely helpful. Along these lines, there are already some promising results with ROS inducers (Sarin et al., 2006; Bey et al., 2007; Mehta et al., 2009) and antioxidant defense compounds (Alexandre et al., 2006; Trachootham et al., 2006; Dragovich et al., 2007), to name a few.

In the mitochondrial intermembrane space reside various proapoptotic factors (e.g., cytochrome c, cyt c), and their release is a common phenomenon in mitochondrial-dependent apoptosis, a phenomenon that usually involves the proapoptotic proteins BAX and BAK (Chipuk et al., 2006). As such, the modulation of the activities of the pro- and antiapoptotic family of proteins (for example, the Bcl-2 family) can provide interesting therapeutic approaches. The compounds ABT-737 (Oltersdorf et al., 2005) and ABT-263 (Tse et al., 2008) are just two examples.

Of course, targeting mitochondrial metabolic activity is also a strong possibility. Inhibition of the pyruvate

dehydrogenase kinase (which blocks PD activity of converting pyruvate into acetyl-CoA) by dichloroacetate leads to increased ROS generation in cancerous, but not in normal cells (Bonnet et al., 2007). Also, inhibition of the expression of lactate dehydrogenase A has shown promising results, by impeding the conversion of pyruvate into lactate (Fantin et al., 2006). Pyruvate is also actively sent toward lipid synthesis, so the block of the key enzyme ATP citrate lyase has also shown promising results (Hatzivassiliou et al., 2005). These are only a few examples of how targeting mitochondrial metabolism is a valid therapeutic strategy to combat cancer.

There are many other compounds and therapeutic strategies and targets being currently tested against cancer, many of them also involving mitochondria. Therefore, it would be no surprise if the cure for cancer came from a strategy that involved mitochondria.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Considering that mitochondria play an essential role in cellular homeostasis and signaling processes, identifying biomarkers of mitochondrial dysfunction and toxicity is of fundamental relevance. Research into these mitochondrial targets is at present a hot topic in several diseases (diabetes, obesity, cancer, etc., to name just a few examples) and drug-induced toxicity. An improved understanding of the changes that occur at the mitochondrial level is essential to discover new therapeutic targets for mitochondria-related diseases and toxicity exposure.

Biomarkers of Blood–Brain Barrier Dysfunction

Rekha K. Gupta[1], *Ramesh C. Gupta*[2]

[1]**School of Medicine, University of Louisville, Louisville, KY, United States;** [2]**Toxicology Department, Breathitt Veterinary Center, Murray State University, Hopkinsville, Kentucky, United States**

INTRODUCTION

Out of all vital organs in the body, the central nervous system (CNS) is the most complex organ in terms of its structure and function. It is composed of certain interfaces, such as the blood–brain barrier (BBB), the blood–cerebrospinal fluid barrier (BCSFB), and the blood–spinal cord barrier. These can collectively be called blood–CNS barriers or brain barriers. Evidence for the existence of the BBB came from the observations (based on staining technique) of Nobel Laureate Paul Ehrlich in the early 20th century. In 1921, the findings of a Russian neurophysiologist, Lina Stern, further supported the existence of BBB and designated it as the "hematoencephalic" barrier. Finally, electron microscopic observations confirmed the presence of the BBB (tight junctions between the endothelial cells that form brain capillaries) (Abbot et al., 2006, 2010; Palmer, 2010). Deli et al. (2005) defined the BBB as a dynamic interaction between cerebral and endothelial cells constituting the anatomical basis of the BBB and other neighboring cells, such as astroglia, pericytes, perivascular microglia, and neurons. The cross talk between these cells endows endothelial cells with a unique BBB phenotype comprising not only the morphological barrier of endothelial tight junctions but also the biochemical (enzymatic and metabolic) barriers, as well as the uptake and efflux transport systems (Abbott et al., 2010).

The BBB is formed of extremely tight junctions offering a wide range of functions, such as transendothelial transport systems, enzymes, and regulations of leukocyte permeation, which thereby generates the transport, enzymatic, and immune regulatory functions of the BBB (Abbott and Friedman, 2012). Studies have also revealed important stages, cell types, and signaling pathways involved in BBB development.

Under physiological conditions, the BBB regulates the exchange of nutrients, waste, and immune cells between the blood and the nervous tissue of the CNS and is the most important component preserving CNS homeostasis and neuronal function (Abbott et al., 2010). The BBB also protects the brain from xenobiotics, pharmaceuticals, nutraceuticals, pathogens, and various cells, proteins, and neurotransmitters present in the blood. Dysfunctional blood–CNS barrier mechanisms contribute to the pathology of neurological conditions, ranging from trauma to neurodegenerative diseases (Erickson and Banks, 2013).

The brain barriers, particularly BBB, are very sensitive to the toxic insult of chemicals and biotoxins, and these barriers play pivotal roles in the initiation and progression of neurodegenerative diseases. It is noteworthy that unlike toxicants that compromise the integrity of BBB, compounds such as melatonin can promote BBB integrity via multiple molecular pathways (Jumnongprakhon et al., 2016). This chapter describes in brief the structure and function of brain barriers and the biomarkers of toxic effects of metals, pesticides, mycotoxins, drugs of abuse, and some diseases involving the CNS.

STRUCTURE AND FUNCTION OF BRAIN BARRIERS

The structure and function of brain barriers are very complex and maintain the neuronal microenvironment, playing pivotal roles in CNS homeostasis, fibrinolysis and coagulation, vasotonus regulation, and blood cell activation, and migration during physiological and pathological processes (Zheng et al., 2003). The BBB is also vital for protecting the CNS from systemic

perturbations and from elements of the peripheral immune system, so that any impairment of its integrity could have far-reaching consequences on the health of the CNS (Drouin-Ouellet et al., 2015). The BBB is formed by a complex cellular system of endothelial cells, astroglia, pericytes, perivascular macrophages, and a basal lamina (Bradbury, 1985; Abbott et al., 2006; Gupta et al., 2015). Endothelial cells regulate the selective transport and metabolism of substances from blood to brain as well as in the opposite direction from the parenchyma back to the systemic circulation. Astrocytes project their end feet tightly to the cerebral endothelial cells (CEC), influencing and conserving the barrier function of these cells (Abbott et al., 2006). The prominent role of astrocytes in supporting a healthy BBB may be the result of trophic factors secreted by astrocytes that nourish and regulate brain microvascular endothelial cells (BMVEC) (Ivey et al., 2009). CEC are embedded in the basal lamina together with pericytes and perivascular macrophages (De Vries et al., 1997; Abbott et al., 2006). Pericytes are characterized as contractile cells that surround the brain capillaries with long processes, and they play a role in controlling the growth of endothelial cells. Pericytes may influence the integrity of the capillaries and conserve the barrier function. The lumen of the cerebral capillaries is covered by CEC in which the functional and morphological basis of the BBB resides.

The BBB acts as a physical and metabolic barrier because a complex tight junction system between adjacent endothelial cells restricts most paracellular movement of ions and solutes across the brain endothelium (Partridge, 2002). Tight junctions of the BBB are composed of an intricate combination of at least three integral transmembrane proteins (claudins, junctional adhesion molecules (JAMs), and occludin), and cytoplasmic accessary proteins, such as zonula occludens (ZO-1, ZO-2, and AF6). Daneman et al. (2010) reported that a large number of transcripts are expressed and enriched at the BBB. These transcripts encode tight junction molecules, transporters, metabolic enzymes, signaling cascades, and proteins of unknown function. The best-characterized molecules at the BBB and tight junctions include claudin-5 and claudin-12, occludin, ZO-1 and ZO-2, marveld2, cingulin-like 1, jam4, and pard3. Also at the BBB, several signaling pathways have been identified and characterized, including serotonin receptor signaling, clathrin-mediated endocytosis signaling, dopamine receptor signaling, wnt/beta-catenin signaling, and several others.

In more than 99% of the brain capillaries, a BBB is present, but in some areas of the brain, a BCSFB can be found. This barrier is present in the circumventricular areas, such as the median eminence, pituitary, choroid plexus, subfornical organ, organum vasculosum of the lamina terminalis, and the area postrema. The BCSFB is not as strict as the BBB, but it does prevent the entrance of blood-borne compounds into the brain. Because the surface of the BBB is 5000-fold greater than that of the BCSFB, the main route of entry for compounds from plasma into the brain is via the brain capillaries (Partridge, 1986). Major tight junction proteins include occludin and claudin. Claudin-5 is a major functional constituent and a critical determinant of BBB paracellular permeability and charge-selective hydrophilic paracellular pores, whereas occludin enhances tight junction tightness. Recently, it has been reported that endophilin-1 regulates the expression of ZO-1 and occludin via the EGFR-JNK signaling pathway (Chen et al., 2015).

Several enzymes (monoamine oxidase A and B, catechol O-methyltransferase, epoxy hydrolase, endopeptidases, acetylcholinesterase (AChE), pseudocholinesterase, dopa decarboxylase, γ-glutamyl transpeptidase, etc.) present in endothelial cells are important elements of the BBB, constituting the so-called metabolic barrier. The role of the BBB as a metabolic barrier was further substantiated by the presence of mitochondria in CECs (Fenstermacher, 1989). Thus, the BBB is considered a physical as well as a metabolic barrier.

The brain barriers have been assigned many vital functions, and one of them is to provide required nutrients to the CNS. These essential nutrients are transported into the brain by means of selective/carrier mechanisms. Several transport systems have been characterized varying from passive transport (such as diffusion) to active and energy requiring processes (De Vries et al., 1997).

The diffusion of compounds across the plasma membranes of the endothelial cells of the BBB is dependent on the physicochemical properties, such as lipophilicity, molecular weight, electrical charge, and extent of ionization. Lipid-soluble compounds penetrate the brain barriers readily and equilibrate easily between blood and brain tissue. Many transporters are expressed at the BBB (Garrick et al., 2003; Zlokovic, 2008) and BCSFB (Herbert et al., 1986; Ghersi-Egea and Strazielle, 2002). Compounds that are a substrate for P-glycoprotein (Pgp) are less efficiently transported across the BBB. Specific carrier systems have been characterized: glucose transporter system (GLUT-1) for sugars and large neutral amino acids system for amino acids, in addition to carrier system for purine, nucleoside, thiamine, monocarboxylic acid, and thyroid hormone. The other two carrier transporters in the human BBB are ATP-binding cassette (ABC) transporters and solute carrier transporters (Geier et al., 2013).

Some transporters that are involved in drug distribution in the brain are also involved in drug efflux. The ABC efflux transporter Pgp has been demonstrated as

a key element of the BBB that can actively transport a huge variety of lipophilic drugs out of the brain capillary endothelial cells (Löscher and Potschka, 2005). Drees et al. (2005) and Löscher and Potschka (2005) reported that the multidrug resistance proteins BMDP/ABCG2 and BCRP are also involved in efflux pump at the BBB.

In Vivo and In Vitro Models to Study the Blood—Brain Barrier

The movement of compounds from the circulating blood into the brain is strictly regulated by the brain capillary endothelial cells, which constitute the BBB. The importance of the BBB is not only in the passage of nutrients and toxicants but therapeutic drugs and antidotes as well. So, to understand the crossing of compounds of various classes, drugs, and antidotes, various in vivo and in vitro models have been developed (reviewed in Gupta et al., 2015).

In Vivo Model

Birngruber et al. (2013) reported a cerebral open flow microperfusion as a new membrane-free technique for measuring substance transport across the intact BBB in Sprague—Dawley rats. This in vivo technique is based on a probe that is inserted into the brain, thereby rupturing the BBB. The BBB is usually reestablished within 15 days, which then allows sampling of interstitial brain fluid under physiological conditions. This technique also allows monitoring of BBB permeability, which can be useful for measuring pharmacokinetics across the BBB and pharmacodynamics in the brain. Using tracers, such as Evans blue (EB), horseradish peroxidase, and [^{131}I]albumin, breakdown of the BBB in humans and experimental animals has been studied under many conditions, such as hypoglycemia, hypertension, seizures/convulsions, inflammation, etc. (Öztaş, 1996).

In Vitro Models

In vitro reconstituted models of the BBB from different mammalian species have been employed since the late 1970s. Bowman et al. (1983) introduced the first in vitro BBB filter model. An insert was made of nylon mesh and polycarbonate tubing, and bovine brain endothelial cells were seated on it for studying the effect of calcium-free medium and osmotic shock on sucrose flux. Since then, a variety of chambers and inserts from different materials and with diverse pore size have become commercially available. Garberg et al. (2005) used an in vitro model for BBB permeability based on the use of a continuous cell line and to investigate the

specificity of this model. These authors developed a coculture procedure that mimics the in vivo situation by culturing brain capillary endothelial cells on one side of a filter and astrocytes on the other. Under these conditions, endothelial cells retain all the endothelial cell markers and the characteristics of the BBB, including tight junctions and enzymes (such as γ-glutamyl transpeptidase and monoamine oxidase (MAO)) activities.

Deli et al. (2005) presented permeability data from various in vitro BBB models by measuring transendothelial electrical resistance (TEER) and by calculation of permeability coefficients for paracellular or transendothelial tracers. These authors summarized the results of primary cultures of cerebral microvascular endothelial cells or immortalized cell lines from bovine, human, porcine, and rodent origin. They also described the effect of coculture with astroglia, neurons, mesenchymal cells, blood cells, and conditioned media, as well as the physiological influence of serum components, hormones, growth factors, lipids, and lipoproteins on the BBB function.

The strong correlation between the in vivo (Oldenhorf method) and in vitro (coculture) drug transport, the relative ease with which such cocultures can be produced in large quantities, and the reproducibility of the system, provide evidence for an efficient system for the screening of drugs that are active in the CNS (Dehouck et al., 1997). These authors suggested that the coculture method is a useful system for investigating passive diffusion, carrier-mediated transport, and P-glycoprotein (Pgp)—dependent drug transport. The in vitro permeabilities of propranolol and cyclosporine A were parallel with indications from in vivo extraction, showing that transporters and Pgp are expressed in the coculture system. For further details, readers are referred to Deli et al. (2005) who reviewed various in vitro models covering bovine, human, porcine, and rodent (murine and rat) brain endothelial cell—based systems. Bovine systems provide a high yield of brain endothelial cells sufficient for pharmacological screening, and they are widely used in basic as well as in applied research. Mouse brain yields the least endothelial cells compared to other species.

Some examples of the modulators of BBB permeability in in vitro models are (1) both cAMP elevator peptide hormone adrenomedulin and calcitonin generelated peptide decrease paracellular permeability, (2) a glucocorticoid hormone, hydrocortisone, improves the barrier properties, (3) insulin exerts a tightening effect on tight junctions, and (4) catecholamines (adrenaline and noradrenaline) increase the sodium fluorescein flux.

In essence, in vitro models have been widely used in pharmacological research for screening drugs and drug

candidate molecules for either modifying BBB permeability or investigating brain penetration (Deli et al., 2005). This area of research is very important for permeability screening during drug development in the pharmaceutical industry (Gerlach et al., 2018).

Toxicants Affecting the Central Nervous System Barriers

Metals

A number of metals (aluminum, copper, iron, lead, manganese, and mercury) are known to modulate directly or indirectly the structure, function, or permeability of the BBB and/or BCSFB. Effects of these metals on brain barriers and the brain are described here in brief (Table 56.1).

Aluminum

Aluminum (Al)-induced neurotoxicity has been known for more than a century. Al has also been involved in neurodegenerative diseases, such as Alzheimer's (AD), encephalopathy, and amyotrophic lateral sclerosis (ALS) (Delonche and Pages, 1997; Savory et al., 2006; Bondy, 2010; Garcia et al., 2010). In a pharmacokinetic study, Yokel (2012) mentioned that Al can enter the brain from blood by two routes: (1) through the BBB and (2) through the choroid plexus into the CSF of the ventricles within the brain and then into the brain. Al appears to bind with transferrin and citrate. Al concentration in serum can be 25-fold higher than in CSF. The glutamate transporter system Xc^- has been suggested to mediate brain Al citrate uptake. Al mainly deposits in the hippocampus, cortex, and amygdala, which are the areas of brain that are also rich in glutamatergic neurons and transferrin receptors.

Al is known to associate with many epithelia and endothelia in the BBB and may be responsible for compromising the properties and integrity of these membranes, thereby altering the barrier function (Vorbrodt et al., 1994). Al-related toxicological effects are observed on both sides of the BBB (Delonche and Pages, 1997). Al is known to cause development of neurofibrillary tangles and degeneration of cerebral neurons in laboratory animals (Zheng, 2001). Al directly affects neuronal pathways and appears to act as a direct BBB toxicant. Accumulation of Al in lysosomes (protease-rich vacuoles) and the hyperphosphorylation of neurofilaments are involved in the molecular mechanism of Al-induced neurotoxicity and neurodegenerative disease, such as AD.

Copper and Iron

Copper (Cu) is an essential element and involved in many vital biochemical reactions and physiological functions, such as in Cu-containing enzymes, angiogenesis, nerve myelination, and endorphin action (Choi and Zheng, 2009; Pal, 2014). Cu access in the body, due to mutation in the Cu-transporter ATP7B gene located on the long arm (q) of chromosome 13 (13Q 14.3), may lead to the neurologic disorder known as Wilson's disease. In contrast, Cu deficiency in liver and brain, due to a genetic disorder in the expression of the Cu-transporter ATP7A, may lead to Menkes disease. An imbalance in Cu homeostasis due to defective Cu transporters or any other reasons at the BBB may play a role in the pathogenesis of neurodegenerative diseases, such as AD, Parkinson's (PD), spongiform encephalopathies, and ALS.

In serum, about 65%—90% of Cu tightly binds with ceruloplasmin, and the rest loosely binds with albumin, transcuprein, and amino acids. It appears that ceruloplasmin sequesters Cu and thus tightly regulates the movement of Cu into the CSF (Choi and Zheng, 2009). Free Cu ions are the main species for Cu transport into the brain, and uptake and distribution of Cu varies between different brain regions. The BBB appears to serve as the main entrance for Cu to get access to brain parenchyma, whereas the BCSFB is more likely involved in the regulation of Cu homeostasis in the CSF. Uptake of Cu into the cells is mediated by two transporter proteins (Cu transporter 1 (Ctr1) and divalent metal transporter 1 (DMT1)). Inside the cells, ATP7A and ATP7B are Cu transport proteins that participate in Cu efflux (Choi and Zheng, 2009; Pal, 2014). Monnot et al. (2011) reported that Cu appears to enter the brain primarily via the BBB and is subsequently removed from the CSF by the BCSFB.

Iron (Fe) is a trace mineral that acts as both an electron acceptor and electron donor, and thereby it is essential to life (McCarthy and Kosman, 2015). Fe enters the brain by crossing the BBB and BCSFB. Fe is essential for normal brain function, as it is involved as a cofactor in myelination, mitochondrial energy generation, neurotransmission, oxygen transport, and cellular division. Fe is also involved in several neurological diseases, such as AD, PD, and aceruloplasminemia. There are two possible mechanisms for Fe uptake into BMVEC: one, which is referred to as transferrin-bound iron uptake involving transferrin (Tf) endocytosis, and the other is uptake of Fe from nontransferrin-bound iron. The latter process involves an Fe transporter, which is a divalent cation transporter such as DMT1.

High intracellular Fe concentration is toxic to cells. The endothelial cells of the BBB sequester Fe from the blood at their apical surface and release Fe into the brain at their basolateral surface. Ferroportin is the only known mammalian cellular Fe exporter.

Monnot et al. (2011) investigated how Fe levels regulated brain Cu levels transport through BBB and BCSFB

TABLE 56.1 Toxicants That Can Cross the Brain Barriers May Cause Dysfunction/Damage to Barriers

Toxicants		Biomarkers	References
Metals	Aluminum (Al)	Decreased serum inorganic phosphorus, neurofibrillary tangles development, cerebral neurons degeneration, neuropeptide delta sleep-inducing peptide (DSIP), transferrin, disruption of BBB, and increased BBB permeability	Vorbrodt et al. (1994), Zheng (2001), and Yokel RA (2012)
	Copper (Cu)	High Cu in Serum/plasma and urine, ceruloplasmin, transporters in BBB and BCSFB, and Cu chaperone for SOD protein	Zheng et al. (2003), Choi and Zheng (2009), and Pal (2014)
	Iron (Fe)	Ferritin, transferrin, amyloid-β precursor protein, increased amyloid-β aggregates, ferroportin, ceruloplasmin, zyklopen, and hephaestin	Zheng et al. (2003) and McCarthy and Kosman (2015)
	Lead (Pb)	Increased BBB permeability, increased $A\beta_{1-40}$ in choroid plexus, protein kinase C (PKC-zeta), reduction of tight junction protein (occludin), and tyrosine kinase Src, and reduction of transthyretin in CSF	Laterra et al. (1992), Bradbury and Deane (1993), Zhao et al. (1998), Zheng et al. (2003), Behl et al. (2009), Song et al. (2014), and Gupta et al. (2015)
	Manganese (Mn)	Blood and saliva Mn levels, and transferrin receptor in BBB and BCSFB	Aschner and Gannon (1994), Zheng (2001), Crossgove et al. (2003), Zheng et al. (2003), Milatovic et al. (2011), and Ge et al. (2018)
	Mercury (Hg)	Hg concentration, and BBB disruption	Chang and Hartman (1972), Aschner and Clarkson (1988), and Zheng et al. (2003)
	Zinc (Zn)	Increased BBB permeability, BBB breakdown, increased Zn and Na concentrations, Cu, Fe, and Mg deficiency in brain, inhibition of Na/K-ATPase	Yorulmaz et al. (2013) and Giacconi et al. (2017)
Pesticides	Organophosphate pesticides and nerve agents	OP residue, increased BBB permeability, AChE inhibition, BuChE inhibition, increased ACh level, seizures, BBB dysfunction, edema, and neuronal damage/loss	Ashani and Catravas (1981), Drewes and Singh (1985), Petrali et al. (1985), Carpentier et al. (1990), Sinha and Shukla (2003), Bhavari and Reddy (2005), Zaja-Milatovic et al. (2009), Mercey et al. (2012), and Martin-Reina et al. (2017)
	Carbamates(including pyridostigmine bromide)	Carbamate residue, AChE inhibition, BuChE inhibition, increased ACh level, seizures, and increased BBB permeability, and neuronal damage/loss	Ropp et al. (2008), Gupta et al. (2007), Amourette et al. (2009), and Martin-Reina et al. (2017)
	Chlorinated hydrocarbons	Increased BBB permeability	Sinha et al. (2003) and Malik et al. (2017)
	Pyrethrins/pyrethroids	Increased BBB permeability, BBB dysfunction, and pyrethrin/pyrethroid residue	Sinha et al. (2004), Amaraneni et al. (2016), and Martin-Reina et al. (2017)
	Neonicotinoids (Imidacloprid)	Imidacloprid residue	Rose (2012)
	Nicotine	Nicotine residue	Rose (2012)
	Rotenone	Mitochondrial complex I inhibition, autoradiographic findings, mitochondrial dysfunction, decreased ATP level, degeneration of dopaminergic neurons, and Parkinsonian motor deficits	Higgins and Greenamyre (1996), Gupta (2012), Heinz et al. (2017), and Terron et al. (2018)
	Herbicides (paraquat)	Paraquat level, reduced tyrosine hydroxylase, and dopamine level	Shimizu et al. (2001) and Prasad et al. (2009)
	PCBs/Dioxin/TCDD		Eum et al. (2008)

Continued

TABLE 56.1 Toxicants That Can Cross the Brain Barriers May Cause Dysfunction/Damage to Barriers—cont'd

Toxicants		Biomarkers	References
Mycotoxins/ Biotoxins/Endotoxin	Aflatoxins	Reduced tight junction proteins (ZO-1, ZO-2, and AF6) AFB1 concentration in brain, AFB1-DNA (AFB1-N7-guanine) adducts, and HBMEC death	Qureshi et al. (2015)
	Deoxynivalenol (vomitoxin)	BBB and BCSFB impairment, reduced BBB integrity, increased BBB permeability, reduced TEER, increased MAPK, decreased claudin-3 and claudin-4, and increased lactate dehydrogenase release	Prelusky et al. (1990), Maresca (2013), and Behrens et al. (2015)
	T-2 and HT-2 toxins	Increased BBB permeability, reduced protein synthesis, decreased MAO activity, and enhanced MMP-9	Wang et al. (1998), Ravindran et al. (2011), and Weidner et al. (2013)
	Fumonisins/moniliformin	Increased BBB permeability, fumonisin B1 level, sphingosine: sphingosine ratio, cerebral edema, and increased albumin and IgG in CSF	Kwon et al. (1997), Foreman et al. (2004), Osuchowski et al. (2005), Behrens et al. (2015), and Smith (2018)
	Ergot (ergotamine, ergocristinine, and others)	Ergot residue in CSF and reduced BBB integrity	Hovdal et al. (1982), Mulac et al. (2012), and Behrens et al. (2015)
	Pertussis toxin	Increased BBB permeability	Brückener et al. (2003)
	Endotoxin	Increased BBB permeability	Osuchowski et al. (2005) and De Vries et al. (1997)
Experimental chemicals/drugs	Lipopolysaccharide (LPS)	Increased BBB permeability, increased nitric oxide and prostaglandins, and increased α-synuclein expression	Wispelwey et al. (1988), Minami et al. (1998), Osuchowski et al. (2005), and Jangula and Murphy (2013)
	Monosodium glutamate	Increased BBB permeability	Škultétyová et al. (1998)
	N-Methyl D-aspartate (NMDA)	BBB breakdown	Zheng (2001)
	Kainic acid (Kainate)	Kainic acid and dihydrokainic acid residue in brain, BBB dysfunction, increased BBB permeability, and brain edema	Gynther et al. (2015) and Han et al. (2015)
	Pentylenetetrazole	BBB breakdown and increased BBB permeability	Sahin et al. (2003) and Oztas et al. (2007)
	Pilocarpine	Brain and plasma concentrations of pilocarpine and increased BBB permeability	Uva et al. (2008) and Römermann et al. (2015)

and Cu homeostasis. Fe deficiency has a more profound effect on brain Cu levels than Fe overload. Fe deficiency increases Cu transport at the brain barriers and prompts Cu overload in the CNS. The BCSFB plays a key role in removing excess Cu from the CSF.

The potential biomarkers of Fe exposure and effects on brain, such a ferritin, transferrin, amyloid-β precursor protein, increased amyloid-β aggregates, ferroportin, ceruloplasmin, zyklopen, hephaestin, are listed in Table 56.1.

Lead

Lead (Pb), a well-known neurotoxicant, can enter the CNS either as free Pb^{2+} or via the exchange of $PbCO_3$ with an anion, or passively in the form of an inorganic complex, such as $PbOH^+$. Kinetic studies with ^{203}Pb continuously infused intravenously into adult rats revealed that ^{203}Pb uptake into different brain regions was linear with time up to 4 h after infusion (Bradbury and Deane, 1993). Pb accumulates in the choroid plexus of humans as well as animals, and the choroid plexus may be the primary target for Pb-induced neurotoxicity. This effect may alter the function of BCSFB. Behl et al. (2009) demonstrated that Pb significantly increased accumulation of intracellular amyloid-β ($A\beta_{1-40}$) in rat choroid plexus tissues in vivo and in immortalized choroidal epithelial Z310 cells in vitro. Mechanisms involved in lead-induced increase in Aβ level at the BCSFB may include (1) a diminished expulsion of Aβ molecules from the plexus cells to the extracellular milieu, (2) an increased uptake of Aβ from the CSF, blood, or both, (3) an increased synthesis of Aβ, and (4) a reduced

metabolism or degradation of Aβ. Pb-induced inhibition of the production of LRP1 (a key intracellular Aβ transport protein in the choroid plexus) may be responsible for the accumulation of Aβ, a major risk factor for AD (reviewed in Gupta et al., 2015). Pb exposure has also been shown to cause abnormal protein kinase C (PKC-zeta) activity in both the BBB (Laterra et al., 1992) and the BCSFB (Zhao et al., 1998). In addition, Pb appears to accumulate in the same intramitochondrial compartment as Ca^{2+}, thereby disrupting intracellular Ca^{2+} metabolism as well as altering transepithelial transport processes (Zheng et al., 2003).

Manganese

Manganese (Mn) binds readily to transferrin without displacing iron (Fe) in plasma. Brain areas (pallidum, thalamic nuclei, and substantia nigra) having high Mn levels differ from those having high levels of transferrin receptors (nucleus accumbens and caudate putamen), suggesting that perhaps these sites may accumulate Mn through neuronal transport. Like Fe, Mn-loaded transferrin is taken up by receptor-mediated endocytosis at the luminal membrane of brain capillaries. Mn levels, transferrin in BBB and BCSFB, and neurodegeneration and dendritic damage may serve as biomarkers (Aschner and Gannon, 1994; Crossgove et al., 2003; Zheng et al., 2003; Milatovic et al., 2011).

Mercury

Mercury (Hg) exists in several forms, such as elemental (metallic), inorganic (e.g., mercurous chloride and mercuric chloride), and organic (e.g., methylmercury, ethylmercury, and phenylmercury). In the environment and mammalian systems, various forms of mercury are interchangeable. For example, inorganic mercury can be methylated to methylmercury (MeHg) and MeHg can change to inorganic or elemental Hg. Animals at the top of the food chain tend to bioaccumulated MeHg in their bodies. Therefore, poisoning by Hg is due to consumption of meat or grain contaminated with Hg. The US Food and Drug Administration estimates that, on an average, most people are exposed to about 50 ng Hg/kg body wt/day in the food they eat.

Metallic Hg can stay in the body for weeks to months. Because of its high lipophilicity, it can readily cross the BBB. When metallic Hg enters the brain, it is readily converted to an inorganic divalent Hg and is trapped there for an extended period. The inorganic divalent cation can, in turn, be reduced to metallic Hg. Inorganic Hg compounds do not readily cross the BBB. Yet, compounds such as mercuric chloride can act as direct BBB toxicants (Chang and Hartman, 1972; Zheng et al., 2003). The distribution of MeHg is similar to that of metallic Hg, i.e., a relatively large amount of Hg can accumulate in the brain because of its ability to penetrate

the BBB either by diffusion or by utilizing a transport system. MeHg reacts with sulfhydryl groups of cysteine. The MeHg–cysteine complex acts as an amino acid analog, similar in structure to methionine, and is transported by the L system carrier across the BBB (Aschner and Clarkson, 1988). Developing fetuses and neonates are most sensitive to MeHg-induced neurotoxicity because MeHg is more readily transported across the immature BBB as well as because of its inhibitory effects on cell division. Microtubules are essential for cell division (main component of the mitotic spindle), and MeHg reacts with the SH groups of tubulin monomers and thereby disrupts the assembly process. The dissociation process continues, and this leads to depolymerization of the tubule.

It is noteworthy that Hg can be involved in the development of AD, multiple sclerosis (MS), and ALS (Mutter et al., 2007).

Zinc

Zn is a component of more than 300 different enzymes that function in many aspects of cellular metabolism, including metabolism of proteins, lipids, and carbohydrates. The BBB is important for zinc (Zn) homeostasis in the brain (Yorulmaz et al., 2013). Zn serves as a mediator of cell—cell signaling and functioning of channels and receptors in the CNS. The transport of Zn into the brain parenchyma occurs via the brain barrier system. Its deficiency or excess can contribute to alterations in behavior, abnormal CNS development, and neurological diseases. In a recent study, circulating Zn has been linked to pathophysiological changes occurring with aging rather than to its nutritional intake (Giacconi et al., 2017). Increased Zn and Na concentrations, inhibition of Na/K-ATPase, increased BBB permeability, and BBB breakdown may serve as biomarkers.

Pesticides

Organophosphates

Several organophosphate (OP) compounds have been reported to cross the BBB, but very little is known about alterations in the BBB structure or function, except that these compounds can increase its permeability. OP nerve agents, which are irreversible AChE inhibitors, have been studied to a greater extent than pesticides with regard to changes in the BBB. Drewes and Singh (1985) reported that the cerebral transendothelial carrier-mediated transport of glucose and amino acids was not affected in mongrel dogs poisoned by soman. Carpentier et al. (1990) investigated acute changes in BBB permeability to proteins, using EB-labeled serum albumin and plasmatic gamma-immunoglobulin G (IgG) as indicators in rats. An increased BBB permeability to the EB—albumin

complex was macroscopically observed in two-thirds of the convulsive rats exposed to soman (85 μg/kg). Soman produced seizures and reversible BBB opening to the greatest extent after 30−60 min of paroxysmal electroencephalographic (EEG) discharges when signs of cerebral hyperactivity (epileptic EEG pattern, and hyperoxia) were also at their peak. Topographically, the protein leakage was bilateral and restricted to anatomically defined brain structures, some of which were thereafter sites of parenchymal edema and neuronal damage. Interestingly, the first signs of increased BBB permeability were shown to precede the onset of edema. OP nerve agents, being small lipophilic molecules, can easily penetrate the BBB by free diffusion and thereby inhibit AChE in the CNS (Mercey et al., 2012). Increased BBB permeability by OP nerve agents or other ChE inhibitors may lead to their enhanced entry into the brain resulting in greater AChE inhibition and possibly in subsequent maintenance of seizures and aggravation of their pathological consequences, such as edema and neuronal loss in certain brain structures. Carpentier et al. (1990) detected the BBB opening in the amygdaloid complex and in some cortical regions (cingulum, entorhinal, and piriform complex), and that the thalamus was the most frequently and intensely affected structure.

Observations from various studies suggest that soman-induced brain alterations are predominantly related to seizures or brain hyperactivity, or to a direct cytotoxic action of soman or acetylcholine (ACh) itself or due to ChE inhibition (McDonough et al., 1987). Domer at al. (1983) found increased permeability of the BBB by systemic administration of ACh. Of course brain hyperactivity alone appears inadequate to be responsible for the BBB opening. Obviously, the short duration of the transient protein leakage (Carpentier et al., 1990) contrasted with the well-known long-lasting brain AChE inhibition induced by soman (Petrali et al., 1985). Several other anti-ChE compounds, such as physostigmine and paraoxon, are also known to cause the BBB opening for macromolecules that were seizure-dependent and reversible and unrelated to brain ChE inhibition. Ashani and Catravas (1981) observed that in soman-intoxicated rats, induced damage to BBB integrity was significantly reduced, despite a high degree of AChE and BChE inhibition, and protected from seizures by Nembutal or atropine. In essence, endothelial AChE or BChE play no role in BBB opening, although they may function as an "enzymatic barrier" to ACh.

Additional factors, such as increased electrical activity, oxidative/nitrosative stress, decreased energy supply and store, deleterious action of excitatory amino acids, enhanced calcium intrusion, and brain edema, seemed to play significant roles in the brain damage (Misulis et al., 1987; Carpentier et al., 1990; Solberg and Belkin, 1997; Gupta et al., 2001a,b; Zaja-Milatovic et al., 2009; Prager et al., 2013). Other mechanisms in soman-induced damage to BBB integrity may be related to vasoactive substances (ACh, amines, amino acids, peptides, free radicals, and steroid hormones of the pituitary adrenal axis) and vasogenic events (acidosis, increased blood flow, and hypertension). It is noteworthy that increased BBB permeability may facilitate the entry of an antidote (oxime class) to the brain, which otherwise has limited access because of the BBB (Gupta et al., 2015).

Organochlorines and Pyrethrins/Pyrethroids

In a number of studies, increased BBB permeability has been reported for organochlorine (Sinha and Shukla, 2003; Malik et al., 2017) and pyrethrin/pyrethroid (Sinha et al., 2004; Amaraneni et al., 2016; Martin-Reina et al., 2017) insecticides.

Rotenone

Rotenone is one of the naturally occurring insecticides obtained from plants of the "*Derris*" species (Gupta, 2012). Rotenone causes inhibition of mitochondrial respiratory chain complex I, (NADH-ubiquinone oxidoreductase) and cell death by apoptosis due to excess generation of free radicals. Rotenone has received enormous attention from neuroscientists because it causes inhibition of mitochondrial respiratory chain complex I, followed by mitochondrial dysfunction, impaired proteostasis, degeneration of dopaminergic neurons, neuroinflammation, and finally Parkinsonian motor deficits (Higgins and Greenamyre, 1996; Heinz et al., 2017; Terron et al., 2018). Mitochondrial complex I inhibition, mitochondrial dysfunction, reduced ATP level, degeneration of dopaminergic neurons, and Parkinsonian motor deficits may serve as biomarkers of rotenone's neurotoxicity.

Herbicides

A bipyridyl herbicide paraquat resembles the structure of N-methyl-4-phenyl pyridinium (MPP^+). MPP^+ is an experimental agent, which causes PD. Paraquat reaches the brain by crossing the BBB possibly by the neutral amino acid transport system (Shimizu et al., 2001; Prasad et al., 2009). Further, paraquat is taken up into striatal neurons by a Na^+-dependent mechanism. Paraquat inhibits the activity of tyrosine hydroxylase and decreases striatal dopamine levels, thereby inducing Parkinson-like dopaminergic toxicity in the brain.

Mycotoxins

In general, the effect of mycotoxins on the BBB is to increase its permeability. Aflatoxin B_1 (AFB_1) has been reported to form AFB_1-DNA (AFB_1-N7-guanine) adducts and kill human BMVECs (Qureshi et al., 2015). One of the trichothecenes deoxynivalenol is reported to cause BBB and BCSFB impairment, reduced BBB integrity, increased BBB permeability, reduced TEER, increased MAPK, decreased claudin-3 and claudin-4 (proteins involved in tight junctions), and increased lactate dehydrogenase release (Prelusky et al., 1990; Maresca, 2013; Behrens et al., 2015). T-2 and HT-2 toxins are known to cause increased BBB permeability, reduced protein synthesis, enhanced matrix metalloproteinase-9 (MMP-9), and alterations in neurochemicals by inhibiting MAO activity (Wang et al., 1998; Ravindran et al., 2011; Weidner et al., 2013). Fumonisin B1 commonly affects the equine species causing equine leukoencephalomalacia, cerebral edema, and an elevation of the albumin and IgG levels in CSF (Foreman et al., 2004; Smith, 2018). Ergot alkaloids (such as ergotamine, ergocristinine, and others) are known to cross the BBB by BCRP/ABCG2 transporter system, accumulate in BBB cells, and impair its integrity (Hovdal et al., 1982; Mulac et al., 2012; Behrens et al., 2015).

Drugs of Abuse and Therapeutic Drugs

Methamphetamine

The BBB has been identified as a target of methamphetamine neurotoxicity (Northrop and Yamamoto, 2015). Methamphetamine causes damage to monoamine terminals and BBB structural proteins, the tight junction proteins, and BBB function. In experimental animals, methamphetamine has been shown to cause decreased expression of occludin, claudin-5, and zona occludens, as well as decreased TEER, indicative of increased paracellular permeability (Mahajan et al., 2008). These alterations in endothelial structures and function are associated with an increase in ROS. In addition, stress appears to exacerbate methamphetamine-induced increases in ROS, induced BBB disruption by potentiating methamphetamine-induced increases in ROS, inflammatory mediators, mitochondrial dysfunction, and extracellular glutamate. The consequences of methamphetamine-induced BBB disruption are significantly enhanced vulnerability to other disease states, such as stress, HIV infection, Hepatitis C, cognitive decline and depression, etc. (Northrop and Yamamoto, 2015).

Cocaine

Depending on the dose and route of administration, cocaine-induced profound hyperthermia and increased plasma and brain serotonin levels lead to BBB breakdown and brain edema (Sharma et al., 2009; Multani et al., 2014). Cocaine also induces cellular stress as seen by upregulation of heat shock protein (HSP 72 kD) expression and results in marked neuronal and glial cell damages at the time of the BBB dysfunction. Increased serotonin levels, hyperthermia, HSP 72 kD expression, and BBB dysfunction can be used as biomarkers of cocaine-induced damage to the BBB (Table 56.2).

TABLE 56.2   Drugs of Abuse That Can Cross the Barriers and May Cause Dysfunction/Damage to the Barriers

Drugs of Abuse	Biomarkers	References
Amphetamine and methamphetamine	Disruption of BBB function, increased BBB permeability, decreased BBB structural proteins (occludin, claudin-5, and zona occludens-1), increased matrix metalloproteinase-9 and nitric oxide, decreased TEER, and increased ammonia and glutamate levels	Mahajan et al. (2008), Silva et al. (2010), Martins et al. (2013, 2017), Multani et al. (2014), Northrop and Yamamoto (2015), and Jumnongprakhon et al. (2016)
MPTP/MPP	Mitochondrial complex I inhibition, mitochondrial dysfunction, reduced ATP level, nigrostriatal degeneration, and Parkinsonian motor deficits	Schildknecht et al. (2017) and Terron et al. (2018)
Cocaine	Increased plasma/serum and brain serotonin levels, increased HSP 72 kD, hyperthermia, increased BBB permeability, BBB dysfunction, and brain edema	Sharma et al. (2009) and Multani et al. (2014)
Alcohol/Ethanol	Myosin light chain kinase activation, decreased occludin, claudin-5, and zona occludens-1, and increased BBR permeability	Haorah et al. (2005), Multani et al. (2014), and Northrop and Yamamoto (2015)
Antipsychotics (chlorpromazine and clozapine)	Increased electrical resistance, apoptosis of BBB endothelia, and impaired BBB permeability	Elmorsy et al. (2014)

Alcohol/Ethanol

Ethanol produces activation of myosin light chain kinase and consequent phosphorylation and degradation of tight junction proteins, such as occludin, claudin-5, and ZO-1 (Northrop and Yamamoto, 2015). A decrease in BBB function evidenced by a decrease in TEER and an increase in monocyte migration are also observed in brain microvascular endothelial cells. It has been suggested that the effects of ethanol on tight junction proteins and barrier function are associated with increases in ROS, resulting from ethanol metabolism and increased calcium concentrations. Ethanol in combination with methamphetamine could potentiate methamphetamine-induced BBB disruption through its proinflammatory and prooxidant effects. Biomarkers of ethanol-induced effects on BBB are summarized in Table 56.2.

For details on biomarkers of drugs of abuse, readers are referred to Chapter 52 of this book.

Neurodegenerative Diseases and Other Conditions

Neurodegenerative Diseases

In a number of CNS diseases, including neurodegenerative diseases (AD, PD, MS, ALS, and Huntington), the structure and function of BBB and/or BCSFB are compromised. The BBB itself may play an active role in the mediation of the neuroimmune response either by production of inflammatory mediators or by the expression of adhesion molecules. In neurological diseases, various inflammatory mediators, such as cytokines (TNF, IL-1β, and IL-6), prostaglandins (PGD$_2$, PGE$_2$, PGF$_{1\alpha}$, and PGF$_{2\alpha}$), thromboxane A$_2$, and leukotrienes, can be used as biomarkers of inflammation. The common adhesion molecules include (1) intercellular adhesion molecule-1, (2) intercellular adhesion molecule-2, and (3) vascular cell adhesion molecule-1; alterations in these parameters can be used as biomarkers.

Brain barriers possibly contribute to the etiology of AD by three aspects: (1) the aging of cerebral vascular structure in the overall aging process of the brain, (2) as the site of transport of extracerebral Aβ into the brain, and (3) the ability to prevent aggregation by producing transthyretin (Zheng, 2001). The neuropathological hallmark of AD is the aggregation of Aβ peptide in senile plaques and neurofibrillary tangles and is often used as a biomarker of AD. Detailed biomarkers of AD are summarized in Table 56.3 and described in Chapter 50 of this book.

The quantification of α-synuclein in CSF has been proposed as a diagnostic biomarker for PD and other α-synuclein—related diseases, such as multiple system

atrophy and dementia with Lewy bodies (Mollenhauer, 2014). Biomarkers of PD are described in detail in Chapter-51 of this book.

BBB disruption is one of the hallmarks of MS. Development of sensitive and specific biomarkers for MS has been a challenge as they could (1) improve the monitoring of disease activity, (2) improve the monitoring of response to MS therapies that target BBB disruption, and (3) advance our understanding of dynamic MS processes participating in BBB disruption (Waubant, 2006). The presence of gadolinium-enhancing lesions on serial brain MRI scans is frequently used to evaluate BBB disruption. In MS, cerebral infections, hypertension, or seizures, enhanced permeability of BBB and is considered to be the result of either opening of tight junctions or of enhanced pinocytotic activity and the formation of transendothelial channels (De Vries et al., 1997).

Several studies for ALS biomarkers have been conducted, while others are ongoing (Su et al., 2013). It has been demonstrated that protein biomarkers in both plasma and CSF may aid the diagnosis and prognosis of patients with ALS (Mitchell et al., 2009, 2010). In CSF, various classes of biomarkers have been investigated with special attention to neurofilament protein, *tau* protein, S100-β, and cystatin C. Cytoskeletal protein *tau* can be measured in CSF and blood and used as a prognostic biomarker of ALS. Su et al. (2013) measured plasma and CSF levels of 35 biomarkers using multiplex and immunoassay analysis for prognosis of ALS. In a recent study, Gendron et al. (2017) identified the use of phosphorylated neurofilament heavy chain as a prognostic biomarker for clinical trials that may likely be useful in developing a successful treatment for C9ALS. Currently, none of the biomarkers is specific to BBB damage or dysfunction induced by ALS.

Epilepsy

Biomarkers in epilepsy play multiple roles because they may (1) predict the development of an epilepsy condition, (2) identify the presence and severity of tissue capable of generating spontaneous seizures, (3) measure progression after the condition is established, (4) be used to create animal models for more cost-effective screening of potential antiepileptic and antiseizure drugs and devices, and (5) reduce the cost of clinical trials of potential antiepileptogenic interventions (Engel et al., 2013). The mechanisms involved in the development of epilepsies and the generation of spontaneous recurrent seizures are multifactorial. Biomarkers linked to a precipitating factor could be useful for seizure prediction and the possible development of interventions. In epilepsy, biomarkers can vary from imaging (MRI, PET, or SPECT) and electrophysiological measurements to changes in gene expression and metabolites in blood or tissues (Engel et al., 2013; Obenaus, 2013). Alterations

TABLE 56.3 Biomarkers of Brain Barriers in Neurodegenerative Diseases and Other Neurological Conditions

Disease	Biomarkers	References
Alzheimer's disease	β-amyloid (Aβ peptide) in senile plaques and neurofibrillary tangles, increased BBB permeability, aberrant protein kinase C (PKC-zeta), dysfunctional BCSFB, decreased transthyretin, haptoglobulin in CSF, IL-1, ICAM-1, increased albumin in CNS, CSF/Serum ratio of albumin, and altered occludin and claudins	Moore et al. (1998), De Vries et al. (1997), Zisper et al. (2007), Abdel-Rehman et al. (2004), Agyare et al. (2013), Erickson and Banks (2013), and Srinivasan et al. (2016)
Parkinson's disease	Intracellular α-synuclein deposition, CSF α-synuclein and β-amyloid, and α-synuclein/total protein ratio	Shaltiel-Karyo et al. (2013), Mollenhauer (2014), Stav et al. (2015), and Wang et al. (2015)
Multiple sclerosis (MS)	BBB disruption, increased CSF osteopontin, pathological legions, gliosis, gadolinium enhancement on MRI scans, and changes in MMPs	Kermode et al. (1990), De Vries et al. (1997), Minagar and Alexander (2003), Palmer (2010), Waubant (2006), and Szalardy et al. (2013)
Amyotrophic lateral sclerosis (ALS)	Increased phosphorylated neurofilament heavy chain in CSF, *tau* protein in CSF and blood, cytokines (IL-1β, IL-1RA, IL-5, IL-9, IL-8, IL-10, IL-12, IL-15), RANTES, high granzyme B, eotaxin, growth factors, plasma L-ferritin, plasma-CSF interferon-γ ratio, high Nogo-A, low cystatin C, genetic biomarkers, and many others	Mitchell et al. (2009, 2010), Su et al. (2013), Bakkar et al. (2015), and Gendron et al. (2017)
Huntington's disease	Mutant Huntingtin protein (mHtt) aggregates, increased transcytosis, increased blood vessel density, reduced blood vessel diameter, reduced occludin-5 and claudin, BBB disruption, and increased permeability	Drouin-Ouellet et al. (2015)
Schizophrenia	Impaired choroid plexus and BCSFB	Rudin (1979)
Allergic encephalomyelitis	BBB disruption, decrease in number of mitochondria, and increased permeability	Claudio et al. (1989) and Hawkins et al. (1991)
HIV-1 and AIDS dementia	Detection of HIV-1 in blood−CNS barriers, increased cytokines (TNF, IL-1β, and IL-6) in CSF, HIV-1 gp-120 proteins, fibrinogen, IgG, increased BBB permeability, and BBB breakdown	Harouse et al. (1989), Petito and Cash (1992), De Vries et al. (1997), Kanmogne et al. (2005), Banks et al. (2006), Ivey et al. (2009), and Northrop and Yamamoto (2015)
Gulf war illness	Increased BBB permeability	Gupta et al. (2015)
Traumatic brain injury (TBI)	Brain edema, BBB disruption, BBB breakdown, loss of tight junction proteins (occludin, claudin-5, ZO-1), reduced expression of PDGFR-β, increased BBB permeability, decreased TEER, increased glutamate, αII-spectrin, GFAP, and serum microRNA let-7i	Ling et al. (2009), Shlosberg et al. (2010), Chodobski et al. (2011), Balakathiresan et al. (2012), Hue et al. (2013), Tate et al. (2013), Tomkins et al. (2013), Shetty et al. (2014), and Dobbins and Pan (2015)
Chronic traumatic encephalopathy (CTE)	*Tau* protein aggregation, tauopathy, and myelinated axonopathy	Goldstein et al. (2014)
Convulsions, seizures, and epilepsy	Increased BBB permeability, BBB dysfunction, electrophysiologic and imaging biomarkers, TGF-β, and GLUT1 deficiency	Ashani and Catravas (1981), Oztas and Kaya (2003), Oby and Janigro (2006), Persidsky et al. (2006), Remy and Beck (2006), Cacheaux et al. (2009), Staba and Bragin (2011), Engel et al. (2013), Obenaus (2013), and Salar et al. (2014)
Reversible cerebral vasoconstriction syndrome (RCVS) (Thunderclap headache)	BBB breakdown, arterial vasoconstriction, and hyper intense vessels	Chen and Wang (2014) and Lee et al. (2017)
Brain edema	Increased BBB permeability	Jangula and Murphy (2013)
Stress (from heat, combat, chemicals, etc.)	Increased serotonin, and increased BBB permeability	Sharma and Dey (1986), Škultétyová et al. (1998), and Amourette et al. (2009)
Hypoxia	Claudin-5	Koto et al. (2007)

in RNA, protein, and metabolites are biomarkers of loss of neurons, gliosis, inflammation, changes in BBB, angiogenesis, neurogenesis, etc. A growing body of evidence has shown that inflammatory mechanisms may participate in the pathological changes observed in epileptic brain, with increasing awareness that blood-borne cells or signals may participate in epileptogenesis by virtue of a leaky BBB (Oby and Janigro, 2006).

In epilepsy, pharmacoresistance to antiepileptic drugs is a common therapeutic challenge, as it occurs in about 30%−70% patients (Salar et al., 2014). These authors and others demonstrated that a dysfunctional BBB with acute extravasation of serum albumin into the brain's interstitial space could contribute to pharmacoresistance (Remy and Beck, 2006). BBB dysfunction per se could serve as a biomarker to direct clinical decisions for alternative drugs with high efficiency and lower affinity or no affinity to albumin. Monitoring BBB integrity may therefore also be important in the management of epilepsy. In addition, modulation of drug transporters such as Pgp, MRP2, and BCRP at the BBB could help in easy entry of antiepileptic drugs (Löscher and Potschka, 2005).

HIV Infection

The BBB can be affected by HIV infection and is also involved in the progression of disease (Banks et al., 2006; Northrop and Yamamoto, 2015). HIV can increase the BBB permeability and infiltration of virus and immune cells. HIV proteins (Tat and gp-120) act on BMECs and result in increased neuroinflammation. HIV proteins cause BBB disruption via oxidative stress and inflammatory mechanisms, decreases in tight junction proteins (claudin-1, claudin-5, and ZO-2) in BMVECs, and cytotoxicity of BMVECs. These alterations are associated with increased expression of MMP-2 and MMP-9. Biomarkers of HIV-induced alterations in BBB are summarized in Table 56.3.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The CNS barriers, such as BBB and BCSFB, play significant roles in protecting the brain from endogenous and exogenous substances thereby maintaining brain homeostasis. These barriers, of course, allow required nutrients to reach the CNS. The structure of the BBB is very complex as it contains many molecules, enzymes, receptors, transporters, and proteins of known and unknown functions. The structure and functions of these barriers are known to be altered by a variety of toxicants (metals, pesticides, and mycotoxins), drugs of abuse and therapeutic drugs in higher doses, neurodegenerative diseases, and conditions of the CNS. These biomarkers may aid in diagnosis, prognosis, and disease interventions. The future of biomarkers of CNS barriers seems bright, and with newer technologies more specific and sensitive biomarkers will be developed that could detect chemical toxicosis and CNS disease very early and allow timely interventions.

INTRODUCTION

Reactive oxygen species (ROS) and reactive nitrogen species (RNS) are molecules or molecular fragments containing one or more unpaired electrons in atomic or molecular orbitals, which characterize free radicals with high reactivity. Exogenous agents (such as pesticides, metals, xenobiotics, and ionizing radiation) and a variety of endogenous processes (cellular respiration, antibacterial defense, phagocytic oxidative bursts, and others) can generate significant amounts of ROS and RNS in the human body (Chakravarti and Chakravarti, 2007; Mangialasche et al., 2009; Il'yasova et al., 2012). Both species of free radicals are also products of normal cellular metabolism.

Mitochondrial oxidative phosphorylation generates the majority of free radicals in the cell (Federico et al., 2012; Morán et al., 2012; Quinlan et al., 2012; Trewin et al., 2018; Sas et al., 2018). ROS are produced mainly as superoxide, when electrons leak onto molecular oxygen in side reactions from prosthetic groups or coenzymes involved in these redox reactions. Superoxide further serves as a precursor to the formation of the hydroxyl radical (HO•), the most reactive radical. The hydroxyl radical is produced by the Fenton and Haber—Weiss reactions from hydrogen peroxide (H_2O_2) and metal species (iron, copper) (Dix and Aikens, 1993; Guéraud et al., 2010). Superoxide easily reacts with nitric oxide (NO•) and forms peroxynitrite ($ONOO^-$), an RNS with very high reactivity (Vatassery, 2004). Peroxynitrite is a powerful oxidant exhibiting a wide array of tissue-damaging effects ranging from lipid peroxidation and inactivation of enzymes and ion channels via protein oxidation and nitration to inhibition of mitochondrial respiration (Virag et al., 2003). Peroxynitrite, which

dissipates during oxidation (Wang et al., 2003), has also been found to nitrate and oxidize adenine, guanine, and xanthine nucleosides (Sodum and Fiala, 2001). Low concentrations of peroxynitrite trigger apoptotic cell death, whereas higher concentrations induce necrosis with cellular energetics (ATP and NAD) serving as a switch between the models of cell death. Superoxide is also involved in the production of nitrogen dioxide radical and hydrogen peroxide, which can be further transformed into lipid peroxidation—initiating species, namely peroxyl and alkoxyl radicals (ROO• and RO•) (Dix and Aikens, 1993; Guéraud et al., 2010).

Furthermore, ROS and RNS are also normally generated by tightly regulated enzymes or enzyme systems located in or associated with cellular membranes or organelles, in both phagocytic and nonphagocytic cells. Nitric oxide synthases (NOSs) and nicotinamide adenine dinucleotide phosphate [NAD(P)H] oxidase isoform—produced ROS/RNS are also involved in cellular signaling, synaptic plasticity in the central nervous system (CNS), neuronal transmission, reactions to stress and various agents, and the induction of mitogenic and apoptotic responses (Beal, 2000; Valko et al., 2007; Mangialasche et al., 2009).

ROS and RNS, produced under various mechanisms, can react with lipids, sugars, proteins, and nucleic acids and inhibit normal cell functions (Deavall et al., 2012; Cheignon et al., 2018). This damage can compromise cell viability or induce cellular response leading to cell death by necrosis or apoptosis (Valko et al., 2007; Mangialasche et al., 2009; Du et al., 2018; Fang et al., 2017). Importantly, living systems have developed several mechanisms to control these harmful effects of ROS and RNS. These mechanisms are mainly based on the presence of antioxidants (enzymatic and

nonenzymatic) and the repair or removal of the injured molecules/systems. Antioxidants are natural or synthetic molecules preventing excessive formation of ROS or inhibiting their reaction with biological structures and/or molecules. Antioxidant defense involves a variety of strategies, both enzymatic, such as superoxide dismutase, catalase, thioredoxin reductase, and glutathione peroxidase (GPx), and nonenzymatic, involving tocopherols, carotenes, ascorbate, glutathione (GSH), ubiquinols, and flavonoids (Halliwell, 2007; Espinosa-Diez et al., 2015; Radomska-Leśniewska et al., 2016, 2017; Valko et al., 2007; Vallejo et al., 2017). Different systems/mechanisms cooperate in the regulation of ROS/RNS production and neutralization, which is essential for avoiding their detrimental effects and preserving equilibrium. This is termed *redox homeostasis* (Droge, 2002).

LIPID PEROXIDATION AND MARKERS OF OXIDATIVE STRESS

Because of the high concentration of substrate polyunsaturated fatty acids (PUFA) in cells, lipid peroxidation is a major outcome of free radical—mediated injury (Montine et al., 2002). Lipid peroxidation is the mechanism by which lipids are attacked by chemical species that have sufficient reactivity to abstract a hydrogen atom from a methylene carbon in their chain. Lipid peroxidation in vivo, through a free radical pathway, requires a PUFA and a reactant oxidant inducer that together form a free radical intermediate. The free radical intermediate subsequently reacts with oxygen to generate a peroxyl radical, which with unpaired electrons may additionally abstract a hydrogen atom from another PUFA. The greater number of double bonds in the molecule and the higher instability of the hydrogen atom adjacent to the double bond explain why unsaturated lipids are particularly susceptible to peroxidation (Pratico et al., 2004; Gao et al., 2006).

A critically important aspect of lipid peroxidation is that it will proceed until the oxidizable substrate is consumed or termination occurs, making this fundamentally different from many other forms of free radical injury in that the self-sustaining nature of the process may entail extensive tissue damage (Porter et al., 1995). Decreased membrane fluidity following lipid peroxidation makes it easier for phospholipids to exchange between the two halves of the bilayer, increase the leakiness of the membrane to substances that do not normally cross it other than through specific channels (e.g., K^+, Ca^{2+}), and damage membrane proteins, inactivating receptors, enzymes, and ion channels (Halliwell, 2007). Increases in Ca^{2+} induced by oxidative stress can activate phospholipase A_2, which then releases arachidonic acid

(AA) from membrane phospholipids. The free AA can then both undergo lipid peroxidation (Farooqui et al., 2001) and act as a substrate for eicosanoid synthesis. Increased prostaglandin synthesis is immediately linked to lipid peroxidation because low levels of peroxides accelerate cyclooxygenase action on polyunsaturated fatty acids (Smith, 2005). Phospholipase A_2 can also cleave oxidized AA residues from membranes.

The use of reactive products of lipid peroxidation as in vivo biomarkers is limited because of their chemical instability and rapid and extensive metabolism (Gutteridge and Halliwell, 1990; Moore and Roberts, 1998). For these reasons, other more stable lipid products of oxidative damage have generated intense interest in recent years as in vivo markers of oxidative damage (De Zwart et al., 1999). These compounds include the F_2-isoprostanes (F_2-IsoPs), F_3-Isops, isofurans (IsoFs), and F_4-neuroprostanes (F_4-NeuroPs) (Morrow et al., 1990; Fessel et al., 2002; Yin et al., 2007; Janicka et al., 2010).

PROSTAGLANDIN-LIKE COMPOUNDS AS *IN VIVO* MARKERS OF OXIDATIVE STRESS

F_2-IsoPs are prostaglandin-like compounds that are produced by a noncyclooxygenase free radical—catalyzed mechanism involving the peroxidation of the PUFA, arachidonic acid (AA, C20:4, ω-6). Formation of these compounds initially involves the generation of four positional peroxyl radical isomers of arachidonate, which undergo endocyclization to PGG_2-like compounds. These intermediates are reduced to form four F_2-IsoP regioisomers, each of which can consist of eight racemic diastereomers (Morrow et al., 1990). In contrast to cyclooxygenase (COX)-derived prostaglandins (PGs), nonenzymatic generation of F_2-IsoPs favors the formation of compounds in which the stereochemistry of the side chains is *cis* oriented in relation to the prostane ring. A second important difference between F_2-IsoPs and PGs is that F_2-IsoPs are formed primarily in situ, esterified to phospholipids, and subsequently released by phospholipases (Famm and Morrow, 2003; Gao et al., 2006), whereas PGs are generated only from free arachidonic acid (Morrow et al., 1990). The basic formation process is depicted in Fig. 57.1.

F_2-IsoPs analog may be formed by peroxidation of docosahexaenoic acid (DHA, C22:6, ω-3), which generates F_4-IsoPs. These compounds are also termed neuroprostanes (F_4-NeuroPs), because of the high levels of their precursor in the brain (Roberts et al., 1998). In contrast to AA, which is evenly distributed in all cell types in all tissues, DHA is highly concentrated in neuronal membranes (Salem et al., 1986). DHA is obtained mainly through dietary means as the human body can only
FIGURE 57.1   Schematic of the compound-forming process.

minimally synthesize this fatty acid. DHA deficiency has been linked to slow mental development (Connor et al., 1992), whereas DHA supplementation has been linked to a variety of health benefits including decreased rates of neurodegenerative diseases (Schaefer et al., 2006). DHA can undergo oxidation both in vitro and in vivo, and increased units of unsaturation suggest its higher susceptibility to lipid peroxidation than AA. Thus, although the measurement of F_2-IsoPs provides an index of global oxidative damage in the brain, integrating data from both glial and neuronal cells, determination of F_4-NeuroPs permits the specific quantification of oxidative damage to neuronal membranes in vivo. In fact, to our knowledge, F_4-NeuroPs are the only quantitative in vivo marker of oxidative damage that is selective for neurons. This is particularly important because of the implication of oxidative damage and lipid peroxidation being causative factors in numerous neurodegenerative diseases (Montine et al., 2004; Milatovic et al., 2005b).

Another F_2-IsoPs analog may be formed by peroxidation of eicosapentaenoic acid (EPA, C20:5, ω-3) that leads to the production of F_3-IsoPs. Levels of F_3-IsoPs can significantly exceed those of F_2-IsoPs generated from AA, perhaps because EPA contains more double bonds and is therefore more easily oxidizable (Gao et al., 2006). It has also been shown that in the presence of increased oxygen tension in the microenvironment in which lipid peroxidation occurs, an additional oxygen insertion step may take place (Fessel et al., 2002). This step diverts the IsoP pathway to form tetrahydrofuran ring–containing compounds termed isofurans (IsoFs), which are functional markers of lipid peroxidation under conditions of increased oxygen tension. Thus, measurements of IsoFs represent a much more robust indicator of hyperoxia-induced lung injury than measurements of F_2-IsoPs. Similar to IsoPs, the IsoFs are chemically and metabolically stable, so they are well suited to act as in vivo biomarkers of oxidative damage.

Stable isotope dilution, negative ion chemical ionization (NICI) gas chromatography/mass spectrometry (GC/MS) with select ion monitoring (SIM) was the first technique used in early discovery and quantification of isoprostanes by investigators at Vanderbilt University (Morrow et al., 1990). This methodology allows the lower limit of detection of the F_2-IsoPs to be in the low picogram range. Quantification of the F_2-IsoPs levels is achieved by comparing the height/areas of the peak containing derivatized F_2-IsoPs (m/z 569) with the height of the deuterated internal standard peak (m/z 573) (Fig. 57.2). These properties, along with the assay's high sensitivity and specificity, allow the F_2-IsoPs to be excellent biomarkers of and the most robust and sensitive measure of oxidative stress in vivo. However, mass spectrometry–based methods necessitate a skilled technical staff and are laborious to execute, because of extensive purification and appropriate derivatization procedures. In addition, over the past 20 years other methods such as enzyme immunoassays, radioimmunoassays, liquid chromatography (LC)–mass spectrometry, LC-MS-MS, and GC-MS-MS (Wang et al., 1995; Basu, 1998; Liang et al., 2003) have been developed and used to exploit the impact of this biomarker on human health and disease (Morrow et al., 1990; Wang et al., 1995; Pratico et al., 1998; Basu, 2008).

Immunoassays, although less specific and quantitative than GC-MS methods, have been found to be helpful tools for new discoveries in medical and pharmaceutical sciences. Immunoassays have a huge sample-analyzing capacity with fairly low expense. Thus, a well-validated technique could be a significant tool for evaluating free radical–mediated reactions in clinical research, where a large number of samples must be analyzed at an affordable cost. Specific antibodies against isoprostanes can also be used for in situ localization by immunostaining in oxidative stress–injured tissues. Immunostaining with specific antibodies opens possibilities for therapeutic application of various radical scavengers in disease-related damage (Basu, 2008).

ALDEHYDES AS LIPID PEROXIDATION PRODUCTS

The enzymatic and free radical peroxidation of PUFAs, which contain at least three double bonds, such as AA and DHA, could lead to malondialdehyde (MDA). This product can be generated by thromboxane synthase, but a report from the Biomarkers of Oxidative
FIGURE 57.2 Chromatograms for F_2-IsoPs and F_4-NeuroPs from the mouse cerebrum. All chromatograms plot abundance versus time (min). (A) m/z 569 chromatogram showing F_2-IsoPs, (B) m/z 573 chromatogram showing internal standard, (C) m/z 593 chromatogram showing F_4-NeuroPs.

Stress Study showed that peripheral levels of MDA derive primarily from nonenzymatic peroxidative degradation of unsaturated lipids (Kadiiska et al., 2005). Because MDA reacts with thiobarbituric acid (TBA), MDA–TBA adducts are used to spectrophotometrically measure the levels of oxidative stress and consequent lipid peroxidation (Spickett et al., 2010; Fang et al., 2017). MDA and MDA–TBA complex assessment can be also measured by high-performance liquid chromatography (HPLC) or GC-MS (Maboudou et al., 2002). Although more specific, this approach does not deduce all the limitations of this biomarker (Devasagayam et al., 2003; Sultana et al., 2006).

4-Hydroxy-2-nonenal (HNE) is a reactive aldehyde arising from peroxidation of ω6 fatty acid (Uchida, 2003; Guéraud et al., 2010; Fang et al., 2017). HNE is formed under various conditions such as auto-oxidation and stimulated microsomal lipid peroxidation (Neely et al., 2005). HNE is found in food (Gasc et al.,

2007) and detected in vivo (Neely et al., 2005). MDA and HNE are able to covalently modify proteins and alter their functions (Butterfield et al., 2006). In addition to protein modification, these lipid peroxidation products can also interfere with synthesis of DNA and RNA, alter cell metabolism and signaling, and mediate brain-induced oxidative damage. Several studies suggest MDA and HNE can promote the degeneration of cholinergic neurons, Aβ aggregation, and amyloidogenesis (Mark et al., 1995; Pedersen et al., 1999; Butterfield et al., 2006). In addition, increased levels of HNE and HNE-protein adducts (Montine et al., 1997; Markesbery and Lovell, 1998) have been described in the ventricular CSF and brain of AD patients compared with control subjects (Montine et al., 1997; Markesbery and Lovell, 1998).

Another highly reactive aldehydic product, acrolein, derived from the metal-catalyzed oxidation of polyunsaturated fatty acid, including AA and DHA, can also

promote the formation of protein adducts and thus promote neuronal damage (LoPachin et al., 2008). Studies suggest that acrolein can modify DNA, promote lipid peroxidation, induce tau oligomerization, and promote neurofibrillary tangles formation (Uchida et al., 1998; Lovell et al., 2000; Kuhla et al., 2007).

REACTIVITY OF LIPID PEROXIDATION PRODUCTS

Metabolization of secondary lipid peroxidation products such as HNE in most cells and tissues is rapid and complete. GSH conjugation seems to be the primary and major step. GSH maintains protein sulfhydryl groups in the reduced form and has been implicated in the regulation of cytoskeletal function. SH groups of cystein constitute a main protein-associated target of HNE (Esterbauer et al., 1991). Indeed, cellular detoxification of HNE is mainly achieved through conjugation to the cystein GSH. This reaction is catalyzed by GSH S-transferase and leads to a transient decrease in cellular GSH (Johnson et al., 1993; Hayes and Pulford, 1995; Kinter and Roberts, 1996; Cheng et al., 1999; Radomska-Leśniewska et al., 2017). If GSH is depleted by buthionine sulfoximine, for instance, or by a concomitant oxidative insult, there is a reduction in GSH-HNE conjugate together with an increase in unmetabolized HNE and HNE toxicity (Picklo et al., 2002). On the other hand, when the oxidative insult occurs some time before treatment of cells by HNE, preconditioned cells acquire resistance to HNE-induced apoptosis by metabolizing and excluding HNE at a higher rate when compared with nonpreconditional cells (Rice et al., 1986; Rabinovitch et al., 1993). We previously demonstrated that another main cellular target to HNE is tubulin, the core protein of microtubules containing abundant cystein (Neely et al., 2005). Our studies demonstrated that the exposure of Neuro2A cells to HNE results in the inhibition of cytosolic taxol-induced tubulin polymerization and thus supported the hypothesis that HNE adduction to tubulin is the primary mechanism involved in the HNE-induced loss of the highly dynamic neuronal microtubule network (Neely et al., 2005).

ROS and RON can react with the DNA molecule and induce purine or pyrimidine base or sugar lesions, nitration and deaminations of purines, DNA—DNA, or DNA—protein cross-links (Dizdaroglu et al., 2002). These processes lead to mutations and impaired transcriptional and posttranscriptional processes and compromise protein synthesis (Colurso et al., 2003). In addition, DNA damage, oxidative phosphorylation, and altered cell metabolism may lead to apoptosis and promote neuronal death (Becker and Bonni, 2004; Fishel et al., 2007). The most investigated DNA adduct, 8-hydroxy-2′-deoxyguanosine (8-OHdG), can be evaluated by multiple techniques including immunoassay, HPLC, GC-MS, capillary electrophoresis, and LC-MS. However, LC-MS techniques for DNA damage evaluation permit the identification of a wide range of base adducts and offer a more complete picture of DNA oxidation (Lovell and Markesbery, 2007; Mangialasche et al., 2009; Fang et al., 2017).

Although ROS and RNS can attack any amino acid, sulfur-containing and aromatic amino acids are the most susceptible (Stadtman and Levine, 2003). The oxidation of amino acids leads to the formation of carbonyl derivatives, produced by fragmentation, due to an attack on several amino acid side chains, and by formation of adducts between some amino acids residues and products of lipid peroxidation. Protein carbonyls can be detected with 2,4-dinitrophenylhydrazine (DNPH) and used as biomarkers of oxidative stress (Dalle-Donne et al., 2003). Oxidation of protein also leads to protein fragmentation and protein cross-linking. In addition, peroxynitrite and a hydroxyl radical can react with tyrosine and form other indexes of protein oxidation, 3-nitrotyrosine and ortho-tyrosine, respectively. These products of oxidative/nitrosative modification of proteins are relatively stable with sensitive assays available for their detection (Chakravarti and Chakravarti, 2007).

EXCITOTOXICITY AND OXIDATIVE DAMAGE

The brain is especially susceptible to oxidative damage. The brain is relatively deficient in antioxidant systems, with a lower activity of GPx and catalase compared to other organs. It has high metabolic activity that requires large amounts of oxygen and contains redox-active metals (iron, copper) that can promote the production of free radicals. During normal physiological conditions, ROS are generated at a low rate in brain and are efficiently removed by scavenger and antioxidant systems. However, in pathophysiological conditions, such as seizures and acetylcholinesterase inhibitors (organophosphates and carbamates) toxicity, a high rate of ATP consumption is accompanied by increased generation of ROS. Previous studies have supported the role for oxidative stress and excessive generation of ROS and RNS in anticholinesterase-induced neurotoxicity (Dettbarn et al., 2001; Gupta et al., 2001a,b, 2007; Milatovic et al., 2005a). During sustained seizures, the flow of oxygen to the brain is greatly increased at a time when the use of ATP is greater than the rate of its generation. This metabolic stress results in a markedly increased ROS generation. A greatly increased rate of

ROS production, overwhelming the capacity of inherent cellular defense systems, results in an attack on the mitochondria and cell membranes, leading to peroxidation of lipids, cell lesions, and, in turn, cell death (Sjodin et al., 1990).

Processes such as excitotoxicity and inhibition of acetylcholinesterase (AChE) lead to unremitting stimulation of nervous tissue and muscle, which, in turn, causes depletion of high-energy phosphates (HEP), ATP, and phosphocreatine (PCr) and ROS generation (Dettbarn et al., 2001, 2006). If this stimulation is sufficiently low in intensity or brief in duration, cellular recovery will ensue without lasting consequences. If, however, intense cholinergic stimulation is allowed to persist, a self-reinforcing cycle of cellular damage is set in motion. ATP depletion for several hours to approximately 30%–40% of normal levels leads to a fall in the mitochondrial membrane potential that is associated with (1) reduced energy production (because of decrease in complex I and complex IV activities), (2) impaired cellular calcium sequestration, (3) activation of protease/caspases, (4) activation of phospholipases, (5) activation of nitric oxide synthase (NOS), and (6) excessive generation of ROS (Milatovic et al., 2006). Several of these steps are associated with exacerbation and propagation of the initial depletion of ATP; most notable are the decreases in complex I and IV activities, the impairment of mitochondrial calcium metabolism that regulates ATP production even in the face of a constant supply of substrates, and the generation of nitric oxide, which binds reversibly to cytochrome c oxidase (COx) in competition with oxygen, with subsequent sensitization to hypoxia. COx is the terminal complex in the mitochondrial respiratory chain, which generates ATP by oxidative phosphorylation, involving the reduction of O_2 to H_2O by the sequential addition of four electrons and four H^+. Electron leakage occurs from the electron transport chain, which produces the superoxide anion radical and H_2O_2. Under normal conditions, COx catalyzes more than 90% of the oxygen consumption in the cells. The chance of intermediate products, such as superoxide anion radical and H_2O_2 and hydroxyl radical, escaping is less under conditions where COx remains active. During the hyperactivity of brain or muscle, the activity of COx is reduced (Milatovic et al., 2001), leading to an increased electron flow within the electron transport chain, thereby increasing ROS generation, oxidative damage to mitochondrial membranes, and vulnerability to excitotoxic impairment (Soussi et al., 1989; Gollnick et al., 1990; Bose et al., 1992; Bondy and Lee, 1993; Yang and Dettbarn, 1998).

Excitotoxicity-induced cell damage is also thought to result from an intense transient influx of calcium leading to mitochondrial functional impairments characterized by activation of the permeability transition pores in the inner mitochondrial membrane, cytochrome c release, depletion of ATP, and simultaneous formation of ROS (Cadenas and Davies, 2000; Nicholls and Ward, 2000; Heinemann et al., 2002; Patel, 2002; Nicholls et al., 2003). In addition, increase in cytoplasmic calcium ions triggers intracellular cascades through stimulation of enzymes, including proteases, phospholipase A_2, and nitric oxide synthase, which also leads to increased levels of free radical species and oxidative stress (Lafon-Cazal et al., 1993; Farooqui et al., 2001). Because free radicals are direct inhibitors of the mitochondrial respiratory chain, ROS generation perpetuates a reinforcing cycle, leading to extensive lipid peroxidation and oxidative cell damage (Cadenas and Davies, 2000; Cock et al., 2002).

Our studies have shown that kainic acid (KA)—induced excitotoxicity and anticholinesterases, such as diisopropylphosphorofluoridate (DFP) and carbofuran (CF), cause neuronal injury by excessive formation of ROS (Yang and Dettbarn, 1998; Gupta et al., 2001a,b; Milatovic et al., 2000a,b, 2001, 2005a; Zaja-Milatovic et al., 2008). Exposure to DFP or carbofuran significantly suppressed AChE activity, induced severe seizure activity, and significantly increased biomarkers of global free radical damage (F_2-IsoPs) and the selective peroxidation biomarker of neuronal membranes (F_4-NeuroPs) (Gupta et al., 2007; Zaja-Milatovic et al., 2009). Although twofold elevations are seen in F_2-IsoPs levels, F_4-NeuroPs levels are fivefold higher compared to controls (Fig. 57.3). The selective increase in F_4-NeuroPs indicates that neurons are specifically targeted by this mechanism.

DFP or CF exposures also caused marked elevation in brain citrulline levels (an indicator of NO/NOS activity) (Gupta et al., 2001b, 2007). Many reports provide evidence that NO impairs mitochondrial/cellular respiration and other functions by inhibiting the activities of several key enzymes, particularly COx, and thereby causing ATP depletion (Yang and Dettbarn, 1998; Dettbarn et al., 2001; Gupta et al., 2001a; b; Milatovic et al., 2001). Results from our experiments also showed that 1 hour after DFP (1.5 mg/kg, s.c.) or CF (1.5 mg/kg, s.c.) treatment, the levels of ATP and PCr were significantly reduced in the cortex, hippocampus, and amygdala (Gupta et al., 2001a,b). The rapid decrease in energy metabolites at the onset of seizures indicates early onset of mitochondrial dysfunction, in turn further increasing ROS production and neuronal injury.

The most consistent pathological findings in acute experiments with anticholinesterases include degeneration and cell death in the pyriform cortex, amygdala, hippocampus (where the CA1 region is preferentially destroyed), dorsal thalamus, and cerebral cortex. The early morphological changes in AChEI-induced status epilepticus (SE) include dendritic swelling of pyramidal
FIGURE 57.3 Effect of DFP (1.5 mg/kg, s.c.) and carbofuran (CF, 1.5 mg/kg, s.c.) on F_2-IsoPs (A) and F_4-NeuroPs (B) levels in rat brain. Rats were sacrificed 1 h after DFP or CF injection. Values are mean $\pm$ SEM (n = 4−6). [a]Significant difference between control and DFP- or CF-treated rats ($P < .05$).

neurons in the CA1 region of the hippocampus (Carpentier et al., 1991). Therefore, we have investigated whether seizure-induced cerebral oxidative damage in adult rats is accompanied by alterations in the integrity of the hippocampal CA1 dendritic system. Our results showed that anticholinesterase induced early increases in biomarkers of global free radical damage (F_2-IsoPs), and the selective peroxidation biomarker of neuronal membranes (F_4-NeuroPs) was accompanied by dendritic degeneration of pyramidal neurons in the CA1 hippocampal area. Anticholinesterase-induced brain hyperactivity targeted the dendritic system with profound degeneration of spines and regression of dendrites, as evaluated by Golgi impregnation and Neurolucida-assisted morphometry (Fig. 57.4).

Rats injected with DFP show a significant decrease in total dendritic length and spine density compared to pyramidal neuron from the hippocampal CA1 area of control rats (Fig. 57.4). Taken together, our results revealed that anticholinesterase exposure is associated with oxidative and nitrosative stresses, alteration in energy metabolism, and consequent degeneration of pyramidal neurons from the CA1 hippocampal region of rat brain. Ultimately, the additive or synergistic mechanisms of cellular disruption caused by anticholinesterase agents lead to cellular dysfunction and neurodegeneration.

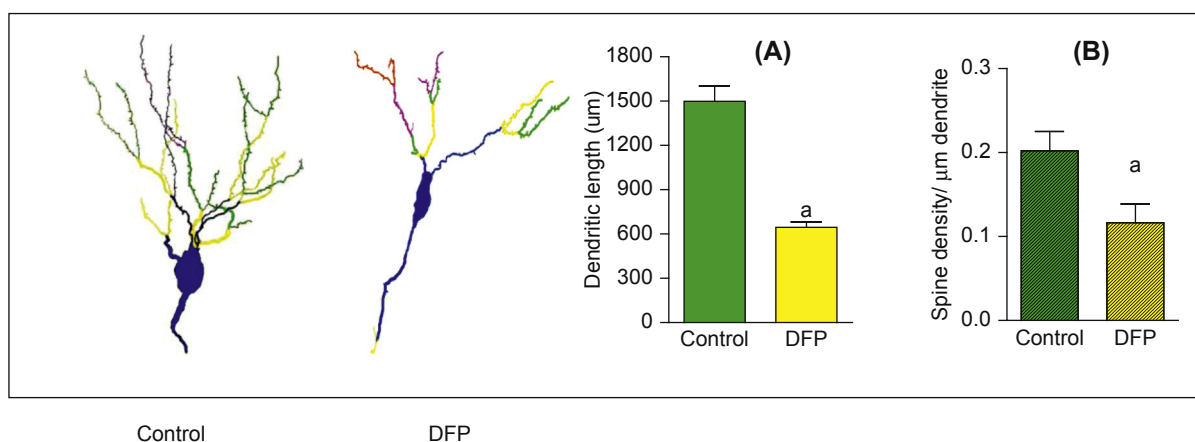
Similar studies investigated the role of glutamatergic excitation, oxidative injury, and neurodegeneration in the model of KA excitotoxicity. We have used intracerebroventricular (icv) injection of KA and investigated whether F_2-IsoPs and F_4-NeuroPs formations correlated with the vulnerability of pyramidal neurons in the CA1 hippocampal area following KA-induced excitotoxicity.


FIGURE 57.4 Morphology and quantitative determination of dendritic length (A) and spine density (B) of hippocampal pyramidal neurons from CA1 sector of rats treated with saline (control) or DFP (1.5 mg/kg, s.c.) and sacrificed 1 h after the treatment. Four to six Golgi-impregnated dorsal hippocampal CA1 neurons were selected and spines were counted using Neurolucida system. [a]Significant difference between control and DFP-treated rats ($P < .05$). Treatment with DFP induced degeneration of hippocampal dendritic system and a decrease in the total length of dendrite and spine density of hippocampal pyramidal neurons. Tracing and counting were done using a Neurolucida system at 100× under oil immersion (MicroBrightField, VT). Colors indicate degree of dendritic branching (blue = 1 degree, yellow = 2 degrees, green = 3 degrees, magenta = 4 degrees, orange = 5 degrees).

Our results showed that icv KA induced an early increase in biomarkers of oxidative damage, F_2-IsoPs and F_4-NeuroPs. Elevated levels of these in vivo markers of oxidative damage are in agreement with our previous findings (Montine et al., 2002; Milatovic et al., 2005b; Gupta et al., 2007), as well as those of others (Patel et al., 2001; Kiasalari et al., 2013, 2016) and indicate that KA injection leads to profound cerebral and neuronal oxidative damage in mice.

Our results also showed that the transient rise in F_2-IsoPs and F_4-NeuroPs is accompanied by rapid evolution of dendritic abnormalities, which is apparent in the significant decrease in dendritic length and spine density of pyramidal neurons as early as 30 min post KA injection. However, the recovery in oxidative damage biomarkers at 60 min following the injection was not paralleled by the rescue of damaged neurons from the CA1 hippocampal area. Extended seizure activity (60 min) induced the same level of dendritic length and spine density decrease when compared to 30 min following KA injection (Table 57.1). Together, these data suggest that both oxidative stress and neurodegeneration occur as an early response to seizures, but they do not establish whether oxidative stress is a cause or effect of seizure-induced CA1 cell damage. Neuronal damage processes triggered by sustained seizure activity may occur as a continuum, last longer than the formation of oxidative lipids and although not evident by the markers, and may already be in progress when the peak increases in F_2-IsoPs and F_4-NeuroPs occur. Thus, we investigated dynamic changes in lipid peroxidation and dendritic structures immediately after seizures, but future studies over the longer period should be able to determine the long-term time course of these spine and dendritic changes. It is very likely that the spine loss seen in our study is the initial phase of more chronic spine loss and progressive neurodegeneration reported in other studies (Isokawa and Levesque, 1991; Muller et al., 1993; Multani et al., 1994; Jiang et al., 1998; Zeng et al., 2007; Fang et al., 2017; Sabens Liedhegner et al., 2012).

NEUROINFLAMMATION AND OXIDATIVE INJURY

Neuroinflammation is a complex response to brain toxicity involving the activation of glia, release of inflammatory mediators, such as cytokines and chemokines, and the generation of ROS and RNS. The links among risk factors and the development of neuroinflammation are numerous and involve many complex interactions that contribute to vascular compromise, oxidative stress, and, ultimately, brain damage (Montine et al., 2002; Milatovic et al., 2003, 2004; Salinaro et al., 2018; Calabrese et al., 2016; Fang et al., 2017; Guangpin and Ping, 2016). Once this cascade of events is initiated, the process of neuroinflammation can become overactivated, resulting in further cellular damage and loss of neuronal functions.

Acute neuroinflammatory response resulting in phagocytic phenotype and the release of inflammatory mediators such as free radicals, cytokines, and chemokines (Tansey et al., 2007; Frank-Cannon et al., 2009) may be generally beneficial to the CNS because it tends to minimize further injury and contributes to repair of damaged tissue. In contrast, chronic neuroinflammation is a long-standing and often self-perpetuating neuroinflammatory response that persists long after an initial injury or insult. Sustained release of inflammatory mediators and increased oxidative and nitrosative stress activate additional microglia, promoting their proliferation and resulting in further release in inflammatory factors. Owing to this sustained nature of inflammation, the blood—brain barrier (BBB) may be compromised, thus increasing infiltration of peripheral macrophages into the brain parenchyma and perpetuating the inflammatory process further (Rivest, 2009). Rather than serving in a protective role, as does acute neuroinflammation, chronic neuroinflammation is most often detrimental and damaging to nervous tissue. Thus, whether neuroinflammation has beneficial or harmful outcomes in the brain may critically depend on the duration of the inflammatory response.

TABLE 57.1 Cerebral Concentrations of F_2-IsoPs and F_4-NeuroPs and Dendritic Degeneration of Hippocampal Pyramidal Neurons Following KA-Induced Seizures in Mice

	F_2-IsoPs (ng/g)	F_4-NeuroPs (ng/g)	Dendritic Length (μm)	Spine Density (Number of Spinal/ 100 μm Dendrite)
Control	3.07 ± 0.05	13.89 ± 0.58	1032.10 ± 61.41	16.45 ± 0.55
KA 30 min	$4.81 \pm 0.19*$	$34.27 \pm 2.71*$	$363.44 \pm 20.78*$	$8.81 \pm 0.55*$
KA 60 min	3.40 ± 0.18	18.55 ± 1.26	$425.71 \pm 23.04*$	$7.44 \pm 0.56*$

Data from KA-exposed mice were collected 30 min or 60 min postinjection. *One-way ANOVA showed $P < .0001$ for each end point. Bonferroni's multiple comparison test showed significant difference ($P < .001$) compared to vehicle-injected control.

Activation of innate immunity occurs simultaneously with several pathogenic processes and responses to stressors and injury, thereby greatly confounding any clear conclusion about cause-and-effect relationships. For these reasons, we have adopted a simple, but highly specific model of isolated innate immune activation: intracerebroventricular (ICV) injection of low dose lipopolysaccharide (LPS). LPS specifically activates innate immunity through a Toll-like receptor (TLR)—dependent signaling pathway (Imler and Hoffmann, 2001; Akira, 2003). Activation of proteins (CD14 and adaptor protein MyD88), signal transduction cascade, primarily via NF-κB activation but also through c-Fos/c-Jun-dependent pathways, culminate in the generation of effector molecules, including bacteriocidal molecules. Free radicals generated by NADPH oxidase and myeloperoxidase (MPO), as well as cytokines and chemokines, are known to attract an adaptive immune response (Milatovic et al., 2004).

We have employed an ICV model and identified the molecular and pharmacologic determinants of LPS-initiated cerebral neuronal damage in vivo (Montine et al., 2002; Milatovic et al., 2003, 2004). Interestingly, the degree of oxidative damage in this model was equivalent to what we observed in diseased regions of brain from patients with degenerative diseases (Reich et al., 2001). Results from our studies with mice showed that single ICV LPS injections induced delayed, transient elevation in both F_2-IsoPs and F_4-NeuroPs 24 h after exposure and then returned to baseline by 72 h postexposure (Table 57.2) (Milatovic et al., 2003). Although others have shown that altered gene transcription and increased cytokine secretion occur rapidly and peak within a few hours of LPS exposure, it is likely that the delay in neuronal oxidative damage observed in our experiments is related, at least in part, to the time required to deplete antioxidant defenses.

To address whether oxidative damage is related to neurodegeneration, we directly examined the dendritic compartment of neurons, which is largely transparent to the standard histological techniques used so far to investigate ICV LPS—induced damage. Using Golgi impregnation and Neurolucida-assisted morphometry of hippocampal CA1 pyramidal neurons (Leuner et al., 2003; Milatovic et al., 2010), we first determined the time course of dendritic structural changes following ICV LPS in mice. Our results show a time course similar to neuronal oxidative damage with maximal reduction in both dendrite length and dendritic spine density at 24 h post LPS and, remarkably, a return to baseline levels by 72 h (Table 57.2). Thus, these data strongly imply that neuronal oxidative damage is closely associated with dendritic degeneration following ICV LPS. We, along with others, have shown that primary neurons enriched in cell culture do not respond to LPS (Minghetti and Levi, 1995; Fiebich et al., 2001; Xie et al., 2002); therefore, our results also showed that LPS activated microglial-mediated paracrine oxidative damage to neurons.

It is becoming increasingly evident that neuroinflammation and associated oxidative damage plays a crucial role in the development and progression of brain diseases. Glia, and in particular microglia, are central to mediating the effects of neuroinflammation. Emerging evidence suggests that the number of activated microglia and the release of inflammatory mediators from these cells increase with age. This amplified or prolonged exposure to inflammatory molecules, including cytokines, chemokines, ROS, and PGs in the aged brain may impair neuronal plasticity and underlie a heightened neuroinflammatory response.

METAL TOXICITY AND OXIDATIVE INJURY

Essential metals are crucial for the maintenance of cell homeostasis. However, excessive exposure to some metals, including manganese (Mn) and mercury (Hg), present great health concerns and may lead to pathological conditions, including neurodegeneration.

TABLE 57.2 Cerebral Oxidative Damage and Dendritic Degeneration in Mice

	24 h ICV Saline	24 h ICV LPS	72 h ICV Saline	72 h ICV LPS
F_2-IsoPs (ng/g tissue)	3.26 ± 0.19	$4.77 \pm 0.26^*$	3.13 ± 0.11	2.98 ± 0.17
F_4-NeuroPs (ng/g tissue)	13.91 ± 1.17	$58.50 \pm 5.98^*$	12.30 ± 1.18	16.80 ± 0.96
Dendritic length (μm)	1018 ± 113	$324 \pm 37^*$	848 ± 60	1030 ± 61
Spine density (spine no./100 μm dendrite)	16.89 ± 1.67	$5.86 \pm 0.57^*$	17.09 ± 1.13	16.77 ± 0.87

Effects of ICV saline (5 μL, control) and ICV LPS (5 μg/5 μL) treatment determined at 24 and 72 h following exposure. Each value represents mean $\pm$ SEM (n = 4−6). *One-way ANOVA showed $P < .001$ for each end point. Bonferroni's multiple comparison test showed significant difference ($P < .01$) compared to vehicle-injected control.

Neurodegenerative mechanisms and effects of Mn and Hg are associated with oxidative stress. Mn can oxidize dopamine (DA), generating reactive species, and also affect mitochondrial function, leading to accumulation of metabolites and culminating with oxidative damage. Cationic Hg forms have a strong affinity for nucleophiles, such as −SH, and target critical thiol and selenol molecules with antioxidant properties. Therefore, mediation of these processes and control of oxidative stress may provide a therapeutic strategy for the suppression of dysfunctional neuronal transmission and a slowing of the neurodegenerative process.

MANGANESE

Mn toxicity is primarily associated with neurological effects. Excessive accumulation of Mn in specific brain areas, such as the substantia nigra, the globus pallidus, and the striatum, produce neurotoxicity leading to a degenerative brain disorder. Although the mechanisms by which Mn induces neuronal damage are not well defined, its neurotoxicity appears to be regulated by a number of factors, including mitochondrial dysfunction, oxidative injury, and neuroinflammation.

Early studies on the cellular actions of Mn reported that mitochondria are the principal intracellular repository for the metal (Cotzias and Greenough, 1958). More recent data indicate that mitochondria actively sequester Mn, resulting in rapid inhibition of oxidative phosphorylation (Gavin et al., 1992). Manganese is bound to inner mitochondrial membrane or matrix proteins (Gavin et al., 1990) and thus directly interacts with proteins involved in oxidative phosphorylation. Mn directly inhibits complex II (Singh et al., 1974; Liu et al., 2013) and complexes I–IV (Zhang et al., 2003) in brain mitochondria and suppresses ATP-dependent calcium waves in astrocytes, suggesting that Mn promotes potentially disruptive mitochondrial sequestration of calcium (Tjalkens et al., 2006). Elevated matrix calcium increases the formation of ROS by the electron transport chain (Kowaltowski et al., 1995) and results in inhibition of aerobic respiration (Kruman and Mattson, 1999).

Our studies with primary astrocytes and neurons have shown that Mn exposure induces an increase in biomarkers of oxidative stress (Milatovic et al., 2007, 2009). We have measured F_2-IsoPs (Morrow and Roberts, 1999; Milatovic and Aschner, 2009) and showed that astrocytes exposed to Mn concentrations known to elicit neurotoxic effects (100 μM, 500 μM, or 1 mM) induced significant elevations in F_2-IsoPs levels at all investigated exposure times (Fig. 57.5). Thus, increases in ROS, potentially damaging mitochondria directly or through the effects of secondary oxidants such as superoxide, H_2O_2, or $ONOO^-$, mediate Mn-induced oxidative
FIGURE 57.5   Effects of $MnCl_2$ on F_2-IsoPs formation in cultured astrocytes. Rat primary astrocyte cultures were incubated at 37°C in the absence or presence of $MnCl_2$ (100 μM, 500 μM, or 1 mM), and F_2-IsoPs levels were quantified at 30 min, 2 h, and 6 h. Data represent the mean ± SEM from three independent experiments. *Significant difference between values from control and Mn-treated astrocytes ($*P < .05$).

damage. Moreover, superoxide produced in the mitochondrial electron transport chain may catalyze the transition shift of Mn^{2+} to Mn^{3+} through a set of reactions similar to those mediated by superoxide dismutase and thus lead to the increased oxidant capacity of this metal (Gunter et al., 2006). Consequent oxidative damage produces an array of deleterious effects: it may cause structural and functional derangement of the phospholipid bilayer of membranes; disrupt energy metabolism, metabolite biosynthesis, and calcium and iron homeostasis; and initiate apoptosis (Attardi and Schatz, 1988; Uchida, 2003; Alaimo et al., 2011).

Consistently preceding the Mn-induced increase in biomarkers of oxidative damage (F_2-IsoPs) (Fig. 57.5), our study showed an early decrease in astrocytic ATP levels (Milatovic et al., 2007). As a consequence, ATP depletion or a perturbation in energy metabolism might diminish the ATP-requiring neuroprotective action of astrocytes, such as glutamate and glutamine uptake and free radical scavenging (Rao et al., 2001). In addition, depletion of high-energy phosphates may affect intracellular Ca^{2+} in astrocytes through mechanisms involving the disruption of mitochondrial Ca^{2+} signaling. This assertion is supported by data showing that Mn inhibits Na^+-dependent Ca^{2+} efflux (Gavin et al., 1990) and respiration in brain mitochondria (Zhang et al., 2004), both critical for maintaining normal ATP levels and ensuring adequate intermitochondrial signaling. A decrease in ATP following Mn exposure is also associated with excitotoxicity, suggesting a direct effect on astrocytes with subsequent impairment of neuronal function. Mn downregulates the glutamate

transporter GLAST in astrocytes (Erikson and Aschner, 2002) and decreases levels of glutamine synthase in exposed primates (Erikson et al., 2008). Studies with a neonatal rat model indicated that both pinacidil, a potassium channel agonist, and nimodipine, a Ca^{2+} channel antagonist, reversed Mn neurotoxicity and loss of glutamine synthase activity, further indicating excitotoxicity in the mechanism of Mn-induced neurotoxicity. Excessive Mn may lead to excitotoxic neuronal injury by both decreased astrocytic glutamate uptake and loss of ATP-mediated inhibition of glutamatergic synapses.

Oxidative stress as an important mechanism in Mn-induced neurotoxicity is also confirmed in our in vivo model. Analyses of cerebral biomarkers of oxidative damage revealed that a one-time challenge of mice with Mn (100 mg/kg, s.c.) was sufficient to produce significant increases in F_2-IsoPs (Table 57.3) 24 h following the last injection, respectively.

Increased striatal concentrations of ascorbic acid and GSH, antioxidants that when increased signal the presence of an elevated burden from ROS, as well as other markers of oxidative stress have been previously reported (Desole et al., 1994; Dobson et al., 2003; Erikson et al., 2007). Mn-induced decrease in GSH and increased metallothionein were reported in rats (Dobson et al., 2003) and nonhuman primate studies (Erikson et al., 2007). ROS may act in concert with RNS derived from astroglia and microglia to facilitate the Mn-induced degeneration of DAergic neurons. DAergic neurons possess reduced antioxidant capacity, as evidenced by low intracellular GSH, which renders these neurons more vulnerable to oxidative stress and glial activation relative to other cell types (Sloot et al., 1994; Greenamyre et al., 1999; Filipov and Dodd, 2011). Therefore, the overactivation of glia and the release of additional neurotoxic factors may represent a crucial component associated with the degenerative process of DAergic neurons (Filipov and Dodd, 2011).

In addition to a decrease in mitochondrial membrane potential and the depletion of high-energy phosphates, Mn-induced ROS generation is also associated with

inflammatory responses and release of inflammatory mediators, including prostaglandins. Our studies have confirmed that parallel to the increase in biomarkers of oxidative damage, Mn exposure induced an increase in the biomarker of inflammation, prostaglandin E_2 (PGE_2), in vitro and in vivo (Milatovic et al., 2007, 2009). Results from our in vivo study showed that Mn exposure induced a time-dependent increase in PGE_2 (Table 57.3). Previous studies have also shown an inflammatory response of glial cells following Mn exposure (Chen et al., 2006b; Zhang et al., 2009; Zhao et al., 2009). Mn potentiates lipopolysaccharide-induced increases in proinflammatory cytokines in glial cultures (Filipov et al., 2005) and an increase in nitric oxide production (Chang and Liu, 1999). An increase in proinflammatory genes, tumor necrosis factor-α, iNOS, and activated inflammatory proteins such as P-p38, P-ERK, and P-JNK have been measured in primary rat glial cells after Mn exposure (Chen et al., 2006b). However, data from our study indicated that release of proinflammatory mediators following Mn exposure is not only associated with glial response but also with neurons, suggesting that these two events are mechanistically related, with neuroinflammation either alone or in combination with activated glial response contributing to oxidative damage and consequent cell injury.

Features of Mn neurotoxicity reflect alterations in the integrity of DAergic striatal neurons and DA neurochemistry, including decreased DA transport function and/or striatal DA levels. The striatum is a major recipient structure of neuronal efferents in the basal ganglia. It receives excitatory input from the cortex and dopaminergic input from substantia nigra and projects to the internal segment of the globus pallidus (Dimova et al., 1993; Saka et al., 2002). Nigrostriatal dopamine neurons appear to be particularly sensitive to Mn-induced toxicity (Sloot and Gramsbergen, 1994; Sloot et al., 1994; Defazio et al., 1996). Intense or prolonged Mn exposure in adulthood causes long-term reductions in striatal DA levels and induces a loss of autoreceptor control over DA release (Autissier et al., 1982; Komura and Sakamoto, 1992). Nigrostriatal DA axons synapse onto striatal medium spiny neurons (MSNs), and these neurons have radially projecting dendrites that are densely studded with spines (Wilson and Groves, 1980).

Postmortem studies of PD patients have revealed a marked decrease in MSN spine density and dendritic length (Stephens et al., 2005; Zaja-Milatovic et al., 2005). Similar morphological changes in MSNs were seen in animal models of Parkinsonism (Arbuthnott et al., 2000; Day et al., 2006). Our study investigated the effects of Mn on degeneration of striatal neurons. Representative images of Golgi-impregnated striatal sections with their traced MSNs from control and Mn-exposed animals are presented in Fig. 57.6.

TABLE 57.3 Cerebral F_2-IsoPs and PGE_2 Levels in Saline (Control) or $MnCl_2$ (100 mg/kg, s.c.) Exposed Mice

Exposure	F_2-IsoPs (ng/g Tissue)	PGE_2 (ng/g Tissue)
Control (saline)	3.013 ± 0.03939	9.488 ± 0.3091
Single Mn	$4.302 \pm 0.3900*$	$12.030 \pm 0.4987*$
Multiple Mn	$4.211 \pm 0.4013*$	$14.220 \pm 1.019*$

Brains from mice exposed once or three times (days 1, 4, and 7) to $MnCl_2$ were collected 24 h post last injection. Each value represents mean $\pm$ SEM (n = 4−6). *One-way ANOVA showed $P < .001$ for each end point. Bonferroni's multiple comparison test showed significant difference ($P < .05$) compared to vehicle-injected control.
FIGURE 57.6 Photomicrographs of mouse striatal sections with representative tracings of medium spiny neurons (MSNs) from mice treated with saline (control) (A) or $MnCl_2$ (100 mg/kg, s.c.) (B). Brain from mouse exposed three times (days 1, 4, and 7) to $MnCl_2$ was collected 24 h post last injection. Treatment with Mn induced degeneration of the striatal dendritic system and a decrease in total number of spines and length of dendrites of MSNs. Tracing and counting were done using a Neurolucida system at $100\times$ under oil immersion (MicroBrightField, VT). Colors indicate the degree of dendritic branching (yellow = 1 degree, red = 2 degrees, purple = 3 degrees, green = 4 degrees, turquoise = 5 degrees).

Images of neurons with Neurolucida-assisted morphometry show that Mn-induced oxidative damage and neuroinflammation targeted the dendritic system with profound dendrite regression of striatal MSNs. Although single Mn exposure altered the integrity of the dendritic system and induced a significant decrease in spine number (Fig. 57.7A) and total dendritic lengths (Fig. 57.7B) of MSNs, prolonged Mn exposure led to a further reduction in spine number and dendritic length. Our results indicate that MSNs neurodegeneration could result from loss of spines, removing the pharmacological target for DA-replacement therapy, without overt MSN death (Stephens et al., 2005; Zaja-Milatovic et al., 2005).

Together, several studies suggest that oxidative stress, mitochondrial dysfunction, and neuroinflammation are the underlying mechanisms in Mn-induced vulnerability of DAergic neurons. The mediation of any of these mechanisms and control of alterations in biomarkers of oxidative injury, neuroinflammation, and synaptodendritic degeneration may provide a therapeutic strategy for the suppression of dysfunctional DAergic transmission and slowing of the neurodegenerative process. In addition, multiple mechanisms of Mn action are not
FIGURE 57.7 Total number of spines (A) and total dendritic lengths (B) of MSNs from striatal sections of mice exposed to saline (control), single Mn injection (100 mg/kg, s.c.), or multiple Mn injections (100 mg/kg, s.c.) on days 1, 4, and 7. Mice were sacrificed 24 h after the last injection. *Significant difference between values from control and Mn-treated mice (*$P < .01$). ^Significant difference between values from single Mn injection versus multiple (8 days) Mn treatment ($^{\wedge}P < .001$).

sufficiently known and may vary with environmental factors and susceptibilities, including single nucleotide polymorphisms that may alter Mn homeostasis, transport, and metabolism.

MERCURY

Mercury (Hg) is one of the most toxic elements in the periodic table. Although Hg is present in nature, it has also been released into the environment for centuries as a result of anthropogenic activities. It exists within the environment in three different chemical forms: elemental mercury vapor, inorganic mercury salts, and organic mercury. The distribution, toxicity, and metabolism of mercury are greatly dependent on its chemical form. Organic mercury compounds, such as methylmercury (MeHg), have been extensively studied because they are able to reach high levels in the central nervous system (CNS), leading to neurotoxic effects (Clarkson and Magos, 2006; Aschner et al., 2007; Dos Santos et al., 2018). Although the precise mechanisms of MeHg neurotoxicity are ill-defined, oxidative stress and altered mitochondrial and cell membrane permeabilities appear to be critical factors in its pathogenesis.

In vivo and in vitro biochemical studies employing glial and neuronal cultures have shown increased ROS formation with MeHg exposure (Yee and Choi, 1996; Sorg et al., 1998; Mundy and Freudenrich, 2000; Gasso et al., 2001; Shanker and Aschner, 2003; Dos Santos et al., 2018). Mitochondria are believed to be major targets of MeHg-induced toxicity (Limke and Atchison, 2002). Specifically, highly enriched Hg concentrations were found in mitochondrial fractions with the lowest Hg concentration found in the cytosol of livers from Hg-exposed animals (Chen et al., 2006a). Most of the bioenergetic experiments with Hg report the uncoupling of oxidative phosphorylation (Weinberg et al., 1982), inhibition of ATP synthesis (Atchison and Harem, 1994), impairment of the respiratory chain (Santos et al., 1997), and depletion of intracellular ATP and ADP (Palmeira et al., 1997). A study using a selective probe for mitochondrial reactive oxygen intermediates as well as other probes demonstrated a significant MeHg-induced increase in intracellular superoxide anion, hydrogen peroxide, and hydroxyl radicals, indicating that the mitochondrial electron transport chain is an early, primary site for ROS formation (Allen et al., 2001; Shanker et al., 2004, 2005). Additionally, MeHg exposure disrupts Ca^{2+} regulation in mitochondria derived from rat brains by decreasing Ca^{2+} uptake and inducing Ca^{2+} release (Levesque and Atchison, 1991). Results from our studies confirmed that MeHg induces increases in ROS and that the lipid peroxidation
FIGURE 57.8 Effect of MeHg on F_2-IsoPs formation in cultured astrocytes. Rat primary astrocyte cultures were incubated at 37°C in the absence or presence of MeHg (1, 5, and 10 μM) and F_2-IsoPs levels quantified at 1 and 6 h, respectively. Data represent the mean ± S.E. from three independent experiments. *$P < .05$ versus control by one-way ANOVA followed by Bonferroni multiple comparison tests.

biomarkers of oxidative injury, F_2-IsoPs, are increased in MeHg-exposed astrocytes (Fig. 57.8).

Another consequence of increased oxidative stress is the induction of the mitochondrial permeability transition (MPT), a Ca^{2+}-dependent process characterized by the opening of the permeability transition pore (PTP) in the inner mitochondrial membrane. This causes increased permeability to protons, ions, and other solutes ≤1500 Da (Zoratti and Szabo, 1995), leading to a collapse of the mitochondrial inner membrane potential ($\Delta\Psi_m$). Loss of the $\Delta\Psi_m$ results in colloid osmotic swelling of the mitochondrial matrix, movement of metabolites across the inner membrane, defective oxidative phosphorylation, cessation of ATP synthesis, and further generation of ROS. Our studies confirmed a concentration-dependent deleterious effect of MeHg on mitochondrial $\Delta\Psi_m$ in cultured astrocytes. It is generally believed that increased $[Ca^{2+}]_i$ triggers ROS formation and increased oxidative stress is a major factor for MPT induction (Castilho et al., 1995; Halestrap et al., 1997) and mitochondrial depolarization.

Of particular importance, in vivo studies with rats showed that MeHg combines covalently with sulfhydryl (thiol) groups from plasma cholinesterase, leading to the enzyme inhibition (Hastings et al., 1975). After this important observation, several in vitro and in vivo experimental studies showed that sulfhydryl-containing enzymes are inhibited by MeHg (Magour, 1986; Kung et al., 1987; Rocha et al., 1993). These observations led to the notion that the direct chemical interaction among MeHg and thiol groups from proteins and nonprotein molecules, such as GSH, plays a crucial role in MeHg-induced neurotoxicity (Aschner and Syversen, 2005).

Together, multiple studies demonstrated that MeHg exposure is associated with changes in membrane permeability and glutamine/glutamate cycling,

increases in ROS formation, and consequent lipid peroxidation. Furthermore, lipid peroxidation increases mitochondrial and cellular permeability alterations involving GSH (Gstraunthaler et al., 1983; Strubelt et al., 1996) and calcium depletion (Strubelt et al., 1996). These outcomes work together to create a continuous cycle where acceleration of the mitochondrial chain induces oxidative stress, lipid peroxidation, and depletion of antioxidant defenses, which, in turn, diminish membrane permeability and accelerate the respiratory chain, thus generating more ROS. Ultimately, the additive or synergistic mechanisms of cellular disruption caused by MeHg lead to cellular dysfunction and cell death.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

It is becoming increasingly evident that oxidative stress and associated neuronal damage plays a crucial role in the development and progression of brain diseases. However, measuring oxidative stress in biological systems is complex and requires accurate quantification of either free radicals or damaged biomolecules. One method to quantify oxidative injury is to measure nonenzymatic lipid peroxidation products, F_2-IsoPs. The quantification of F_2-IsoPs has provided a powerful approach to advance our understanding of the role of oxidative damage in a wide variety of research models and disease states. We have applied this methodology and explored cerebral oxidative damage in several models of neurodegeneration, including excitotoxicity generated by kainic acid, neurotoxicity associated with anticholinesterase agents and metals, and innate immune activation by lipopolysaccharide. Results from our studies supported an association between oxidative stress and neurotoxicity and suggested that oxidative stress, mitochondrial dysfunction, and neuroinflammation are underlying mechanisms in excitotoxicity- and metal-induced degeneration of dendritic systems in different brain areas. Future studies should be directed at deciphering the mechanisms of protection and addressing attenuation of neurotoxicity via radical scavenging mechanisms. Complementary studies should also guide the development of selective and efficacious antioxidant therapies that target neurotoxic mechanisms while maintaining neuroprotective actions.

INTRODUCTION

The eukaryotic cytoskeleton comprises a network of three interconnected protein filamentous arrays known as microtubules (MTs), microfilaments (MFs), and intermediate filaments (IFs). Many MT and MF arrays are dynamic structures that can undergo changes in organization, activity, and function at key stages in neural cell development. These phenomena are regulated by a variety of posttranslational modifications and interactions with a range of accessory proteins (Carlier, 1998; Joshi, 1998; Biernat et al., 2002; Ishikawa and Kohama, 2007; Akhmanova and Steinmetz, 2008; Janke and Kneussel, 2010; Svitkina, 2018). IFs, however, are relatively stable but may be modulated by cross-linking interactions with associated proteins or by their phosphorylation status (Herrmann and Aebi, 2000; Omary et al., 2006).

The cytoskeleton is involved in the control of key cellular processes in nervous system development and maintenance, such as cell division, cell migration, cell differentiation, intracellular transport, and structural support. Its disruption by the interaction of neurotoxins with core proteins or cytoskeletal regulatory systems can therefore be detrimental to a wide range of phenomena including neural development (Hargreaves, 1997; Flaskos, 2014).

There is a growing body of evidence for the induction of developmental neurotoxicity via disruption of cell signaling and cytoskeleton-dependent physiological processes by several groups of chemicals including organophosphorus esters (OPs), heavy metals, polybrominated diphenyl ethers (PBDEs), and solvents (Sachana et al., 2017; Pierozan et al., 2017). This chapter focuses on studies showing cytoskeletal disruption associated with impairment of neural development following exposure to such compounds, supporting the idea that cytoskeletal disruption can be a useful biomarker of developmental neurotoxicity.

MICROTUBULES

The main component of the MT network is the heterodimeric protein tubulin, which is composed of α and β subunits that form head-to-tail protofilaments, which in turn come together to make the tubular structure with an external diameter of 25 nm (Amos, 2004). MT assembly requires GTP binding to tubulin and MT dynamics are dependent on GTP hydrolysis, which occurs shortly after subunit addition to the growing MT end ("plus" end) (Carlier et al., 1984).

Both α- and β-tubulins have several isoforms encoded by different genes (Ludueña, 1998; Amos, 2004; Tischfield and Engle, 2010). Recent findings concerning congenital human neurological syndromes further emphasize the unique roles of specific α- and β-tubulin isoforms during nervous system development (Tischfield and Engle, 2010). For example, isotype III of β-tubulin (βIII-tubulin) appears almost exclusively in neuronal cells, plays an important role in neuritogenesis (Katsetos et al., 2003), and is among the earliest neuronal cytoskeletal proteins to be expressed during CNS development (Lee et al., 1990; Easter et al., 1993). Tubulin can be chemically modified by a variety of posttranslational adjustments, which may affect stability and location of MTs or act as a guidance cue for MT-binding proteins (Janke and Kneussel, 2010; Baas et al., 2016).

Many proteins can potentially interact with MTs, including the most studied microtubule associated proteins (MAPs). In neurons, these interactions influence MT dynamics, and it is believed that they are necessary for neuronal migration, differentiation, and axon guidance (Wade, 2009; Penazzi et al., 2016). Phosphorylation events have been found to regulate the association of MAPs with MTs, suggesting their potential involvement in cascade events relevant to neuronal development and degeneration (Biernat et al., 2002; Baas and Qiang, 2005).

An important member of the MAP family is the protein tau, which has tandem repeats of a tubulin-binding domain and contributes to tubulin assembly. Tau is abundant in neurons and is mainly located in axons, where it is closely associated with MTs. Changes in tau-protein levels and its phosphorylation state have been detected in numerous neurodegenerative diseases (Johnson and Stoothoff, 2004). Phosphorylation is also very important from a developmental point of view and is encountered extensively in fetal rather than adult tau (Watanabe et al., 1993). Indeed, increased phosphorylation of tau and dynamic MTs seem to coexist during brain development (Brion et al., 1994).

It has also been shown that MAP-1B is an essential protein for the development and function of nervous system both in vitro (Brugg et al., 1993; Di Tella et al., 1996) and in vivo (Meixner et al., 2000; Villarroel-Campos and Gonzalez-Billault, 2014). On the other hand, MAP1A dynamics are very closely associated to spine plasticity and any alterations in MAP1A may indicate changes in synaptic density (Jaworski et al., 2009). As a counter measure to MT-stabilizing MAPs, other groups of MAPs can bind to and destabilize MTs. An example is stathmin, which has been shown to regulate MT stability in the formation of dendritic branches in neuronal cells (Ohkawa et al., 2007). This low molecular weight protein can bind to and sequester tubulin heterodimers and hydrolyze GTP at the growing ends of MTs, leading to reduced MT stability (Howell et al., 1999).

The key role of MTs in intracellular transport (e.g., along developing axons) is regulated by another group of MAPs, which act as ATPase motor proteins. Such MAPs include kinesin and dynein, which direct anterograde and retrograde transport along axonal MTs respectively (Vale, 2003), a process which is essential for neurite growth and development. The interaction of such proteins with MTs or their ATPase activities could potentially be affected under conditions where ATP levels are depleted.

Several studies have dealt with the effects of established developmental neurotoxicants on MT assembly, organization, protein levels, posttranslational modifications, cell distribution, and gene expression. Altered status or intracellular distribution of MT proteins could reflect a range of adverse effects on the regulation of neural development. As discussed in the following text, most of the available experimental evidence from cell culture studies suggests that several well-established developmental neurotoxicants cause alterations in MTs of neuronal and glial cells under culture conditions, a common finding being a reduction in the levels of MAPs.

Effects of Organophosphorus Esters on Microtubules

The effects of several OP pesticides have been studied in the distant past, mainly in relation to posttranslational modifications of MT proteins and their role in organophosphate-induced delayed neuropathy (Abou-Donia, 1993, 1995). More recently, chlorpyrifos (CPF) and diazinon (DZ), the two OPs for which there are supporting data for developmental neurotoxicity, have been investigated regarding their potential effect on MTs both in vitro and in vivo. MAP-2 levels decreased following challenge with chlorpyrifos oxon (CPO) in organotypic slice cultures of immature rat hippocampus (Prendergast et al., 2007), whereas the parent compound CPF caused similar effects in the prefrontal cortex of Wistar rats (Ruiz-Muñoz et al., 2011) and in the mouse embryonic stem cells (mESCs) that were differentiated into neuronal cells (Visan et al., 2012). However, α-tubulin levels were not altered by $1-10\,\mu M$ CPO exposure, suggesting that the general structure of MTs was not modified (Prendergast et al., 2007). Similar findings were reported in the case of N2a cells exposed to CPF at the time of the induction of cell differentiation, as well as 16 h after the induction of differentiation (Sachana et al., 2005). Interestingly, levels of total α-tubulin were also found unaltered in the case of DZ or diazoxon (DZO)-treated differentiating N2a cells (Flaskos et al., 2007; Harris et al., 2009a; Sidiropoulou et al., 2009a), whereas MAP-1B levels were reduced after 10 μM DZ exposure (Flaskos et al., 2007). No change in the levels of β-tubulin isotypes I and III were detected in differentiating N2a cells following exposure to DZ (Harris et al., 2009b). In contrast, in the same cell model, DZO induced a significant reduction in the levels of the βIII-tubulin isotype but had no effect on total β-tubulin levels, suggesting a neuron-specific effect (Sachana et al., 2014) In animal models, oral administration of CPF on postnatal days $1-6$ did not affect the expression of the genes coding for the neuronal-specific marker βIII-tubulin (Betancourt et al., 2006).

The polymerization of bovine brain tubulin was inhibited by low concentrations of CPO $(0.1-10\,\mu M)$ (Prendergast et al., 2007). The ability of tubulin to polymerize is very important because, apart from contributing toward the maintenance of neuronal

morphology, MTs also support axonal transport of mitochondria, components of ion channels, receptors, and scaffolding proteins. Perturbation of assembly and transport mechanisms in neurons due to CPF and CPO reaction with tubulin and its organophosphorylation has been suggested from several experimental works both in vivo (Terry et al., 2007; Jiang et al., 2010) and in vitro (Gearhart et al., 2007; Grigoryan et al., 2009b; Grigoryan and Lockridge, 2009).

In glial cells, 24 h exposure to CPF or CPO suppresses extension outgrowth in differentiating C6 cells (Sachana et al., 2008). CPO had a stronger morphological effect than CPF that has been associated with a significant decrease in the levels of tubulin and MAP-1B (Sachana et al., 2008). Similarly, only the in vivo metabolite of DZ, DZO, triggered inhibition of the development of C6 cell extensions, an effect linked also to the reduction in the levels of tubulin (Sidiropoulou et al., 2009b). Immunofluorescence staining revealed normal MT networks in control and CPF-treated cells and, although there was no evidence for a major collapse of the MT network, there were increased levels of localized patchy staining compared to the control, particularly in CPO-treated cells (Sachana et al., 2008).

Effects of Heavy Metals on Microtubules

MT proteins have also been investigated in relation to methylmercury—induced developmental abnormalities of the nervous system. Exposure of N2a neuroblastoma cells to methylmercury revealed significant disruption in MT organization after staining the cells with antibody that recognizes β-tubulin (Kromidas et al., 1990). The same research group further emphasized the predominant effect of methylmercury on MTs compared to IFs and MFs by using scanning electron microscopy (Trombetta and Kromidas, 1992). In the same cell line, cells demonstrated decreased reactivity against C-terminally tyrosinated α-tubulin following only 4 h exposure to a sublethal concentration of methylmercury chloride compared to controls, which was associated with inhibition of neurite outgrowth (Lawton et al., 2007).

The importance of the cytoskeleton in methylmercury neurotoxicity was further emphasized in a study by Castoldi et al. (2000) using primary cultures. In this study, rat cerebellar granule cells exhibited MT depolymerization within 1.5 h of exposure to 1 μM methylmercury and long before disturbance of neurite processes (Castoldi et al., 2000).

Methylmercury was found to suppress tubulin polymerization in vitro, to disrupt the MT network, and to reduce tubulin synthesis in mouse glioma cells (Miura et al., 1984; Miura and Imura, 1987). This corresponded

to a decrease in tubulin mRNA levels but no effect on the transcription rates of β-tubulin genes were found, suggesting that exposure had disrupted the autoregulatory control of tubulin synthesis in a manner similar to that described for the antimitotic agent colchicine (Miura et al., 1998).

It is well documented that lead exposure can cause learning and memory impairment, particularly in developing organisms. However, the molecular mechanisms are not fully understood, although several studies investigated the potential role of MTs in disruption of memory formation. In human primary cultures, exposure to biologically relevant concentrations of lead (5, 10, 20, and 40 μg/dL) was associated with hyperphosphorylation of tau protein, as determined by Western blotting and immunocytochemistry, due to upregulation of protein phosphatases (Rahman et al., 2011). These findings were also confirmed in both Wistar rat and mouse pups, emphasizing the importance of tau hyperphosphorylation in cognitive impairment (Li et al., 2010; Rahman et al., 2012). Recent data further support this as the pre- and neonatal exposure to lead causes a significant increase in the phosphorylation of tau and upregulates tau protein level in the rat brain cortex and cerebellum (Gąssowska et al., 2016).

In a study by Scortegagna et al. (1998), the detectable levels of MAP-2b and MAP-2c were found to decrease 24 h after a 3 h exposure to 3 or 6 μM lead in serum-free medium maintained E14 mesencephalic rat primary cultures. However, in the same study, these protein levels remained similar to controls in serum-cultured cells, suggesting that a serum factor prevents cytoskeletal changes otherwise noted in this primary culture containing differentiating neurons and proliferating astrocytes (Scortegagna et al., 1998). On the other hand, lead (II) acetate reduced the number of MAP-2 stained cells and the mRNA levels of MAP-2 in a concentration-dependent manner, by applying default differentiation of mESCs (Beak et al., 2011; Visan et al., 2012). Inorganic lead had no effect on the in vitro assembly of MTs from porcine brain, whereas trimethyl lead blocked and completely inhibited MT assembly at 300 μM, as monitored by turbidity measurements and electron microscopy (Roderer and Doenges, 1983). In contrast, triethyl lead chloride inhibited MT assembly and depolymerized preformed MTs in porcine brain preparations (Zimmermann et al., 1988), whereas the same research group reported no change in MT network in mouse N2a neuroblastoma cells after exposure to the same organic lead compound (Zimmermann et al., 1987).

Regarding arsenic, it was shown that tau gene expression can be increased in ST-8814 schwannoma and SK-N-SH neuroblastoma cell lines by exposure to inorganic trivalent and monomethyl pentavalent

arsenic metabolites, respectively (Vahidnia et al., 2007b). In addition, the phosphorylated state of MAP-tau has been found altered in both in vitro and in vivo studies (Vahidnia et al., 2007a). More specifically, Giasson et al. (2002) reported hyperphosphorylation of tau-protein in Chinese hamster ovary cells after treatment with inorganic trivalent arsenic. Similarly, subchronic exposure of rats to this arsenic metabolite increased the phosphorylation of tau in sciatic nerves (Vahidnia et al., 2008a). However, a more recent study shows that sodium arsenite causes neurite inhibition in N2a cells that was associated with alterations in cytoskeletal proteins. More specifically, sodium arsenite decreased the mRNA levels of tau and tubulin in a dose-dependent manner but had no significant effect on the mRNA levels of MAP-2 (Aung et al., 2013). The inhibitory effect of arsenic trioxide on the migration of primary neurons established from the brains of neonatal rats has also been recently investigated; the study revealed that it was associated with a decrease in the protein levels of doublecortin, which is a MT-associated protein expressed during the neuronal migration (Zhou et al., 2015).

Effects of Organic Solvents and Polybrominated Diphenyl Ethers on Microtubules

Ethanol is the only organic solvent studied in relation to its neurotoxic potential against MTs in *in vitro* models. Ethanol had no effect on the rate and extent of bovine tubulin polymerization in vitro, whereas the ethanol metabolite acetaldehyde inhibited MT formation (Jennett et al., 1980). Similarly, McKinnon et al. (1987) demonstrated that acetaldehyde had an inhibitory effect on the polymerization of MT protein derived from calf brains, further emphasizing the acetaldehyde-mediated alteration of cytoskeletal MTs. Continuous exposure of developing neural crest cells to ethanol has also been found to cause MT disruption (Hassler and Moran, 1986).

In PC12 cells, chronic exposure to ethanol led to alterations in the balance between free tubulin in the cytoplasm and tubulin polymerized into MTs, enhancing the content of the latter, possibly through phosphorylation (Reiter-Funk and Dohrman, 2005). In contrast, chronic alcohol exposure was found to decrease the levels of polymerized tubulin in cultured hippocampal neurons and simultaneously to reduce the amount of MTs and the levels of MAP-2 in dendrites (Romero et al., 2010). The same research group also described impairment of MT dynamics and reassembly in primary cultures of rat astrocytes treated with ethanol (Tomas et al., 2003). However, in a short-term exposure of rat C6 glioma cells to acute levels of ethanol (50, 100, and 200 mM), there was no detectable change in the MT network (Loureiro et al., 2011).

In whole cerebral hemisphere model, developing Layer 6 neurons exposed to ethanol exhibited diminished MAP-2 levels in dendritic processes (Powrozek and Olson, 2012). Similarly, MAP-2 immunostaining intensity was reduced in hippocampal slice cultures from neonatal Wistar rats subjected to ethanol treatment (200 mM) for up to 4 weeks (Noraberg and Zimmer, 1998). MAP-2 immunolabeling has also been used to determine the effect of ethanol (70 mM) on dendrites of rat embryonic hippocampal pyramidal neurons in culture, revealing decreases in both length and number of dendrites compared with controls (Lindsley et al., 2002; Lindsley and Clarke, 2004).

Stimulation of MAP-2 phosphorylation has been detected in MT preparations from rat brain exposed to low and biologically relevant doses of ethanol (6, 12, and 24 mM), whereas higher doses (48, 96, 384, and 768 mM) decreased phosphorylation (Ahluwalia et al., 2000). In the same study, MAP-1 was found to show increased phosphorylation with only 12 and 24 mM of ethanol and tubulin only from the lower dose tested (6 mM) (Ahluwalia et al., 2000).

More recently, the application of neural stem cell technology indicated disturbance of neuronal differentiation from noncytotoxic concentrations of alcohol (25–100 mM), as recorded by reduced immunostaining and levels of MAP-2 protein (Tateno et al., 2005). Immunolabeling of axons derived from rat hippocampal pyramidal neurons with a βIII-tubulin antibody was used to assess the effect of ethanol on the length of axons (VanDemark et al., 2009). Indeed, ethanol alone had no effect on axon length, whereas carbachol-treated cells in the presence of ethanol (50 and 75 mM) did cause shortening of axons compared to controls (VanDemark et al., 2009).

In the P7 rodent model, which is extensively used for mechanistic elucidation of ethanol-induced neurodevelopmental toxicity, it was found that ethanol elevated the phosphorylation state of tau, as demonstrated by two different phospho-specific antibodies (Saito et al., 2010). Similarly, in a human neuroblastoma cell line after tau induction, ethanol caused a dose-dependent increase in tau levels and cell mortality (Gendron et al., 2008). A more extensive overview on the effects of ethanol on the neuronal cytoskeleton, covering both in vivo and in vitro studies, can be found in Evrard and Brusco (2011).

MICROFILAMENTS

MFs are formed by the polymerization of monomeric G-actin into filaments with a diameter of 5 nm (Dominguez and Holmes, 2011). MF assembly is

ATP-dependent, and the dynamic properties of MFs are dependent on the hydrolysis of actin-bound ATP following incorporation at the filament plus end (Carlier, 1998). MF dynamics are also influenced by a wide variety of actin binding proteins (ABPs) that regulate its organization and function by acting as either nucleating factors (e.g., ARP 2/3, formin), cross-linking proteins (e.g., fascin), destabilizing factors (e.g., ADF/cofilin, gelsolin, fragmin), membrane cross-linkers (e.g., spectrin, GAP-43), or MF-associated motor proteins (e.g., myosin) (Ishikawa and Kohama, 2007; Dominguez, 2009; Lee and Dominguez, 2010; Dominguez and Holmes, 2011; Jansen et al., 2011; Svitkina, 2018). The interaction between actin and its ABPs is in turn regulated by cell signaling pathways (Endo et al., 2003; Ishikawa and Kohama, 2007). MFs play key roles in mitosis, neural cell differentiation, and the regulation of cell migration (Gungabissoon and Bamburg, 2003; Kunda and Baum, 2009). The inhibition of neurite outgrowth from explants of embryonic chick spinal cord cultured in the presence of the MT-stabilizing agent taxol and the MF-disrupting agent cytochalasin D clearly demonstrates the importance of both MT and MF integrity in the developmentally important process of neurite outgrowth (Rösner and Vacun, 1997). Given the important roles played by MFs in cytokinesis, receptor trafficking, and neurite outgrowth, their disruption by toxin exposure could have major effects on neural development.

Effects of Organophosphorus Esters on Microfilaments

In early work, Carlson and Ehrich (2001) tested the ability of several OPs including paraoxon, parathion, diisopropyl fluorophosphate (DFP), phenyl saligenin phosphate (PSP), tri*ortho*tolyl phosphate (T*O*TP), and triphenyl phosphite at 0.1—1 mM to disrupt the filamentous actin (F-actin) network in mitotic SH-SY5Y cells using a fluorescently labeled phalloidin probe. Significant decreases in the levels of F-actin were observed within 30 min exposure of cells treated with PSP and T*O*TP, whereas other OPs required longer exposure times and DFP had no observable effect. The data clearly support the idea that some OPs can disrupt the MF network, although the concentrations used were relatively high and cytotoxic within a few hours, as determined by protein assay (Carlson and Ehrich, 2001). However, proteomic studies on differentiating N2a neuroblastoma cells exposed to sublethal neurite inhibitory concentrations of the OP pesticide DZ showed that inhibition of neurite outgrowth by 10 μM DZ was associated with increased levels but decreased LIM kinase—mediated phosphorylation of the actin-destabilizing protein cofilin (Harris et al., 2009a). Although total actin levels were unaffected by DZ, the altered levels and phosphorylation status of cofilin, together with reduced staining intensity of neurites with antiactin antibody, suggest that DZ exposure leads to a reduction in the levels of F-actin in neurites due to disruption of MF dynamics caused by altered expression and phosphorylation of cofilin.

Another important modulator of MF organization in the axonal growth cone of developing neurons is growth associated protein 43 (GAP43), which has been shown to exhibit reduced mRNA and/or protein levels following exposure to sublethal neurite outgrowth inhibitory concentrations of OPs (Sachana et al., 2003; Flaskos et al., 2011; Ta et al., 2014). A transient reduction in GAP43 protein levels was also observed to be associated with the retraction of neurites in predifferentiated N2a cells exposed to sublethal concentrations of CPF and CPO (Sindi et al., 2016). It has been suggested that these phenomena may, at least in part, be the result of upstream events such as OP-induced autophagy or disruption of Ca^{2+} homeostasis, which could impact on the activity of Ca^{2+}-dependent ABPs and other MF-regulatory proteins (Chen et al., 2013; Fernandes et al., 2017).

Thus, OPs can disrupt MF organization and functions by interacting with ABPs and/or signaling pathways that modulate MF dynamics. However, in vitro studies by Grigoryan et al. (2009a) and Schopfer et al. (2010) demonstrated a covalent interaction of OPs with lysine and tyrosine residues on actin, raising the possibility that a direct interaction with actin might also be involved in the disruption of MFs by OPs. Further in vivo and in vitro studies to determine the role of OP-actin adduct formation would be worthwhile.

Effects of Heavy Metals on Microfilaments

Many cytoskeleton-related developmental neurotoxicity studies with heavy metals have focused on the MT network. However, micromolar concentrations of mercurial compounds can block SH groups on purified actin, thereby inhibiting its ability to interact with myosin and induce myosin ATPase activity in vitro (Perry and Cotterill, 1964; Martinez-Neira et al., 2005). The ability of mercury (as well as cadmium, copper, and zinc) ions to interfere with actin—ABP interactions has also been demonstrated by native gel electrophoresis (Kekic and dos Remedios, 1999), suggesting that direct binding of heavy metal ions to actin, ABPs, or other MF-regulatory proteins could induce toxic effects directed at the MF network.

Studies on the inhibition of glioma cell migration by arsenic suggested that this heavy metal compound may be able to disrupt F-actin by interference with

MF-regulatory cell signaling pathways such as protein kinase C (Lin et al., 2008). Sodium arsenite was also observed to inhibit neurite outgrowth in differentiating N2a neuroblastoma cells; although this was not found to involve alterations in mRNA levels for β-actin (Aung et al., 2013), the possibility that changes to MF dynamics may involve alterations to the levels and post-translational modification of ABPs or other regulatory pathways cannot be ruled out and warrants further investigation. Changes were observed in the levels of mRNA for NFL and NFM (both elevated) and for tubulin and tau (both reduced) in arsenic-treated cells; the possibility that these changes, if they are reflected at the protein level, may cause disruption of F-actin organization could also be further investigated.

In a study of the effects of methylmercury chloride on postnatal rat brain development, it was found that the degradation of the ABP α-spectrin by μ-calpain was significantly greater in cerebral cortex extracts from treated animals than in controls at postnatal day 16 (Zhang et al., 2003). Calpain activation could also target a range of other cytoskeletal proteins that act as substrates for calpain. In this respect it is interesting to note that exposure to other metal compounds has also been linked to the activation of calpain in brain (Zhang et al., 2012), neural cells (Vahidnia et al., 2008b; Rocha et al., 2011), or in other tissues (Lee et al., 2007).

Furthermore, studies in primary cultures of fetal mouse brain—derived cerebellar granule cells and human placental tissue showed that submicromolar levels of methylmercury chloride induced a significant decrease in the phosphorylation of the ABP cofilin and the translocation of actin and cofilin to mitochondria (Vendrell et al., 2010; Caballero et al., 2017). The fact that these changes were associated with elevated levels of protein carbonylation (detected by immunoassay) and could be blocked by cotreatment with the antioxidant probucol, suggest that they were triggered by elevated levels of protein oxidation (Caballero et al., 2017).

Moreover, evidence for the inhibition of both neurite outgrowth and neuronal cell migration via disruption of MFs through altered regulatory signaling pathways comes from a combination of cell culture and in vivo developing rodent brain studies following exposure to methylmercury chloride (Fujimura and Usuki, 2012; Usuki and Fujimura, 2012; Guo et al., 2013; Hernández et al., 2018). Thus, direct binding to SH groups, elevated protein oxidation, and disruption of MF-regulatory signaling pathways have a major impact on the regulation of MF dynamics, suggesting that exposure to heavy metal compounds can disrupt the regulation of MF dynamics in a variety of ways.

Effects of Organic Solvents and Polybrominated Diphenyl Ethers on Microfilaments

Chronic ethanol exposure has been shown to be associated with disruption of the MF network in cultured PC12 cells and in primary cultures of hippocampal neurons. In PC12 cells, chronic exposure was found to reduce dopamine release via protein kinase C—dependent pathways, an effect that was attenuated by cotreatment with the MF-disrupting agent cytochalasin, indicating the need for MFs in this exocytotic process (Funk and Dohrman, 2007). In ethanol-exposed hippocampal neurons, a reduction was observed in the levels of F-actin compared to untreated control cell cultures, as determined by FITC-labeled phalloidin staining, which corresponded to reduced protein levels of total Rac1, RhoA, and cdc42 (small GTPases known to be involved in the regulation of MF assembly and dynamics), as determined by G-LISA assays (Romero et al., 2010). However, although the levels of activated (GTP-bound) forms of Rac1 and cdc42 were reduced, ethanol had no significant effect on the levels of active RhoA, suggesting that only the inactive form of this GTPase was downregulated by ethanol treatment. Western blotting analysis indicated that the levels of total cofilin (which destabilizes MFs) were unchanged, although the levels of inactive (phospho-) cofilin were not assessed (Romero et al., 2010).

Chronic exposure to ethanol was also found to inhibit endocytotic uptake of serum albumin and transferrin by cultured fetal rat hippocampal neurons (Marín et al., 2010) This effect was associated not only with altered levels of proteins involved in vesicle formation and docking but also with proteins involved in the regulation of MF assembly and dynamics, including Arf6 (upregulated), cdc42, and RhoA (both downregulated). Furthermore, the ability of ethanol to inhibit neural cell differentiation in a human embryonic stem cell model of early brain development was also associated with disruption of the MF network (Taléns-Visconti et al., 2011).

In a study of chronic ethanol exposure on cultured rat astrocytes, the impairment of glucose uptake was associated with disassembly of actin stress fibers; the fact that lysophosphatidic acid attenuated these effects by stabilizing the MF network suggested that a major disruption of MF dynamics was caused by ethanol exposure (Tomas et al., 2003). Although there was no detectable change in the MT network following short-term exposure of rat C6 glioma cells to acute levels of ethanol, the resultant formation of reactive oxygen species was associated with major disruption of the MF network (Loureiro et al., 2011). Taken together, these data illustrate not only the fact that MFs are disrupted by this

solvent but also that MF-dependent processes of importance in neural development are impaired when this occurs.

INTERMEDIATE FILAMENTS

The most abundant IF proteins found in differentiating and mature neurons are the three neurofilament (NF) triplet proteins (NF-L, NF-M, and NF-H), whereas in glial cells the most important IF protein is GFAP. Nestin is the main IF specifically expressed in immature neural cells. Indeed, most of the genes coding for IF proteins are expressed in a tissue- or cell type—specific manner, except for the nuclear lamins. Thus, the NF proteins are present only in neurons and GFAP only in glia (and more specifically in astrocytes). As a result, NF proteins and GFAP have been widely used in neurotoxicology as markers for specific effects on neurons and glia, respectively. In the context of developmental toxicology, changes in NF proteins and GFAP have been commonly employed as a measure of the capacity of a toxicant to interfere with neuronal and glial differentiation.

Although NFs are typically considered to be more stable than MFs and MTs, their dynamic capability is demonstrated by their reorganization that occurs during several neurodevelopmental stages including proliferation (mitosis), apoptosis, and axonogenesis (Omary et al., 2006). NFs can facilitate axonal elongation by stabilizing the axonal cytoskeleton and inhibiting the retraction of long axons (Lariviere and Julien, 2003). Apart from their use in developmental neurotoxicity studies as a neuronal differentiation marker, NF proteins may constitute a mechanistically relevant marker for assessing specific biochemical cytoskeletal effects in some cases. This is particularly true for the studies on OPs and arsenic discussed in the following paragraphs, where NFs have been proposed to be a direct target for these neurotoxicants.

NF parameters assessed in neurodevelopmental toxicity studies include NF protein levels, distribution, assembly, transport, phosphorylation, and expression of NF genes. A review of the available data on established developmental neurotoxicants (see the following) indicates that in most cases there is a decrease in the levels of at least one of the three NF proteins, whereas NF gene expression data are inconsistent, with both increases and decreases in NF mRNA levels caused by the toxicants. The distinct features of the three NF proteins in terms of structure, properties, and function and their differential expression during neuronal development imply that assessment of toxicant-induced changes in one NF protein cannot substitute for measurements in the other two. Finally, because NF protein phosphorylation is known to be the major factor in the regulation of the dynamics and function of NFs (Omary et al., 2006; Sihag et al., 2007), assessment of changes in NF phosphorylation-related parameters (determination of relevant kinases and upstream cell signaling molecules) may provide valuable markers for developmental neurotoxicity.

In developmental neurotoxicity studies both protein and mRNA levels of GFAP have been assessed. These studies have usually reported decreases in these parameters, indicating specific repression of glial cell differentiation, whereas any increases obtained have been attributed to reactive gliosis because of high dosing and primary damage to neurons.

Effects of Organophosphorus Esters on Intermediate Filaments

NF parameters have been assessed to a larger extent in toxicological studies involving OP pesticides than other developmental neurotoxicants. This may be partly because of the prior existence of data implicating NF (and other cytoskeletal) abnormalities as being etiologically important in delayed OP neurotoxicity (Abou-Donia, 1993; Jiang et al., 2010). In this context, in some OP neurodevelopmental studies NF parameters have not been employed as a common marker for neuronal cell-specific differentiation but as a mechanistically relevant marker for specific biochemical effects on the neuronal cytoskeleton.

Parameters assessed in OP neurodevelopmental studies include the levels and intracellular distribution and posttranslational modification (phosphorylation) of NF proteins and the expression of NF genes. Exposure of both mitotic and differentiating rat PC12 pheochromocytoma cells to a sub-lethal concentration of CPF (30 μM), led to the upregulation of nfl and nef3 genes (which encode NF-L and NF-M, respectively), whereas expression of the nefh gene (which encodes NF-H) was unaffected (Slotkin and Seidler, 2009). On the other hand, exposure of PC12 cells to 30 μM DZ under the same conditions caused upregulation of the nef3 but had no effect on the expression of nfl and nefh genes (Slotkin and Seidler, 2009). The expression of genes encoding NF-L and NF-H, used as a marker for neuronal differentiation, was studied in primary neuronal cultures of cerebellar granule cells prepared from 7-day-old rat pups treated with parathion (Bal-Price et al., 2010). Exposure to this OP, used at concentrations of 10—50 μM, for up to 12 days caused a concentration-dependent decrease in mRNA levels for both NF-L and NF-H.

A series of studies have assessed changes in several NF parameters following exposure of differentiating mouse N2a neuroblastoma cells to CPF and DZ, the two OPs for which there is the most evidence for

developmental neurotoxicity. In these mechanistic studies of OP-induced developmental neurotoxicity, determination of NF (and other cytoskeletal) parameters were extended to include the influence of CPO and DZO, the two in vivo oxon metabolites of CPF and DZ, because there is now considerable evidence to suggest that these compounds can interfere with neuronal differentiation and development (Flaskos, 2012). These studies have demonstrated decreases in the levels of NF-H protein by both CPF and DZ. Thus, exposure of N2a cells to 3 μM CPF for 8 h (Sachana et al., 2001) and to 10 μM DZ for 24 h (Flaskos et al., 2007) leads to reduced NF-H protein levels. Indirect immunofluorescence studies also showed that, apart from an alteration in the expression of NF-H, there was a change in the intracellular distribution of this protein, with NF-H located mainly in cell body aggregates of DZ-treated N2a cells (Flaskos et al., 2007).

NF parameters were also affected by exposure to CPO and DZO. For example, at a concentration of 10 μM, CPO exposure for 24 h reduced the total levels of NF-H and disrupted NF-H intracellular distribution in differentiating N2a cells (Flaskos et al., 2011). On the other hand, CPO had no effect on the levels of phosphorylated NF-H under these experimental conditions, in which the OP was added at the point of induction of cell differentiation. However, in N2a cells induced to differentiate for 20 h prior to OP exposure, CPO induced a transient increase in ERK 1/2 activation and NF-H phosphorylation after 2 h, which preceded neurite retraction (Sindi et al., 2016), suggesting a mechanistic link between NF-H hyperphosphorylation and neurite destabilization. In contrast, the oxon metabolite DZO, applied at concentrations of 5 and 10 μM for 24 h, had no effect on total NF-H levels, but increased phosphorylated NF-H levels in differentiating N2a cells compared to the control (Sidiropoulou et al., 2009a). Under these conditions, DZO had no effect on the total levels of NF-L and NF-M (Sachana et al., 2014). Further work is required to determine the molecular basis of these effects in more detail.

Determination of GFAP in neurodevelopmental studies of OPs has involved measurement of both its protein and mRNA levels. Following developmental exposure to OPs, GFAP protein and mRNA levels exhibited both decreases and increases, the latter being attributed to the occurrence of reactive gliosis because of high dosing. Thus, in aggregating brain cells of fetal rat telencephalon, GFAP levels were found to be increased following parathion treatment, indicative of gliosis (Zurich et al., 2000). Postnatal exposure of rats to CPF for 4 days initially decreased GFAP levels, indicating specific repression of normal glial (astrocytic) development. At a later stage, however, increases in the levels of GFAP occurred, typical of reactive gliosis

following neuronal cell damage (Garcia et al., 2002). Postnatal administration of CPF to rats for 6 days at doses high enough to cause significant cholinesterase inhibition also led to increased GFAP mRNA levels, reflecting increased astrocyte reactivity (Betancourt et al., 2006). On the other hand, administration of DZ to neonatal rats for 4 days resulted in a decrease in the expression of the gene coding for GFAP (Slotkin and Seidler, 2007). Similarly, the in vivo metabolite of DZ, DZO (at 1−10 μM) caused, after 24 h in N2a cells, a reduction in GFAP protein levels, indicating repression of specific glial cell/astrocytic differentiation (Sidiropoulou et al., 2009b).

Effects of Heavy Metals on Intermediate Filaments

Both NF-L and NF-M levels were found to be altered in a number of mammalian cell lines after exposure to mercuric oxide. Thus, exposure of differentiating human SK-N-SH neuroblastoma cells for 6 days to mercuric oxide decreased particularly NF-L levels (Abdulla et al., 1995). Because this effect correlated well with effects on neurite outgrowth, it was suggested that determination of NF-L might afford a rapid measure of effects on neuronal differentiation. More recently, methylmercury exposure was also found to decrease the mRNA levels for NF-L and NF-H in primary cultures of rat cerebellar granule cells, whereas GFAP mRNA expression was unaffected (Hogberg et al., 2010).

NF organization was disrupted following exposure of N2a cells to triethyl lead (Zimmermann et al., 1987). NF assembly was also disrupted. These effects led to suggestions that interaction of triethyl lead with NFs may be responsible for triethyl lead neurotoxicity in vivo. In addition, in rats exposed for 13 weeks to lead acetate, transport of NF proteins was retarded, indicating impairment of slow axonal transport (Yokoyama and Araki, 1992). Apart from NF organization, assembly, and transport, NF protein phosphorylation was also affected by lead; exposure of mice to lead acetate throughout gestation and postnatally led to increased phosphorylation of both NF-M and NF-H in auditory brainstem nuclei (Jones et al., 2008). Lead also affects GFAP, as suggested by decreased GFAP expression in four human and two rat glioma cell lines, indicating interference with glial cell differentiation (Stark et al., 1992). The mRNA levels for GFAP were also reduced after lead treatment of primary cultures of rat cerebellar granule cells for 12 days (Bal-Price et al., 2010).

In neurotoxicity studies involving arsenic, NF parameters constitute a mechanistically relevant marker because NFs (and other cytoskeletal elements) have been suggested to represent a possible target in arsenic neuropathy. Although these studies have been not

always carried out in a developmental context, the known significance of NFs in neurodevelopment implies that any neurotoxic effects on NFs obtained in adult animals or differentiated neurons may be of potential relevance in neurodevelopment.

Both acute (Vahidnia et al., 2006) and subchronic (Vahidnia et al., 2008a) administration of arsenite to adult rats induced a reduction in NF-L levels in the sciatic nerve. In contrast, NF-M and NF-H expressions remained unchanged. In addition, NF-L was found to be hyperphosphorylated (Vahidnia et al., 2008a). These NF-L changes have been proposed to contribute to the disruption of the NF network, ultimately leading (in combination with other cytoskeletal changes) to the axonal degeneration seen in arsenic neuropathy (Vahidnia et al., 2007a, 2008a). However, in a study by the same group involving cell lines and assessment of NF gene expression, the results obtained were not compatible with the above data. In this case, exposure of SK-N-SH neuroblastoma and ST-8814 schwannoma cells to arsenite for up to 48 h had no effect on the expression of genes coding for NF-L and NF-M (Vahidnia et al., 2007b). However, the metabolites monomethyl- and dimethyl-arsenic induced alterations in the expression of NF genes in both cell lines and particularly in the expression of the gene coding for NF-H. Mechanistically important NF parameters assessed under the influence of arsenite also included axonal transport and phosphorylated NF distribution. For example, exposure of differentiated mouse NB2/dl neuroblastoma cells and dorsal root ganglion neurons cultured from embryonic day 12 chicks to arsenite decreased NF transport into axons and caused accumulation of phosphorylated NFs in the perikaryon leading to changes in NF dynamics that may contribute to arsenic neuropathy (De Furia and Shea, 2007).

Effects of Organic Solvents and Polybrominated Diphenyl Ethers on Intermediate Filaments

Ethanol exposure inhibited the expression of NF proteins in N2a cells, indicating disruption of neuronal differentiation (Chen et al., 2009). In contrast, at a concentration of 100 mM, ethanol induced an increase in GFAP levels in differentiating neural stem cells, which was thought to imply increased glial differentiation as a compensatory mechanism to repair the impaired neuronal differentiation (Tateno et al., 2005). However, exposure to environmentally relevant low levels of toluene (down to 0.2 ppb), decreased GFAP levels during differentiation of mouse embryo cells into an astrocytic lineage in serum-free medium (Yamaguchi et al., 2002, 2003).

In a study that adopted a proteomic approach, exposure of neonatal mice to 2,2′,4,4′,5-pentabromodiphenyl ether (PBDE 99) induced significant alterations in several cytoskeletal and other proteins in the cerebral cortex. However, one of the greatest changes noted was an increase in the levels of NF-L (Alm et al., 2008).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

It is well established that the cytoskeleton plays a key role in a range of cellular processes involved in neural development. From the mechanistic studies of developmental neurotoxicity to date, there is now a significant body of evidence pointing to the disruption of one or more of the cytoskeletal networks following exposure to a range of developmental neurotoxicants, with changes at the protein level currently being more consistent than those at the level of gene expression. Taken together, the findings from studies discussed in this chapter strongly suggest that cytoskeletal disruption is a common feature of adverse outcome pathways associated with chronic exposure to many developmental neurotoxicants. Thus, despite the diversity of molecular initiating events associated with exposure to different developmental neurotoxins, subsequent molecular changes invariably converge on pathways that regulate the cytoskeleton, causing cytoskeletal disruption. In some cases, the molecular initiating event may be direct binding to cytoskeletal proteins themselves. A schematic view of cytoskeletal disruption as a convergence point in developmental neurotoxicity is summarized in Fig. 58.1.

Further work to characterize the ability of well-established developmental neurotoxins to disrupt cytoskeletal elements would be worthwhile, as this would help to identify the key events in each adverse outcome pathway in more detail. This could, for example, involve the study of upstream events such as kinase/phosphatase activities in cases where the phosphorylation status of cytoskeletal proteins is disrupted, or RT-PCR and/or proteolytic enzymes (calpain, proteasomes, etc.) cases where protein levels are significantly affected by exposure to toxin. The monitoring of these molecular events in high throughput screening platforms would help to establish a more comprehensive battery of rapid tests.

In summary, the monitoring of cytoskeletal disruption is an integral part of mechanistic studies of developmental neurotoxicity and is becoming an increasingly important component in a battery of in vitro tests to rapidly screen large numbers of compounds for their ability to induce developmental neurotoxicity.

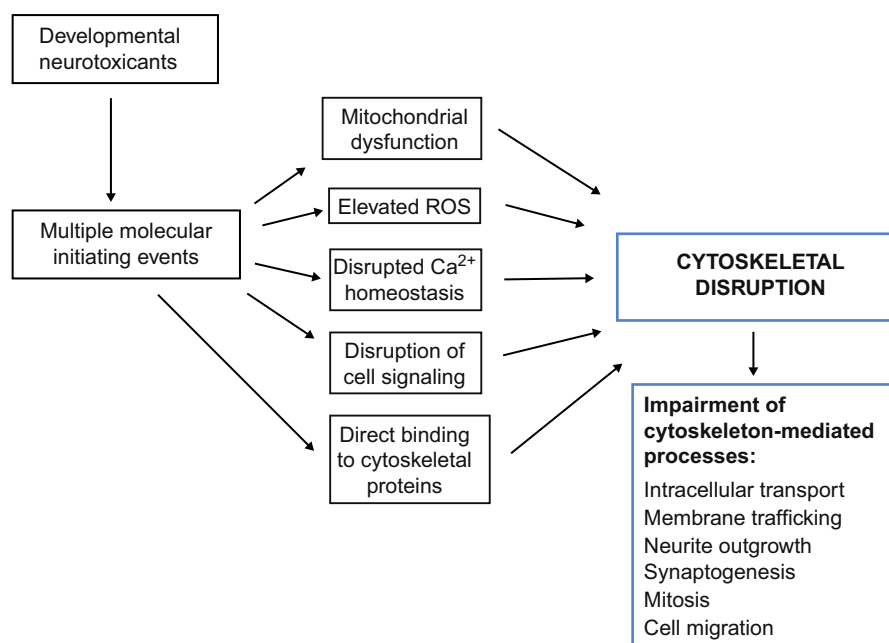
Cytoskeletal disruption as a convergence point in developmental neurotoxicity pathways


FIGURE 58.1 Simplified schematic representation of the involvement of cytoskeletal disruption in developmental neurotoxicity. Developmental neurotoxicants may act via many different molecular initiating events, such as direct binding to membrane or nuclear receptors and disruption of gene expression patterns. They may also induce the generation of increased ROS and/or cause disruption of mitochondrial function, both of which could interfere with a range of cellular activities, including intracellular transport, protein folding, and degradation. Similarly, the disruption of Ca^{2+} homeostasis could interfere with a host of Ca^{2+} dependent activities, including cell signaling pathways, proteolytic degradation (e.g., by calpain), and cytoskeletal dynamics. Finally, direct binding of toxins to cytoskeletal proteins could induce conformational changes that affect subunit assembly and/or the interaction of subunits with accessory proteins that regulate cytoskeletal dynamics.

MicroRNA Expression as an Indicator of Tissue Toxicity and a Biomarker in Disease and Drug-Induced Toxicological Evaluation

Gopala Krishna[1] , Saurabh Chatterjee[2] , Priya A. Krishna[1] , Ratanesh Kumar Seth[2]

[1]**Nonclinical Consultants, Ellicott City, MD, United States;** [2]**Department of Environmental Health Sciences, Arnold School of Public Health, University of South Carolina, Columbia, SC, United States**

INTRODUCTION

Noncoding RNA sequences, termed microRNAs (or miRNAs or miRs), have been shown to posttranscriptionally regulate messenger RNA (mRNA). They contain a seed sequence (positions 2−7) that binds to the complementary sequence of mRNA causing an alteration in gene expression. miRNAs are short (∼22 nucleotides) and relatively stable. Studies have shown their presence in plasma with a half-life of hours to days (Creemers et al., 2012). Because of their inherent stability and ease of sampling, the number of studies evaluating miRNAs as potential biomarkers both for disease- and drug-induced states has markedly increased. For a biomarker to be successfully utilized, it must satisfy a number of criteria such as ease of sampling, rapid detection, injury or disease sensitivity and specificity; discrimination between variations in the injury or disease; and stability within the biological matrix (Etheridge et al., 2011). miRNAs fulfill a number of these requirements.

Much effort has been spent in making correlations between various disease states and miRNA levels in both biological fluids and tissues (Mikaelian et al., 2013). These efforts have also been extended to include not just biomarker data in support of diagnosis but also more recently in the drug development process, where relationships between miRNA levels and toxicologic or pathologic signs (Wang et al., 2013) may be used to generate earlier safety data in advance of more expensive animal or clinical trials. Perhaps most importantly,

a biomarker must be associated with the biological mechanisms of a disease or treatment, and it must be possible to make a statistical correlation between the biomarker and the clinical effect.

Although the bulk of data reported in the literature refers to the relationship between miRNAs and therapeutic effects, less has been published regarding the relationship between changes in miRNA expression following administration of xenobiotics and the utility these extracellular molecules may have a correlating drug effect with, for example, a toxicologic endpoint.

REGULATORY MECHANISMS OF MIRNA BIOGENESIS

miRNAs are an important regulatory molecule in many biological processes and pathways. Being said that, the biogenesis and expression profile of the miRNAs are changed considerably in various diseases (O'Reilly, 2016). The miRNA profiling has been extensively studied in several diseases especially in cancer and the results of these studies indicate that miRNA expression profiling is an important tool for diagnostic and therapeutic strategy. Therefore, it is important to illustrate the molecular mechanism that regulates the miRNA expression, and it would allow an explanation of variation in protein coding genes (Gulyaeva and Kushlinskiy, 2016). The two steps in such regulation involve (1) transcriptional regulation and (2) posttranscriptional regulation (Fig. 59.1). Endogenous and/or xenobiotic

FIGURE 59.1 Schematic representation of miRNA biosynthesis and regulation: transcription, cleavage, transport to cytoplasm, and targeting of the target gene mRNA 3′UTR (Winter et al., 2009).
stimulation either activates transcription factor (TF) binding to the promotor region to facilitate miRNA transcription or methylation of promotor region of intergenic or intragenic miRNA genes to inhibit miRNA transcription (Gulyaeva and Kushlinskiy, 2016). The posttranscription regulation represents changes in miRNA processing and stability. The transcript of intronic region of host gene or independent miRNAs gene is known as mirtrons or primary miRNAs (primiRNAs). The Pri-miRNA further processed by Drosha and DGCR8 into precursor miRNA (pre-miRNA) inside the nucleus. DGCR8 contains RNA binding domain and it binds with pri-miRNA to stabilize it and facilitate the cleavage by Drosha (Yeom et al., 2006). The pre-miRNA

was then exported to cytoplasm, where Dicer cleaved pre-miRNA to form mature miRNA (Merritt et al., 2010). Therefore, changes in miRNA profile at processing levels depend on availability and activity of these enzymes. The mature miRNA forms RNA-induced silencing complex (RISC), which binds with complementary sequence of mRNA and cleaves the mRNA using RNase or destabilize or inhibit translation of mRNA (Mendell and Olson, 2012; Vermeulen et al., 2005).

The Ingenuity Pathway Analysis tool by Qiagen Inc. can precisely predict the target mRNA (Bam et al., 2017). In summary, the endogenous molecules such as hormones and cytokines, and exogenous molecules such as xenobiotics, can alter miRNA expression. These

comprehensive mechanisms of miRNA regulation solely depend on cell type, physiological conditions, and external or internal factors (Gulyaeva and Kushlinskiy, 2016). Thus, it is clear that the study of miRNAs expression profile enables us for the diagnosis, prognosis, and treatment of a wide variety of diseases.

STANDARD TOXICITY MEASUREMENTS (TISSUE AND CIRCULATING BIOMARKERS)

For many years, the standard continuum approach employed in the discovery and development of new chemical or molecular entities (NCEs or NMEs) has been to first screen large numbers of molecules using in vitro (biochemical and cell-based) assays followed by testing a smaller number of active compounds in preclinical efficacy, safety, and toxicity models. In general, it is only at the in vivo testing stage that biomarkers are given the attention they deserve. Within the drug development setting, it has long been standard practice to focus on easily accessible matrices, for example, blood, saliva, and urine, as potential reservoirs of information for drug safety and efficacy and as correlates for disease progression. It is perhaps interesting to note that although analytical technologies have advanced significantly in biomarker measurement (genomics, metabolomics, proteomics, etc.), the corresponding information technology tools required to process the large amounts of information generated have lagged (Starmans et al., 2012).

TOXICOLOGY

Toxicological evaluations typically include body weights, clinical observations, food consumption, ophthalmologic examination, clinical pathology, body temperatures, electrocardiographic evaluation (large animals only), neurobehavioral evaluation (usually only done in rodents), toxicokinetic evaluation, organ weights, and gross and microscopic pathology of tissues. Several of the items listed above are typical standard biomarkers utilized both preclinically, as part of a drug development program, and clinically, for both injury and disease diagnosis and monitoring. Further details are highlighted below.

CLINICAL PATHOLOGY

Overview

The standard clinical pathology analyses routinely performed include hematology and clinical chemistry

evaluations and, less frequently, urine and coagulation analyses. The results of these noninvasive tests may suggest a pathology that impacts the function of various organs. Limitations exist in the sensitivity and specificity of these analyses and, as such, they are used primarily to screen for health problems. An advantage, however, is that information on general animal health may be gathered via a nonterminal bleed throughout the duration of a study.

HEMATOLOGY

Hematological tests are used to examine the components of blood, specifically erythrocytes, leukocytes, and platelets, as well as specific parameters related to each cell type. The most common test is the complete blood count/hemogram, which is used as a broad screening panel that provides information such as, but not limited to, the erythrocyte: red blood cell count, hematocrit, hemoglobin, mean cell volume, and reticulocyte percentage, and count; leukocyte: count and differential; platelet: count and mean platelet volume. This information is used to screen for processes such as anemia, infectious or noninfectious inflammation, and thrombocytopenia or thrombocytosis. Microscopic examination of the peripheral blood may also be performed. This provides information regarding erythrocyte, leukocyte, and platelet number and morphology. Certain insults may result directly or indirectly in alterations in cellular morphology (e.g., Heinz body or eccentrocyte formation in erythrocytes resulting from oxidative damage) that may provide additional information regarding the pathologic process.

CLINICAL CHEMISTRY

A variety of different serum clinical chemistries may be analyzed to provide an overview of the general health status of the individual including the electrolyte balance and the status of several organs. Interpretation of the quantitative levels of the individual analytes may be affected and complicated by factors such as the site of production (i.e., a single cell type/organ that is the origin vs. multiple potential cell types/organs) and physiological regulation critical for homeostasis, as well as potential sites of loss or processing by various organ systems. Generally, there is no single analyte that is specific in indicating the dysfunction of one organ system; as such, multiple different analytes are typically measured. For example, blood urea nitrogen (BUN) and creatinine classically increase with kidney failure (renal azotemia). In contrast, if there was a concern for

hepatic toxicity, specific chemistry tests of interest would include analytes such as albumin, total protein, alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), lactate dehydrogenase, and bilirubin. Therefore, if the target organ of interest is known, it is possible to rank the chemistry analytes based on the degree of importance.

URINALYSIS

Urine is produced by the kidney and is a means by which the body eliminates waste products and regulates fluid homeostasis. A complete urinalysis is composed of three types of examination (visual, chemical, and microscopic) during which the levels of various biochemical products and cellular components are determined. Therefore, a urinalysis may function as a screening or diagnostic procedure in the assessment of renal as well as various other metabolic functions. Currently, the chemical portion of urinalysis is semiquantitative and utilizes dry-chemistry methodology via a commercially manufactured reagent stick. Quantitative measurements of selected analytes may be performed using the Cobas c501 chemistry analyzer, a wet-chemistry based methodology.

COAGULATION TESTS

Prothrombin time (PT), activated partial thromboplastin time (aPTT), and fibrinogen levels are assays commonly performed in various species. These tests are ex vivo screening measures used to assess coagulation. Multiple factors are involved in the cascade of reactions that result in clot formation in the PT and aPTT test(s). A significant decrease ($\sim$<30%) of a single or multiple factor(s) may result in the prolongation of clotting time in either PT or aPTT test(s). The PT and/or aPTT may increase in situations such as hepatic disease, vitamin K deficiency/antagonism, and consumption (e.g., disseminated intravascular coagulopathy). In contrast, fibrinogen is the precursor to fibrin, which is the end product of the coagulation cascade. Therefore, with hepatic dysfunction or secondary to increased consumption, fibrinogen levels may decrease. Additionally, fibrinogen is an acute phase protein, and its levels may increase with inflammation.

ANATOMIC PATHOLOGY

Pathological alterations by novel test agents need to be evaluated in laboratory animals before human testing. The alterations are monitored by macroscopic

(gross) and microscopic (histologic) structural (morphologic) changes, as well as by conventional histopathological analysis, which evaluates tissue and cellular patterns. The ultimate outcome of this comprehensive evaluation is the integration of the information into meaningful biological conclusions. Commonly used tissues for a toxicology study and follow-up histopathological evaluation are listed in Table 59.1.

For morphological examination of both paraffin-embedded and frozen sections, hematoxylin-eosin staining (H&E) is commonly used, with hematoxylin for nuclear staining and eosin for cytoplasmic staining. This staining procedure often enables diagnostic determination because structural discriminations can be made as to normal or pathological changes in the tissue, though special staining techniques are used as required for further detailed subtyping.

TABLE 59.1 List of Organs and Tissues Typically Studied in a GLP Toxicology Study

Adrenal glands	Lungs
Aorta	Lymph nodes (bronchial, mandibular, mesenteric)
Bone, femoral head with articular surface	Mammary gland (when present in regular abdominal skin section)
Bone marrow (sternum)	Rectum
Bone marrow (rib, costochondral junction)	Pancreas
Bone marrow (sternum) slides for differential	Pituitary gland
Brain	Prostate gland
Cecum	Salivary gland, mandibular
Colon	Sciatic nerve
Duodenum	Skeletal muscle
Epididymides	Skin (ventral abdomen)
Esophagus	Spinal cord, thoracic, and spinal cord, lumbar
Eyes	Spleen
Gall bladder	Stomach (cardiac, fundic, and pyloric)
Gonads	Thymus
Gross lesions	Thyroid gland/Parathyroid gland
Heart	Tonsils
Ileum	Trachea
Jejunum	Urinary bladder
Kidneys	Uterus
Liver	

GLP, Good Laboratory Practice

In addition, these early preclinical studies may also provide valuable information on the kinetics and in vivo absorption, distribution, metabolism, and excretion properties of a new chemical entity (NCE). Typically, the use of a biochemical measurement as a surrogate indicator of efficacy is used to demonstrate the correlation between the pharmacokinetics (PK) of the NCE and the pharmacodynamic (PD) effect produced (PK/PD). As noted earlier, it is generally accepted that these biomarker measurements can be hugely predictive during the drug development process and thus are highly relevant for their potential contribution to understanding, for example, the mechanism of action of NCE.

There are currently no routinely accepted or standardized assays for miRNAs that are required in the regulatory submission, i.e., investigational new drug process. As described earlier, existing histological measurements are based on commonly used staining techniques, and clinical chemistry assays are well defined and documented and have a significant historical database to which to refer. For those of us involved in the development of new drugs, these techniques have been the backbone of understanding and recording toxicity as applied to various compartments—either tissues or circulating physiological markers. We believe that the correlation of single or multiple miRNAs with toxic effects studied temporally will aid significantly in the understanding of the pathophysiological nature of injury and disease and the effects of NCEs on specific test systems.

NOMENCLATURE

miRNAs were originally discovered in the model organism, *Caenorhabditis elegans* (*C. elegans*). *lin-4* was the first of the miRNAs to be implicated in gene regulation (Ambros, 2001). It was shown to bind to the 3′UTR of *lin-14*, which is involved in larval development in *C. elegans*. Ambros et al. (2003) further presented guidelines for new miRNA annotation for diverse organisms, thus preventing confusion when considering other forms of RNA (e.g., small interfering RNAs, or siRNAs) (Ambros et al., 2003). In a summary of annotation on the miRBase website (University of Manchester, 2013), it is noted that the numbering of newly assigned miRNA genes follows a sequential pattern (n+1) from the most recently assigned miRNA, whereas the 3 to 4 letter prefix indicates the species of miRNA. Differentiation of the mature miRNA and the miRNA gene are indicated by the capitalization of the r in miR. The capitalized miR references the mature miRNA, whereas the lowercase mir references the miRNA gene and refers to the pri-miRNA transcript's stem loop portion.

miRNA with identical sequences that are located in different areas of the genome are indicated by numbering suffixes. miRNAs that are closely related are indicated by lettered suffixes. Interestingly, some exceptions to the rules created do exist; for example, different naming conventions are used for plants and viruses. Additionally, the historical miRNA such as *lin-4* will be maintained and homologues will continue with *lin-4* naming.

DATABASE

The primary online database for miRNA sequences and annotations is miRBase (Kozomara and Griffiths-Jones, 2011) This database coordinates the naming of new miRNA genes and is administered by the University of Manchester, United Kingdom, and can be utilized prior to publication of unique miRNA. miRBase provides users with the ability to search annotated and published miRNA sequences. For each miRNA, the database displays the predicted hairpin portion (mir) and the mature miRNA sequence (miR) and its location. For a full definition of hairpin and mature sequences, readers are referred to Ambros et al. (2003). There are many options for searching miRNA in miRBase, such as hairpin sequences, mature sequences, name, keyword, references, and annotation. These sequences and annotated data can be downloaded from the miRBase website (University of Manchester, 2013). Maintenance of a single repository for miRNA sequences enables consistency among the miRNA nomenclature. This facilitates the ability of researchers to search and download miRNA data, as well as providing access to data supporting the miRNA annotation. This also allows a central location for predicted miRNA targets and validations of these targets. miRNA expression studies generate large amounts of data, and this database provides a central source for computer-parsable annotation of miRNA sequences (for example, functional data, references, genome mappings). It is free and available online.

miRNEST (Laboratory of Functional Genomics, 2013) is a database generated by searching expressed sequence tags (ESTs), a short subsequence of a cDNA sequence (NCBI, 2013), to identify novel miRNA (Szczesniak et al., 2012). It is a database containing miRNA from diverse plants, animals, and viruses. This database was developed to address the need for a central location for a wide range of species, which is important because of the conservation of miRNA among species. For the analysis, 225 animal and 202 plant ESTs were analyzed for novel miRNAs. Szczesniak et al. (2012) identified over 10,004 potential miRNAs across 221 animal and 199 plant species. Interestingly, for 239 of the species

used in this study, no miRNA had been previously identified and of the miRNAs identified, only 299 had been deposited in miRBase. Furthermore, to expand the analysis capability, miRNEST incorporates published data and 13 additional databases. The user-friendly website combined with the diverse species' data make miRNEST an integral miRNA evaluation tool.

The miR2Disease database, which is manually curated, links human diseases to miRNA alteration (Jiang et al., 2009). This database allows researchers to correlate miRNA expression changes with specific diseases. The database maintains information about the detection method used to identify the differentially expressed miRNA as well as gene targets that have been verified experimentally with references to the data.

There were over 20 different databases, many of which are curated in academic settings in countries far apart as China, Korea, Switzerland, Germany, Greece, Poland, and the United States. A list of many of these databases is provided by Mikaelian et al. (2013). Because of the rapid advancement of miRNA research and identification, it is difficult to maintain the current databases. For example, the number of submissions to miRBase has risen exponentially in the last 3 years alone, and the number of miRNA sequences has tripled.

A clear area of development for this field could be adding or linking in preclinical and clinical toxicity data with miRNA data based on studies performed in the development of new therapeutics in a variety of disease states.

SAMPLE PREPARATION

Numerous studies have shown that differences in sample collection, extraction methodology, normalization, and data analysis can lead to variation in expression profiles of miRNA, and these differences pose significant challenges with implementation of miRNA biomarkers in a clinical setting. Low RNA levels in the plasma and serum dictate that sampling protocols and normalization be carefully considered in the development of a biomarker assay.

Control of sample collection is critical because cross-contamination by different cell types can interfere with subsequent analysis and interpretation of results. In addition, the method of collection or storage can lead to up- or downregulation of miRNA, which in turn can lead to alterations in gene expression resulting from potential bias imposed on the experimental procedure. To ensure robust evaluation in the validation of fluid or tissue biomarkers, multiple site studies (i.e., at different laboratories) need to be undertaken, thus demonstrating assay reproducibility. Accordingly, this means that a consistent and well-developed protocol

for handling samples is required and should be delineated before initiation of studies.

There are many extraction methods commercially available and optimized for RNA in general. These kits either extract total RNA, including small RNA molecules or specifically enrich for small RNA molecule extraction. Some kits offer protocols for both options. Commonly used kits include miRNeasy Mini Kit (Qiagen), MirVana miRNA Isolation Kit (Life Technologies), High Pure miRNA Isolation kit (Roche), PureLink miRNA Isolation Kit (Life Technologies), and miRCURY RNA Isolation Kit (Exiqon). Direct comparison of several commercially available kits showed that a majority of the differentially expressed miRNA were consistent between extractions (Ach et al., 2008). This study identified a small population of differentially expressed miRNA, which was found to be due to the specific extraction method. Therefore, in expression profiling, it is important to use the same extraction method throughout the entire experimental design.

Many methods are available for expression analysis of miRNA, and some include northern blotting, next-generation sequencing (NGS), and in situ hybridization; however, currently, the most commonly used methods are microarray analysis and real-time PCR analysis. Because the conversion of miRNA to cDNA is typically required with many of these methods, it is common practice to perform this in a sequence-specific manner, typically using stem-loop primers or with the addition of a common sequence to the end of the miRNA. However, microarray analysis can directly identify miRNAs without the generation of cDNA and analyze thousands of targets simultaneously. One of the drawbacks to microarray analysis is the inability to identify miRNA in low abundance, due to the amount of RNA required for the input—a fact that is important when analyzing serum or plasma that may yield low levels of RNA. Also, many microarrays have the inability to differentiate similar miRNA species, some of which will only differ by a single nucleotide change, as well as mature miRNAs and their precursor.

There are many commercially available microarray platforms, and multiple studies have demonstrated that similar results can be obtained across different microarray platforms; however, differences in input RNA concentrations should be factored in when choosing a platform (Git, 2012; Yauk et al., 2010). When specific miRNA targets are identified by microarray analysis, the results are typically confirmed with real-time PCR. The use of real-time PCR for miRNA expression profiling allows for the differentiation of isoforms of miRNA, as well as precursors of the mature miRNA using probe technology such as TaqMan MGB probes (Schmittgen et al., 2008). A drawback to real-time PCR analysis is the limited number (as compared

to microarrays) of miRNAs that can be evaluated per reaction plate. Also, bias may be introduced during the cDNA amplification process, depending on the amplification efficiencies of the many targets. Currently, NGS is labor-intensive. Typically, before sequence analysis, the adaptor sequence needs to be removed; however, because this is not limited by probe design, identification of novel miRNA and differentiation of isoforms is an advantage. NGS is also able to detect miRNA in low abundance.

To aid in the identification of miRNA in the presence of the background RNA, many software tools have been developed, such as miRDeep, miRanalyzer, miRExpress, miRTRAP, DSAP, miRTools, MIReNA, MiRNAkey, and MIREAP. These tools have various advantages and disadvantages; therefore, depending on the organism and study needs, the software tools utilized may change. Comparison of these software tools using three organisms was performed by Li et al. (2012), which highlights the advantages of each program.

For expression profiling, many disease states or toxicity profiles are human specific and therefore require human tissue for analysis (Li et al., 2012). This can be problematic when the disease states contribute to the degradation of RNA or when postmortem degradation of the RNA is observed in the tissue. Therefore, tissue collected at tissue banks needs to provide high-quality RNA and be thoroughly analyzed by indicators such as RNA integrity and 260/280 absorbance ratio before use for miRNA expression profiling. Also, the clinical history should be properly documented for the tissue and biofluid sample.

Most analytical techniques compare the relative concentrations of the miRNA rather than the absolute quantities. This is due to the variation on binding efficiencies for the miRNA and variation in labeling efficiencies by ligase for microarray analysis (Bissels et al., 2009), as well as the difficulty identifying miRNA reference genes for normalization. For diagnostic purposes, an internal control for normalization of samples is imperative. However, differential regulation throughout the tissue, fluids, and changes due to disease state(s) makes identification of reference genes difficult. Currently, this is one of the main drawbacks of the use of miRNAs as biomarkers. When evaluating the use of miRNAs for drug toxicity assessment, additional confusion can occur because standard "reference" or "housekeeping" gene expression may also be affected by the drug. Typically, therefore, small RNAs RNU 48 and U6 are commonly used as reference genes for miRNA. Chen et al. (2011) confirmed that these were reliable reference genes during the treatment of tissue culture cells with various chemicals. However, levels of these RNAs are variable across different pathological conditions and, thus, they are not appropriate as reference genes for all studies

(Chen et al., 2011). These authors also identified RNU44 and RNU47 as suitable reference genes and suggested that a combination of these reference genes would be ideal. Synthetic miRNA addition to reactions may be one way to circumvent the endogenous control issue similar in concept to the addition of an internal standard to a bioanalytical or pharmacokinetic analysis (Chen et al., 2011). These synthetic miRNAs could also be used as extraction controls and allow for normalization between samples. Because of the RNase activity in plasma, it has been noted that the synthetic miRNA should not be added to the sample until the RNase activity is inactivated (Mitchell et al., 2008). However, for plasma, it has also been suggested that normalization to the sample volume can be utilized like the standard for other biomarkers (Cheng et al., 2010). Obviously, more studies are needed to evaluate the most reliable method of normalization.

One of the greatest challenges is identifying miRNA target genes. This limits the ability to define the mechanism of action of miRNA deregulation leading to injury, toxicity, and/or disease. Typically, only 2–7 nucleotides (seed sequence) of the mature miRNA are found in the regulated target. This is further complicated by the fact that many miRNAs are cotranscribed as a single pri-miRNA and then cleaved into mature miRNA. The commonly used prediction algorithms include Targets-can, miRanda, DIANA-mircoT, PITA, Rna22, and PicTar. Many of these algorithms align the seed sequence with the 3′UTR. However, recent reports suggest that some miRNAs interact with 5′UTR and the open reading frame. Another challenge with target identification is that 100% alignment between the seed sequence and binding regions is not always required. However, Zhao et al. (2007) demonstrated that the secondary structure of mRNA is also important for regulation by miRNA. The miRNA requires accessibility to the binding site for regulation of the mRNA; therefore, a less structured 3′UTR is optimal. By evaluating the free energy required to unfold the surrounding nucleotides, binding sites may be eliminated because of inaccessibility of the binding site to the miRNA. Potential binding sites may also be evaluated based on conservation among closely related species, allowing the elimination of targets that are not conserved. Note that conservation is not always the case and needs to be applied with caution. Many of the prediction tools consider many of these factors, and thus it is important to use multiple prediction tools because of the variation in the algorithms; each algorithm will predict different sites within a single gene. Because of the complexity of identifying miRNA targets, it is optimal to evaluate targets predicted by multiple algorithms (Zhao et al., 2007).

Validation of the miRNA regulations can be done in many ways. Regulation can be assessed by reporter

gene assays, such as cloning of the entire 3′UTR containing the binding site upstream of a reporter gene such as green fluorescent protein. Utilizing cells that do not express the miRNA of interest, the interaction can be evaluated by cotransfecting the reporter construct with a vector expressing the miRNA or a miRNA mimetic and measuring the reporter gene expression levels. This approach also can be expanded with the use of miRNA inhibitors. This method is limited in the number of targets that can be analyzed during an experiment. High-throughput analyses, including microarray and proteome analysis, have been utilized, but have issues with distinguishing direct and indirect regulation. Microarray analysis can be utilized by inhibiting the miRNA of interest and then evaluating the transcriptome, although not all interactions can be identified by this method. Proteome analysis employs the labeling of amino acids that are then quantified by mass spectrometry. However, this method can also identify proteins that are regulated in an indirect manner by the miRNA−mRNA complex. Immunoprecipitation has also been utilized with similar specificity issues.

The FDA defines changes in miRNA levels as a "genomic biomarker" (FDA Guidance for Industry E15, 2008). To date, the pertinent regulatory guidance documents (FDA Guidance for Industry E15, 2011, 2008) focus on definitions and submission processes without articulating specific requirements for testing or validation. It is our expectation that, as more potential miRNA biomarkers are identified by the scientific community and evaluated therein, specific requirements for validation of miRNA-based biomarkers will be defined.

KINETICS AND PHARMACOKINETICS/PHARMACODYNAMICS

It has been shown that reduced or elevated levels of certain circulating miRNAs can be related to certain disease states. It is also well known that treatment of a wide variety of disease states with xenobiotics can result in adverse effects related directly to the drug administered or to a biotransformation of the parent drug (metabolite). As noted earlier, biomarkers, whether applied as diagnostics or as indicators of toxicity, can be found in a wide variety of compartments (e.g., blood, urine, tissues). Furthermore, there are numerous examples of measurement of a biomarker following administration of a drug, resulting in correlation with the PK of the drug and a PD effect. It has been demonstrated that administration of a known cardiotoxic drug (isoproterenol) to rats results in perturbations in serum miRNA expression levels with a combination of up- and downregulation of over 60 individual miRNAs (Table 59.2). In a study of miRNA

turnover in mouse fibroblasts following an inhibition in miRNA synthesis (Gantier et al., 2011), the half-life of miRNA was established as approximately 5 days or 10-fold greater than that of mRNA as modeled in a theoretically nondividing cell. They also noted significant variations in half-lives between individual miRNAs, suggesting that kinetic variations may be relevant if targeting an individual miRNA as, for example, a biomarker of toxicity, tissue injury, or disease state. Using saliva, Park et al. (2009) identified certain miRNAs as markers of oral cancer and further profiled their endogenous and exogenous degradation patterns over time. Krol et al. (2010) demonstrated that levels of specific miRNAs in mouse retina can change rapidly in response to light and dark exposure.

It has been a challenge to find many publications documenting the correlation of miRNA expression with toxic drug effects, although this may be a function of the somewhat guarded nature of pharmaceutical companies developing NCEs. Even less information is available in the public domain regarding measurement of tissue-specific miRNAs, either from clinical biopsy or preclinical terminal procedures.

MIRNA BIOMARKERS OF TOXICITY IN ORGAN SYSTEMS

In toxicologic pathology or disease etiology, biofluid-based biomarkers can pave the way for identifying and monitoring potential safety risks in nonclinical studies and human populations. In the recent years, many studies and reviews have been focused on whether miRNA profiling in biofluids more specific and sensitive biomarkers of tissue toxicity are as compared with conventional biomarkers. A summarization of candidate miRNA biomarkers and comparison to traditional clinical or research biomarkers is provided in Table 59.3. An overview of how toxin exposure regulates miRNA release in circulation has been given in Fig. 59.2.

ESOPHAGUS

Esophagus, commonly called as food pipe, connects pharynx to stomach. The inner lining of esophagus is consisting of three layers of stratified squamous epithelial cells unlike single layer of columnar cells of stomach. Prolonged esophagitis, especially gastric reflux, plays major role in replacing stratified squamous epithelial cells by columnar cells and develop Barrett's esophagus (BE), which is refered as metaplasia (abnormal changes) in the cells. The later stage outcome of Barrette's esophagus is known as esophageal adenocarcinoma (EAC).

$P \leq .001$.

More than 90% EAC cases arise from delayed detection because the current method has failed to identify at BE stage (Corley et al., 2002; Shaheen and Hur, 2013). The urgent need of effective detection strategy for BE may pave the way to halt the significant increase in the rate of EAC. Because miRNAs are considered more specific than mRNA profiles for diagnosis in several cancers, targeting specific miRNA could be the best diagnostic biomarker for BE (Lu et al., 2005). A pilot study published by Bansal et al., in 2014 suggest that the "BE miRNA signature has shown significant promise and should be evaluated further as a specific marker for the presence of intestinal-type BE; this signature has the potential to improve our understanding of BE pathogenesis" (Bansal et al., 2013).

To discover miRNAs associated with BE pathogenesis, entire miRNA transcriptome has been sequenced and analyzed from chronic gastroesophageal reflux disease (GERD) and BE patients followed by verification of the sequencing results by quantitative real-time polymerase chain reaction in several independent patients (Bansal et al., 2013). After extensive analysis, the three miRNAs: miR-192-5p (240611 reads per million [RPM] in BE, fold change 7.9 vs. GERD), miR-215-5p (69250 RPM in BE, fold change 9.6 vs. GERD), and miR-194-5p (8209 RPM in BE, fold change 6.5 vs. GERD) showed promising result and excellent accuracy in BE diagnosis. In another study of metastatic transformation of esophagus, the circulating miRNA expression profile reveals the significant upregulation or downregulation of miRNAs at

For conciseness, only the miRNA(s) and traditional biomarker(s) of primary interest are compared based on referenced studies. Some evaluations were treatment or assay dependent, as specified in parenthesis.

[a]"Yes" indicates that the miRNA was predominantly expressed in the target tissue.

[b]"Yes" indicates that miRNA alterations correlated with histopathological changes of target tissue more precisely than the protein biomarkers after injury. "Similar" indicates significant alterations of miRNA and protein biomarkers exhibited similar patterns. "No" indicates that the protein biomarkers correlated with histopathological changes of target tissue more precisely than the miRNA biomarker. When available, significant differences according to ROC curve analyses for biomarker performance were used to make assessments.

[c]"Yes" indicates that miRNA biomarker alterations occurred at a sooner time point or lower dose than protein biomarkers. "Similar" indicates these dynamics were similar. "No" indicates traditional biomarkers altered at an earlier time or lower dose than the miRNA biomarkers.
FIGURE 59.2 **Overview of miRNA release in blood circulation on toxin exposure.** Irrespective of toxicant exposure biological routes, the cells exposed to toxicant may experience stress and alteration in several biological pathways including miRNA transcription and processing. Further, processed and mature miRNA will incorporate into the RISC (expand what the abbreviations mean!) element and target mRNAs for degradation or protein translation inhibition. These mature miRNAs can be released from the producing cell after packaging them into membrane-bound vesicles such as exosomes, microvesicles by normal processes. The function of miRNA release is unknown, but it is speculated that this may serve as paracrine or endocrine signaling. Depending on type and levels of cellular stress, the amount and types of released miRNAs may alter. However, overt toxicity can result in cellular necrosis or apoptosis, leading to passive release of cellular miRNA contents or entrapment in apoptotic bodies, thereby increasing the presence of miRNAs in accessible biofluids. Released miRNAs encapsulated in vesicles or associated with lipoproteins or other proteins are protected from the highly RNase-rich environment and can be sampled and measured through several quantitative techniques. Those miRNAs that are predominantly expressed in certain tissues may therefore serve as specific biomarkers for tissue stress and toxicity (Harrill et al., 2016).

different stages of disease progression (Cabibi et al., 2016). The summary of expression profile in BE (n = 8), columnar-lined esophagus (CLO (n = 12)), and esophagitis (n = 10) has been provided in Table 59.4 and Fig. 59.3.

Changes in miRNAs could be important in the development of BE and its progression (Feber et al., 2008; Wijnhoven et al., 2010; Yang et al., 2009). Among them, miR-143, miR-145, miR-194, miR-203, miR-205, and

TABLE 59.4   Mean, Median, and Standard Deviation of miR-143, miR-145, miR-194, miR-203, miR-205, and miR-215 Relative Expression Values in Relation to the Histologic Phenotype (Barrett, CLO, Esophagitis) (log Scale) (Cabibi et al., 2016)

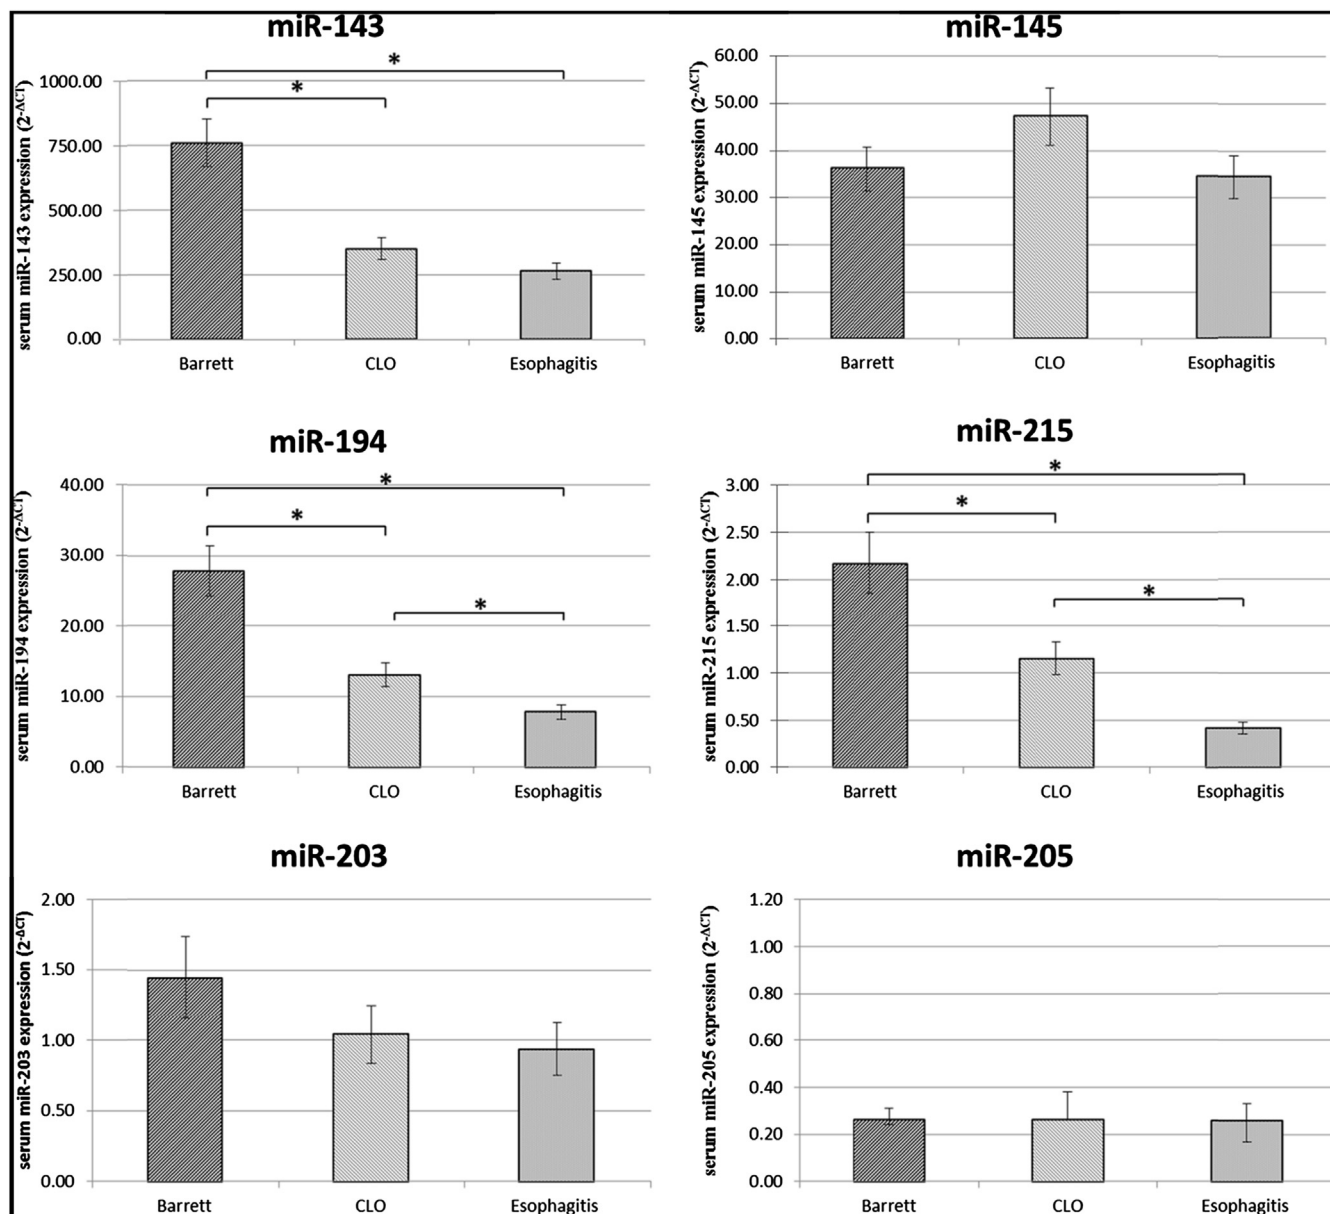
miRNA ID	Barrett (n = 8)			CLO (n = 12)			Esophagitis (n = 10)		
	Mean	Median	SD	Mean	Median	SD	Mean	Median	SD
miR-143	4.55	4.32	1.69	3.13	3.31	1.10	0.68	0.55	1.17
miR-145	4.79	4.59	1.20	3.27	3.34	1.20	0.72	0.57	0.75
miR-194	7.99	8.27	1.31	5.30	6.25	3.16	0.56	0.24	1.74
miR-203	−3.92	−4.32	1.41	−3.09	−3.13	2.59	−0.91	−0.49	1.28
miR-205	−5.62	−5.43	2.97	−4.60	−1.96	5.25	−0.39	−0.27	0.66
miR-215	8.23	8.56	2.33	5.06	5.56	2.53	0.14	−0.20	1.86


FIGURE 59.3   Serum miR-143, miR-145, miR-194, miR-203, miR-205, miR-215 expression levels (2−ΔCT) in Barrett, CLO, and Esophagitis groups. Differences in miRNA expression between the different groups were considered significant when the *P* value was under 0.05 (Cabibi et al., 2016).

miR-215 appear to have a key role in the metaplasia and in neoplastic progression. Numerous studies reported the downregulation of miR-143, miR-145, miR-203, miR-205, and miR-215 in EAC (Kan and Meltzer, 2009; Wijnhoven et al., 2010). However, few studies have been performed on lesions preceding the adenocarcinoma and on miRNA expression in different types of columnar mucosa and esophagitis. In conclusion, these findings suggest that miRNAs may be involved in the neoplastic/metaplastic progression and miRNA analysis might be useful for progression risk prediction as well as for monitoring of BE/CLO patients.

MIRNAS AS BIOMARKERS OF PANCREATIC TOXICITY

Pancreas is a large organ behind the stomach that produces digestive enzymes and several hormones. Pancreatic injury or pancreatic toxicity is generally characterized in two stages: (1) early or reversible stage with dysregulation of lipid metabolism and edema followed by (2) advance nonreversible stage with massive necrosis resulting in inflammation, with or without fibrosis (scarring of the tissue). The sequence of pancreatic injury follows a similar pattern for most of the

TABLE 59.5 Pancreas Enriched miRNAs Conserved Between Rat and Dog

Tissue enriched miRNAs conserved between rat and dog were identified and are shown above. These miRNAs were analyzed for changes in the serum in rat and dog caerulein toxicology studies. Bases underlined indicate bases that are not conserved between the rat and dog isomiRNAs with the highest sequencing counts.

etiologies and does not depend on the types of etiological agents. It is evident that a portion of patients with pancreatitis can also develop pancreatic cancer at the later stage (Kaphalia, 2014). Overall, chronic pancreatitis is a disastrous disease with significant psychological, social, and economic impact. The prognosis of pancreatitis and pancreatic cancer is very poor, and many patients die before reaching the clinical stage of the disease. Therefore, identification of biomarkers for both pre- and postpancreatitis stages could be important for clinical interventions. Early detection and prevention of pancreatic injury, progressing to inflammation and fibrosis and possibly pancreatic cancer, should be critical for the success of both clinical and surgical interventional therapies.

Although a significant literature available on biomarkers of pancreatic diseases is focused on various forms of pancreatic cancer, identification of biomarkers for early pancreatic injury and precancerous stages should be the key to early prevention and therapy. To better understand toxicities in preclinical and clinical settings and to speed the development of new therapies, body fluid—based biomarkers of organ damage have been sought to both identify and monitor toxicities. It is evident that identifying tissue specific, species translatable blood-based miRNA expression profiling could serve biomarkers of tissue injury. The potential pancreas biomarkers were tested in rat and dog toxicology studies using the pancreatic toxicant caerulein. In these proof-of-concept studies, miRNAs performed as well as or better than traditional markers of pancreatic injury, demonstrated a much larger dynamic range and increased tissue specificity over traditional biomarkers. The tissue specificity and/or enrichment of pancreas miRNA were identified and confirmed as: miRNAs − 216a-5p, 217-5p, 375-3p, 148a-3p, 141-3p and 200c-3p. (Bravo-Egana et al., 2008; Kong et al., 2010; Wang et al., 2010).

Eli Lilly investigated the isomiRNA expression of pancreas tissue specific and enriched miRNAs, and the analysis revealed that isomiRNAs generally mirror their parent miRNA expression, but some isomiRs are more tissue specific than others as shown for miRNA 217-5p in the pancreas. For example, the mature miRNA-217-5p sequence is 5′TACTGCATCAGGAAC TGACTGG-3′ and the isomiRNA-217-5p sequence 5′-TACTGCATCAGGAACTGACTGGAC-3′ are both highly enriched in the pancreas, but the miR-217-5p isomiR lacks expression in the stomach, intestine, and ovary, whereas other isomiRNAs of miRNA-217-5p are expressed in the stomach, intestine, and ovary. Conserved pancreas tissue—enriched miRNAs were examined in the rat and dog models of caerulein pancreatic toxicity to begin to characterize miRNAs as species translatable serum-based biomarkers of pancreatic injury (Table 59.5).

LIVER

Liver injury, which is chronic in nature, increases in severity over time. Examples of chronic liver injury include steatosis (fatty liver), fibrosis, cirrhosis, and cancer. Acute liver injury occurs rapidly and may include

drug-induced liver failure or cholestasis (Benichou, 1990). For the noninvasive diagnosis of liver injury, serum levels of ALT, AST, ALP, and bilirubin are commonly used. Although these parameters are typically part of a standard clinical pathology evaluation, they are not specific in nature and cannot be used to identify a specific type of liver injury. Additionally, Nathwani et al. (2005) showed that these factors may increase in cases of non-liver injury (e.g., muscle damage), whereas Shi et al. (2010) demonstrated that parameters such as ALT do not always correlate well with liver histopathology. Furthermore, serum aminotransferase levels may rise too late for therapeutic intervention (e.g., cases of acute acetaminophen [APAP] toxicity). Serum transaminase concentrations do not delineate between different types of liver injury; they are general rather than specific indicators. With these limitations, the identification of specific, reproducible, sensitive biomarkers of both acute and chronic liver injury is needed, and below a few examples are cited to show how miRNAs may serve as biomarkers for hepatic toxicity, injury, and disease states.

Of the many distinct miRNAs found in liver tissue, miR-122 is the most highly expressed, comprising 70% of the hepatic miRNA population (Lagos-Quintana et al., 2002). Girard et al. (2008) demonstrated the interplay between miR-122 and metabolism and stress–response pathway targets. Hepatocyte nuclear factors, among other liver-specific TFs, are thought to be involved in miR-122 transcriptional regulation (Coulouarn et al., 2009). Interestingly, Coulouarn et al. (2009) described miR-122 as defining the phenotype of a hepatocyte. Peters and Meister (2007) demonstrated that primarily protein complexes containing an Argonaute (Ago) protein carry serum miR-122, and Ago proteins and miRNAs interact in such a way as to ultimately target and repress mRNA translation in cells (Dueck et al., 2012). The cellular source of miR-122 in liver (e.g., sporadic diffuse, distinct, and pattern driven) is not yet known (Arroyo et al., 2011) nor is its release mechanism during a drug-induced liver injury (DILI) (Starkey Lewis et al., 2011). One hypothesis is that DILI-driven miR-122 release may occur in two phases, first export then leakage from necrotic cells (Starkey Lewis et al., 2011).

Plasma levels of miR-122 are significantly increased in chronic hepatitis B virus–infected patients and in mice treated with ethanol (8 g/kg body weight via gastric perfusion) and D-galactosamine (700 mg/kg body weight)/lipopolysaccharide (5 µg/kg body weight) treatment (Zhang et al., 2010). Furthermore, significant increases in plasma levels of miR-122 and another liver-enriched miRNA, miR-192, were identified in a mouse model of acetaminophen (APAP)–induced hepatotoxicity, wherein liver injury was induced following a single dose of 75, 150, or 300 mg/kg APAP

with levels of miRNAs and ALT evaluated at 1 and 3 h posttreatment (Wang et al., 2009). The significantly increased levels of miR-122 and miR-192 preceded alterations in serum ALT both in time and by APAP dose level. Yamaura et al. (2012) compared changes in plasma miRNA levels in rat models of acute hepatocellular injury (APAP or methapyrilene treatment), cholestasis (α-naphthyl isothiocyanate treatment or through bile duct ligation), and chronic liver injury (steatosis [high fat diet], steatohepatitis [methionine choline-deficient diet], and fibrosis [carbon tetrachloride treatment]). Using miRNA array analysis, they identified plasma miRNA profiles that could potentially differentiate between the types of liver injury. These miRNAs included miR-122, which was induced more rapidly and dramatically than plasma ALT levels in the acute hepatic injury models. Clinically, Starkey Lewis et al. (2011) evaluated circulating miR-122 levels in healthy human controls, patients with acute liver injury resulting from APAP overdose, patients with APAP overdose without observable hepatic injury, and patients with acute liver injury without relation to APAP. To assess specificity, samples from chronic kidney disease patients also were evaluated in the study. Results showed that circulating levels of miR-122 were increased in the liver injury patients only and correlated with serum ALT levels, though miR-122 levels decreased prior to ALT levels. Studies by Dattaroy et al. (2015) and Pourhoseini et al. (2015) suggest that liver tissue–specific miRNA21 expression level increased in toxin-induced nonalcoholic steatohepatitis.

Elucidating the sequential steps resulting in miR-122 release, comparing this mechanism(s) to those of standard (e.g., ALT) and other potential liver injury biomarkers (e.g., haptoglobin, matrix metallopeptidase 8), and discerning differences between transitory damage and chronic hepatic injury, is critical for establishing whether circulating miR-122 levels can offer prognostic/diagnostic value.

HEART

Whether as part of normal physiological development, disease initiation/progression, or in response to cardiac injury, miRNAs have been recognized as important regulators of cardiovascular functions (Mayr et al., 2013; Wang et al., 2008b). Across many studies, increased plasma levels of various miRNAs have been reported with their concomitant reduction in infarcted myocardium. Examples of such miRNAs include miR-208a, miR-1, miR-133, and miR-499 (Devaux et al., 2012; Gidlof et al., 2011; Wang et al., 2010).

As reviewed by Oliveira-Carvalho et al. (2013), miR-208a levels are prominent in the heart and measurable

in peripheral blood and may be valuable as a noninvasive biomarker of cardiovascular injury and/or disease, though it may not be the only circulating miRNA of utility in this regard. To illustrate, a heart attack (i.e., myocardial infarction, or MI) occurs when a disruption in blood flow to the heart is of sufficient duration to cause damage to or destruction of heart tissue. Of the aforementioned miRNAs, Wang et al. (2010) showed that plasma levels of miR-208a could successfully discriminate with 100% specificity and 90.9% sensitivity of those patients with acute MI. Importantly, in consideration of the timing of appearance in the circulation, cardiac troponin levels reportedly rise within 4–8 h of myocardial injury (Wu and Feng, 1998). In contrast, an increase in circulating levels of plasma miR-208a was observed in the aforementioned study in all MI patients within 1 h of coronary ligation, whereas cardiac troponin was measurable in only 85% of patients (Wang et al., 2010). Furthermore, Ji et al. (2009) showed in rats that miR-208 and cardiac troponin I levels were very comparable following isoproterenol-induced myocardial injury; wherein, miR-208 levels were not present at time zero (baseline), but significantly, increased over time following isoproterenol treatment (320 mg/kg body weight) through 12 h. Other studies in rat models of MI (Cheng et al., 2010; Wang et al., 2010) have shown that levels of other miRNAs, such as the muscle-enriched miR-1, miR-133a, and miR-499, have a similar temporal response with a quick rise in levels within 1 h after coronary artery ligation to reach highest levels between 3 and 12 h, decreasing thereafter, with a return to baseline levels by 3 days after MI induction. In an occlusion–reperfusion closed-chest pig model of MI, Gidlof et al. (2011) observed comparable time courses to those described above in that plasma levels of miR-208b, miR-1, miR-499-5p, and miR-133a were not detectable at baseline, were present at 1 h, and peaked at 2 (miR-208b, miR-1, miR-133a) or 2.5 (miR-499-5p) hours following initiation of the procedure.

Although levels of miR-499-5p persisted through the final time point evaluated (2.5 h), levels of the other miR-NAs did not and, while still present in plasma, were at appreciably lower levels, illustrating a somewhat differential response between the circulating miRNAs. Gidlof et al. (2011) also evaluated the time course of miRNA release in patients with ST-Elevation Myocardial Infarction, a category of heart attack in which blood flow is impeded for a protracted period and found similarities to that observed in the preclinical animal models; miR-1 and miR-133a and -b levels were highest at 2.5 h after MI symptomatology appeared. Meanwhile, circulating levels of miR-499 and cardiac troponin I increased more slowly with highest levels observed at 12 and 6 h, respectively. Like the protraction observed in the previously noted pig model of MI, miR-499 levels were still present 48 h following MI, though levels of all miR-NAs had returned to baseline after 3 days. Thus, these results indicate that plasma levels of certain miRNAs (e.g., miR-208, miR-1, miR-133a) may have greater sensitivity when compared to cardiac troponin levels for diagnosis of MI.

Coronary artery disease (CAD) results from a build-up of plaques in the coronary arteries. These plaques narrow the arterial lumen preventing blood flow to the heart. The first study evaluating levels of circulating miRNAs in CAD patients was conducted by Fichtlscherer et al. (2010) in which RNA was isolated from 36 CAD patients and 17 normal volunteers. In addition to perturbations in several different circulating miRNAs, they reported that plasma levels of miR-208a and miR-133 were elevated in CAD patients as compared to controls, which is reasonably consistent with results described above for MI. As reviewed by Tijsen et al. (2012), other studies investigating changes in miRNA levels in CAD patients have utilized sources alternative to plasma, including serum, whole blood, platelets, and peripheral blood mononuclear cells (Tijsen et al., 2012). Although miRNA levels were detected in all the aforementioned matrices, there were no consistent changes such that an overarching CAD signature was apparent, implying selectivity in miRNA changes dependent on the matrix assayed.

Failure of the ventricles to fill with or empty themselves of blood, because of any structural or functional abnormality, results in heart failure (HF). In two separate studies with relatively small cohorts of HF patients versus healthy controls, Tijsen et al. (2010) and Goren et al. (2012) identified circulating miR-423-5p levels as able to differentiate left ventricular HF patients from controls. In both studies, circulating miR-423-5p levels correlated with B-type natriuretic peptide, a commonly used clinical biomarker of HF (Tijsen et al., 2010; Goren et al., 2012). Notably, however, when circulating levels of miR-423-5p were evaluated in right ventricular HF patients versus healthy controls, it was not able to distinguish between the groups, implying perhaps a degree of selectivity of miR-423-5p for left ventricular HF (Tutarel et al., 2013). Other miRNAs were not evaluated in this study (Tutarel et al., 2013).

Thus, the possible utility of circulating miRNAs as biomarkers for cardiac injury and disease is quite promising, though significant additional work is required to assess levels prior to and following cardiovascular injury or disease initiation, as well as to further evaluate, confirm, and validate those miRNAs currently identified (larger cohorts of patients, inclusion of multiple disease states to assess specificity, etc.).

KIDNEY

Acute kidney injury (AKI) is a key risk factor in the disease process, potentially leading to the complete, or almost complete, failure of kidney function. Current biomarkers used for indications of kidney injury include BUN and serum creatinine levels; however, these parameters lack the sensitivity or specificity needed to appropriately detect renal damage at its earliest stages. Several other parameters have been proposed for AKI detection, including urinary measurements for interleukin (IL)-18, kidney injury molecule-1, liver-type fatty acid binding protein (L-FABP), and cystatin C and plasma and urinary measurements of neutrophil gelatinase-associated lipocalin. Although the aforementioned are promising, doubt remains as to their full utility in a clinical setting (for review see Schiffl and Lang (2012)), and whether they can be utilized reliably as biomarkers for either AKI or other types of kidney injuries. Thus, the need remains for the identification and validation of reliable biomarkers of renal damage to enable appropriate and timely treatment intervention, and efforts are focused on the potential utility of miRNAs in this regard, both in acute injury and chronic renal diseases.

Multiple miRNA studies in the kidney have dealt with tissue expression patterns in various renal diseases (e.g., renal allograft, renal cell carcinoma, polycystic kidney disease). Early work by Gottardo et al. (2007) identified miR-28, miR-185, miR-27, and let-7f-2 as being differentially expressed in renal cell carcinoma tissues as compared to normal kidney tissues, whereas Spector et al. (2013) reported the use of 24 miRNAs to differentiate/classify four types of renal cell carcinomas (i.e., clear cell, papillary, chromophobe, and oncocytoma) from one another. Additional renal diseases, such as lupus nephritis and IgA nephropathy, may benefit diagnostically using miRNA expression as well as acute renal allograft rejection. For example, levels of 35 of 132 miRNAs, identified by Dai et al. (2008) in IgA nephropathy renal biopsies versus control kidney biopsies, were increased. Preclinically, Bhatt et al. (2010) treated mice with cisplatin (single injection at 30 mg/kg body weight), a chemotherapeutic known to induce AKI, and found that miR-34a levels in the kidney were increased at 1, 2, and 3 days following treatment.

To date, few studies have focused on miRNAs in urine as potential biomarkers for detection of kidney injury and disease. One example, though, is a study conducted by Saikumar et al. (2012) in which miRNA levels of miR-21, miR-155, and miR-18a were evaluated in rat kidney tissue, blood, and urine following bilateral ischemia/reperfusion injury and after subcutaneous gentamicin treatment (200 or 300 mg/kg body weight).

In kidney tissue, levels of miR-21, miR-155, and miR-18a were increased with levels of miR-21 and miR-155 decreased in blood and urine as compared to controls.

Given that the various cell types in kidneys are affected in different ways based on the type of renal injury or disease, it is important to understand which miRNAs are expressed in which cells and how the miRNA levels change during injury or disease and are thereafter released into circulation.

BRAIN

Brain biomarkers have not been as extensively studied as those for other tissues such as cardiac biomarkers. Although biomarkers for brain injury have been identified, many of them lack specificity for brain injury. These biomarkers include S100 calcium binding protein B (S100B), neuron-specific enolase (NSE), glial fibrillary associated protein (GFAP), and myelin basic protein (MBP). SB-100B increases in blood and cerebrospinal fluid because of multiple types of brain injury; however, it also increases with an injury to muscle, fat, and bone marrow (Laterza et al., 2006). Similarly, NSE levels increase following stroke but also increase in small-cell lung cancer, neuroblastoma, melanoma, and other cancers.

Biomarkers as early indicators of neurodegenerative diseases and in neuronal injury are important for many factors, but two of the most critical factors are diagnosis and appropriate treatment. Traditionally, clinical manifestations and imaging are widely used for diagnosis although, by the time these interventions are made, neuronal damage may have already occurred. There is a significant and unmet medical need for a rapid diagnostic that could assist in predictive assessment or in the identification of brain disease prior to neuronal damage.

It is known that miRNAs are important for the normal development of the brain and distinct profiles have been shown in brain tissue, which suggests their importance in neural development. This has been demonstrated using expression pattern changes in miRNAs during development versus maturation. Through these studies, miRNA-134 has been shown to contribute to synaptic plasticity (Schratt et al., 2006). In addition, miR-9, miR-124a, miR-125b, miR-127, miR-128, miR-131, miR-132, and the let-7 family were highly expressed in the mouse brain when compared to other tissue (Hohjoh and Fukushima, 2007; Bak et al., 2008). Studies have shown regional specificity for miRNAs in the brain, such as miR-195, miR-497, and miR-30b in the cerebellum; miR-34a, miR-451, miR-219, miR338, miR-10a, and miR-10b in the medulla oblongata; miR-7 and miR-7b

in the hypothalamus; miR-218, miR-221, miR-222, miR-26a, miR-128a/b, miR-138, and let7c in the hippocampus; and miR-375, miR-141, and miR-200a in the pituitary (Bak et al., 2008; Landgraf et al., 2007).

Stroke is one of the leading causes of death in industrialized countries and many surviving cases result in severe disability due to tissue damage. The rapid development of apoptosis and neuronal death due to stroke has limited effective clinical therapies. Because of the complexity of ischemic strokes, identifying blood biomarkers for clinical applications has been difficult with current clinical practice including assessment by the physician in conjunction with imaging. Application of ischemic stroke biomarkers is important in facilities where imaging is not available, as well as in cases of ambiguous diagnosis. Current stroke biomarkers include S100B, NSE, MBP, and GFAP (Rothstein and Jickling, 2013). However, they are only released into systemic circulation on the breakdown of the blood−brain barrier; therefore, they do not directly correlate with the severity of the stroke. Inflammatory proteins, such as C-reactive protein, IL-6, matrix metallopeptidase 9, and vascular cell adhesion molecule also have shown potential as biomarkers of ischemic stroke. However, because they are inflammatory biomarkers, they may not differentiate stroke from other disease states that increase other biomarkers of inflammation, making clinical application difficult. Visinin-like protein 1 was shown to be present in both the blood and CSF of stroke patients, although it also has been shown to be increased in the CSF of Alzheimer's patients. Gene expression analysis with multiple gene panels shows promise for the diagnosis of stroke as well as an understanding of the cellular pathways involved, which may also lead to new treatments. Many multiple gene panels evaluating mRNA have been identified that diagnose stroke. However, the stability of the sample and variation due to sample processing make use of this as a diagnostic tool problematic. Because of the lack of specificity and stability of the previously identified biomarkers, identification and utilization of stroke miRNA biomarkers may dramatically enhance diagnosis and treatment.

In rats, miRNA-145 upregulation was observed in transient ischemia, which was shown to downregulate the expression of superoxide dismutase-2 (SOD2) (Dharap et al., 2009). SOD2 is important for neuroprotection. Inhibition of miRNA-145 led to increased SOD2 in neurons, further linking miRNA-145 to SOD2 expression. In mice, miRNA-497 was shown to be induced during transient ischemia (Yin et al., 2010b). This induction correlated with increased neuronal death, which was decreased with a miRNA-497 inhibitor. Furthermore, these studies showed that miRNA-497 repressed antiapoptotic proteins, Bcl-2 and Bcl-w. miRNA-15a was also shown to regulate *bcl-2* by directly binding to the

3′UTR and inhibiting translation (Cimmino et al., 2005). This study was further confirmed by Yin et al. (2010a), who found that peroxisome proliferator-activated receptor δ provided a protective role during stroke by inhibiting miRNA-15a. Not only do these miRNAs hold potential for rapid diagnosis of stroke, but they also show potential for therapeutic treatment.

miRNA-124 has been shown to be a brain-specific miRNA. Previous studies showed 260-fold or higher expression of miRNA-124 in the brain when compared to other tissues (Laterza et al., 2009). Using the middle cerebral artery occlusion model for brain injury due to stroke, miRNA-124 increased in the plasma 8 h after transient occlusions. Twenty-four (24) hours after both transient and permanent occlusions, miRNA-124 was increased 150-fold when compared to sham samples. However, miRNA-124 did not increase with liver or muscle injury, suggesting that miRNA-124 may be a specific brain biomarker for neuronal injury.

A study evaluating miRNA expression profiles in young stroke patients identified a panel of miRNAs present in the blood of these patients (Tan et al., 2009). This panel included the increased expression of miRNA-16, miRNA-19b, miRNA-23a, miRNA-103, miRNA-106b, miRNA-185, miRNA-191, miRNA-320, miRNA-451, and let7c and the decreased expression of let-7a. Therefore, considering the multitude of miRNAs that appear to be relevant, it may be the case that a panel of different miRNAs in blood ought to be utilized when searching for biomarkers of stroke.

Inflammation is an important factor in the neuronal death. Microglia cells become activated on brain injuries such as ischemia and traumatic brain injury (TBI) due to oxygen deprivation. This leads to inflammation of the neurons by the production of proinflammatory cytokine and neurotoxic products such as reactive oxygen species. Evaluation of these activated cells identified the downregulation of miRNA-181c, which leads to the upregulation of TNF-α (Zhang et al., 2012). TNF-α is an important proinflammatory cytokine that has been linked to neuronal damage in ischemia and in neurodegenerative and neurotoxic diseases.

TBI is damage due to the brain hitting the inside of the skull, or an object reaching the brain causing damage. Current diagnosis involves the use of head computed tomography scan, as well as monitoring of altered functions (e.g., cognitive, sensory, and motor). Magnetic resonance imaging (MRI) is also used, but because of the high cost, time involved, and limited availability of MRI machines, its use has been limited. Biomarkers would aid in monitoring the severity of the damage. S100B is one of the most extensively studied biomarkers of TBI. Very low levels are found in the CSF and serum under normal conditions. The levels have been shown to increase after an injury to astrocytes.

However, the correlation between levels in CSF and serum are inconclusive. As S100B does not cross the blood—brain barrier, identification in the serum may be an indicator of the loss of integrity of the blood—brain barrier. It also has issues with specificity as described earlier (Jeter et al., 2013). GFAP is released by astrocytes after TBI. It has been shown to be elevated in the serum within 1 h after injury. In adult rats, proinflammatory cytokines such as IL-α, IL-β, and TNF increased within 3 h after injury, likely due to microglia activation (Hernandez-Ontiveros et al., 2013).

Many patients with traumatic brain injuries have other bodily injuries, making differentiation difficult. Redell et al. (2010) compared TBI miRNA to those upregulated in orthopedic injuries. In this study, they found that repression of miRNA-16 and miRNA-92a and upregulation of miRNA-765 in plasma was specific for severe TBI when compared to healthy volunteers and orthopedic injury patients (Redell et al., 2010). In contrast, miRNA-16 and miRNA-92a were upregulated in mild TBI patients. Studies in rats by Balakathiresan et al. (2012) identified 47 differentially expressed miRNA in the serum when the rodents were exposed to multiple blasts over short (2 h) and long (24 h) intervals. It was found that miR-let-7i, miR-122, and miR-340-5p were upregulated in both groups. Therefore, there are several potential miRNAs for easier diagnosis of TBI (Balakathiresan et al., 2012).

Current biomarkers for the neurodegenerative disorder, Alzheimer's disease (AD), involve imaging tools that make use of radioactive tracers that bind to beta-amyloid plaques. Diagnosis is also enhanced by the presence of proteins total tau, phosphorylated tau, and beta-amyloid in the CSF and blood. Genetic testing can also be a powerful tool, given that the presence of the ApoE4 allele suggests a high risk for developing the disease. Because of the ability of the brain to adjust to neuronal death, clinical manifestations of AD occur at the late stages of the disease, limiting the success of the pharmacological intervention.

Differentially expressed miRNAs have been identified in neurodegenerative disorders, such as AD and Parkinson's disease (PD). Many studies are elucidating the role of miRNA in the sporadic AD and have identified BACE1 as a key enzyme regulated by miRNA (Saugstad, 2010). BACE1 is one of the key enzymes required for the aggregation of beta-amyloid peptides in the brain. miRNA-107 is predicted to bind to the 3′UTR of BACE1 and was shown to be decreased in AD patients. Wang et al. (2008) showed that expression of BACE1 and miRNA-107 is inversely correlated, such that as miRNA-107 decreases and BACE1 increases (Wang et al., 2008a). Alexandrov et al. (2012) showed miRNAs implicated in inflammation and AD were also upregulated in extracellular fluid surrounding brain cells and CSF of patients with the AD, which confirmed similar findings in brain tissue. All the patients evaluated had at least one ApoE4 allele. These miRNAs include miRNA-9, miRNA-125b, miRNA-146a, and miRNA-155 (Alexandrov et al., 2012). NF-κB inhibited the expression of these miRNAs. This suggests that these miRNAs may be suitable biomarkers for the AD and that inflammation plays an important role in neuronal death.

α-Synuclein (ASYN) is a major component of neuronal inclusions called Lewy bodies, which are a characteristic of PD. The presence of ASYN in CSF can differentiate α-synucleinopathies from other neurological disorders such as an AD. Similarly, to other complicated diseases, a panel of biomarkers accurately differentiated Parkinson's from other diseases using CSF; these markers include total tau, phosphorylated tau, beta-amyloid, Flt3 ligand, and fractalkine. Imaging has also been effectively used as a biomarker.

Minimal expression of miRNA-133b has been shown to be important for PD. Functional studies showed that it is important for the maturation of dopaminergic neurons (Kim et al., 2007). Let-7 and miRNA-184 are important in regulating LRRK2, an important protein involved in sporadic and familial PD (Gehrke et al., 2010). Furthermore, decreased levels of miRNA-34b/c in the brain tissue of PD patients have been shown to be important in multiple stages of disease development (Minones-Moyano et al., 2011). The aggregation of ASYN leads to decreased neuronal function and cell death. Junn et al. (2009) identified that the 3′UTR of ASYN is regulated by miRNA-7. The induction of miRNA-7 leads to decreased levels of ASYN. Because ASYN is a key protein in the development of PD, the therapeutic use of miRNA-7 has great potential (Junn et al., 2009). Using blood samples, Margis et al. (2011) identified that expression of miRNA-1, miRNA-22, and miRNA-29 can differentiate individuals with PD from healthy individuals. Furthermore, miRNA-16-2, miRNA-26a2, and miRNA-30a can differentiate treated and untreated individuals with PD. In a small set of patient samples, Sheinerman et al. (2012) identified biomarker pairs that were able to predict mild cognitive impairment before clinical presentation. They grouped these pairs into families. The mir-132 family includes miR-128/miR-491-5p, miR-132/miR-491-5p, and miR-874/miR-491-5p, and the miR-134 family includes miR-323-3p/miR-370, miR-382/miR-370, and miR-134/miR-370 (Sheinerman et al., 2012). Larger populations need to be analyzed for validation for AD or PD. Because of the extent of neuronal damage on diagnosis of AD and PD, earlier detection could dramatically aid in treatment options.

ENVIRONMENTAL EXPOSURE AND MIRNA

Our inbuilt environment is the major effector of our health or disease status. In combination with genetic factor, environmental exposure can lead to severe complication in most of the disease. In the last two decades, the noncoding gene product such as miRNA has gained huge interest in environment associated epigenetic effects. Consulting several review articles, experimental articles and database search, a strong relation has been observed in environmental pollution exposure and miRNA levels. The environmental pollution potentially regulates miRNA expression in disease pathogenesis, and therefore, miRNAs could potentially be novel biomarker of environmental associated disease (Vrijens et al., 2015). The review published by Vrijens et al (2015) clearly suggests the challenges of epidemiological studies. Thus, the collection of information on the tissue specific miRNAs is limited and depends on the levels of circulatory, free and exosomal miRNAs. The effects of environmental pollution and toxin and/or personal exposure on miRNA expression have been summarized in Table 59.6. It has been observed that the miRNAs frequently reported in response to personal or environmental exposure are directly associated with cancer etiology especially lung and breast cancer and leukemia or complication in cardiovascular system and also hypertension, HF, myocardial infarct, and atherosclerosis (Vrijens et al., 2015).

ROLE OF MIRNA IN ARSENIC-INDUCED CARCINOGENESIS

Skin cancer is the most common of all human cancers, and arsenic is second to UV in sunlight as a cause of skin cancer. In multiple epidemiologic studies, arsenical keratosis, hyperpigmentation, and multiple cutaneous malignancies were associated with arsenic exposure (Centeno et al., 2002; Maloney, 1996). The signs of arsenic toxicity appear clearly in the skin as arsenical keratosis in the palms, soles, and trunk (Centeno et al., 2002; Hunt et al., 2014). Chronic arsenic exposure causes both basal cell carcinoma and squamous cell carcinoma (SCC) of the skin. Several arsenic toxicity and carcinogenicity mechanisms have been suggested and proposed including abnormal signaling cascades, oxidative stress, and chromosomal aberrations as well as abnormal transcriptional activity and global gene expression (Isokpehi et al., 2012). Moreover, arsenic can induce environmentally driven epigenetic alterations that are known to influence disease development, including differential miRNA expression (Gonzalez et al., 2015; Su et al., 2011). An in vitro study by Al-Eryani et al. (2018) identified three of the six miRNAs with predicted targets that were differentially expressed after 3 and 7 weeks (miR-1228, miR-1254, miR-645). These miRNAs were associated with cancer in previous studies (Foss et al., 2011; Lin et al., 2015; Sun et al., 2015). MiR-1228 (suppressed at 3 weeks, induced at 7 weeks) was reported to be induced in breast cancer tissues and cell lines and regulates the levels of mRNA and protein of SCAI (suppressor of

TABLE 59.6 Expression Levels of miRNAs That Are Responsive to Personal and/or Environmental Exposure and Their Roles in Human Disease (Vrijens et al., 2015)

miRNA	Regulated	Exposure	Diseases
Let-7e	Down	TCDD	HCC, lung, pituitary, and breast cancer, GEP tumors
	Up	RDX	Heart failure, asthma
Let-7g	Down	BPA,	PM Lung carcinoma, GEP tumors, breast cancer
miR-9	Down	PM	Brain cancer, Huntingon's disease
	Up	Aluminum	Hodgkin lymphoma, breast cancer
miR-10b	Down	Formaldehyde, PM	Gastric cancer
miR-21	Down	Smoking	Diabetes type 2
	Up	DEP, metal-rich PM	Breast cancer, glioblastoma, neo-intimal lesions, cardiac hypertrophy, atherosclerosis
miR-26b	Down	DEP, BPA, PFOA	Schizophrenia, CRC, breast cancer
miR-31	Down	DEP, TCDD	Medulloblastoma, T-cell leukemia
miR-34b	Down	Smoking (2×)	CRC, pancreatic, mammary, ovarian, and renal cell carcinoma

Continued

TABLE 59.6 Expression Levels of miRNAs That Are Responsive to Personal and/or Environmental Exposure and Their Roles in Human Disease (Vrijens et al., 2015)—cont'd

miRNA	Regulated	Exposure	Diseases
miR-92b	Down	Smoking, DDT	Medulloblastoma
miR-122	Down	Smoking	HCC
	Up	TCDD	Hepatitis C, renal cell carcinoma, male infertility, sepsis, hyperlipidemia
miR-125b	Down	Smoking (2×)	Breast cancer, head and neck cancer
	Up	Aluminum sulfate (2×)	Endometriosis, cardiac hypertrophy, Alzheimer's disease
miR-135b	Down	DEP	Medulloblastoma
	Up	Smoking	CRC
miR-142	Down	Formaldehyde	Heart failure
	Up	Smoking	B-cell ALL
miR-143	Up	PM, ozone	Colon cancer
miR-146a	Down	Smoking	Postpartum psychosis, type 2 diabetes
	Up	BPA, aluminum sulfate (2×)	Alzheimer's disease, Creutzfeldt-Jakob disease, atherosclerosis, leukemia, protection against myocardial injury
miR-149	Up	BPA, DDT	Melanoma
miR-155	Down	PM	Hypertension
	Up	PM	Breast cancer, Hodgkin lymphoma, B-ALL
miR-181a	Down	Formaldehyde	Leukemia, glioma, NSCLC, breast cancer, metabolic syndrome, and CAD
	Up	TCDD	Severe preeclampsia, male infertility
miR-203	Down	Smoking, formaldehyde	Myeloma
miR-205	Up	Smoking (2×)	Heart failure, lung cancer
miR-206	Up	Smoking, RDX	Myocardial infarct, slows ALS progression, myotonic dystrophy
miR-222	Up	Metal-rich PM, BPA	Severe preeclampsia, thyroid carcinoma, prostate cancer, breast cancer
miR-223	Down	Smoking	AML
	Up	Smoking	Heart failure, atherosclerosis
miR-338-5p	Down	Formaldehyde	Melanoma
	Up	DEP	Oral carcinoma
miR-340	Down	Smoking	NA
	Up	Smoking	Heart failure, breast cancer
miR-638	Up	BPA, DDT, arsenic	Lupus nephritis
miR-663	Up	BPA, DDT, arsenic	CTCL, nasopharyngeal carcinoma, burns

ACC, acute lymphocytic leukemia; *ALS*, amyotrophic lateral sclerosis; *AML*, acute myeloid leukemia; *B-ALL*, B-cell acute lymphocytic leukemia; *BPA*, bisphenol A; *CAD*, coronary artery disease; *CRC*, colorectal carcinoma; *CTCL*, cutaneous T-cell lymphoma; *DDT*, dichlorodiphenyltrichloroethane; *DEP*, diesel exhaust particles; *GEP*, gastro-entero pancreatic; *HCC*, hepatocellular carcinoma; *NA*, not applicable; *NSCLC*, nonsmall cell lung carcinoma; *PFOA*, perfluorooctanoic acid; *PM*, particulate matter; *RDX*, hexahydro-1,3,5-trinitro-*s*-triazine; *TCDD*, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin.

cancer cell invasion) (Lin et al., 2015). MiR-1254 (suppressed at 3 and 7 weeks) was reported to be induced in the sera of nonsmall cell lung cancer patients (Foss et al., 2011). MiR-645 (induced at 3 and 7 weeks) was induced in head and neck SCC, and its induction was found to promote cell invasion and metastasis (Sun et al., 2015). Arsenite dysregulated (mostly suppressed) several snoRNAs. SnoRNAs are 60–300 nucleotide small RNAs that are concentrated in the nucleolus (Williams and Farzaneh, 2012). SnoRNAs are involved in guiding premature ribosomal and other spliceosomal RNAs for nucleoside posttranscriptional modifications, crucial for accurate ribosomes. SnoRNAs have two main classes: C/D box and H/ACA box snoRNAs, both reported to be dysregulated in several diseases including cancer (Dong et al., 2009; Williams and Farzaneh, 2012). These results suggest that dysregulation of snoRNAs may play a role in arsenic-induced carcinogenesis.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

There are several areas where it would seem obvious to continue to advance the study of miRNAs as potential biomarkers of injury, toxicity, and disease including compartment (e.g., retina, tears, saliva, amniotic fluid, and muscle). Clearly, the volume of data generated requires that there be systems available to handle such large amounts of data in a meaningful way. The work performed thus far in building databases to aid in correlations of miRNA levels with disease states would seem a logical place to start to extend this to biomarkers of injury and toxicity following administration of an NCE. Clearly, however, where commercial interests prevail, this may not happen to the extent that would be meaningful.

A second area that may be ready for further advancement is in the understanding of the relationships between the various miRNAs and the impact that these molecules themselves may have on a disease state.

A further area for research is in the design of novel sampling procedures that may allow small tissue samples to be taken that might permit the correlation of a pathologic value with a circulating biomarker such as miRNA.

Finally, these authors believe that the proliferation of human cell–based *ex vivo* systems to model efficacy and toxicity testing is ripe for exploitation in terms of validation of these approaches to replace the use of animals in preclinical drug development. Generation of robust biomarker data including miRNA information, such as may be generated from validated assays, could result in the faster acceptance and more routine use of these technologies, thus decreasing the time to bring a new drug to market.

The last two decades or so have seen a monumental rise in the amount of data generated because of continued efforts in miRNA biomarker development. Correspondingly, the value of these data in aiding our understanding of toxicology is not yet fully understood. It has been well documented that most biomarkers do not reach clinical use for many different reasons, such as failure to consider external factors, lack of understanding of temporal variations, or simply an analytical error (Starmans et al., 2012). However, the future of miRNAs as potential biomarkers to better facilitate the understanding of tissue injury and toxicology, and therefore aid in the drug development process, appears promising. In addition, miRNA technology is expected to play a significant role in environmental monitoring and in understanding the natural and/man-made insults to the biological systems over time.

Citrulline: Pharmacological Perspectives and Role as a Biomarker in Diseases and Toxicities

Shilpa N. Kaore, Navinchandra M. Kaore

Raipur Institute of Medical Sciences, Raipur, India

List of Abbreviations

AA Amino acid
Ab Antibody
ACP Anti-cyclic Citrullinated peptide
ACPA Anticitrullinated protein antibodies
ACR American College of Rheumatology
ACR Acute cellular rejection
ADMA Asymmetric dimethylarginine
Ag Antigen
AKA Anti-keratin antibodies
AKI Acute kidney injury
ALT Alanine aminotransferase
AMCV Antibodies to modified citrullinized vimentin
Anti-CarP Anti-carbamylated proteins
Anti-CCP1 First generation of anti-CCP antibodies
Anti-CCP2 Second generation of anti-CCP antibodies
Anti-CCP3 Third generation of anti-CCP antibodies
APACHE Acute Physiology and Chronic Health Evaluation
APF Antiperinuclear factor
ARDS Acute respiratory distress syndrome
ARF Acute renal failure
Arg Arginine
ASL Argininosuccinate lyase
ASS Argininosuccinate synthase
AST Aspartate aminotransferase
ATP Adenine triphosphate
AUC Area under curve
BPD Bronchopulmonary dysplasia
BUN Blood urea nitrogen
C(max) Concentration maximum
C(min) Concentration minimum
CCP Cyclic citrullinated peptide
cGMP Cyclic guanylyl monophosphate
Cit Citrulline coupled with polyethylene glycol 5000
CPS Carbamoyl phosphate synthetase
CPS1D Carbamoylphosphate synthase 1 deficiency
CRP C-reactive protein
CTLN2- Citrullinemia type II
DBS Dried blood spot
DFP Diisopropylflourophosphate
ED Erectile dysfunction
ELISA Enzyme linked immunoassay

eNOS Endothelial Nitric oxide synthase
FTTDCD Failure to thrive and dyslipidemia caused by Citrin deficiency
GFD Gluten-free diet
GVHD Graft versus host disease
HCit Homocitrulline
HDL-C High density cholesterol
HU Hydroxyurea
HuArgI (Co)-PEG5000 Human recombinant arginase I cobalt [HuArgI (Co)]
IDDM Insulin-dependent diabetes mellitus
IgA Immunoglobin A
IgM Immunoglobin M
IL-10 Interleukin 10
IL-6 Interleukin 6
iNOS Inducible Nitric oxide synthase
IUGR Intra uterine growth retardation
KA Kainic acid
mTOR Mammalian Target of Rapamycin
NAGSD N-acetylglutamate synthase deficiency
NICCD Neonatal intrahepatic cholestasis caused by Citrin deficiency
nNOS Neuronal Nitric oxide synthase
NO Nitric oxide
NOS Nitric oxide synthase
NPV Negative predictive values
OAT Ornithine-δ-aminotransferase
OTC Ornithine transcarbamylase
OTCD Ornithine transcarbamylase deficiency
PAD Peptidylarginine deiminase
PAD2 Peptidylarginine deiminase 2
PCOS Polycystic ovary syndrome
PH Pulmonary hypertension
PI Protease inhibitors
PRISM Pediatric Risk of Mortality
RF Rheumatoid factor
RNS Reactive nitrogen species
ROS Reactive oxygen species
RVF Right ventricular function
SBS Short bowel syndrome
sGC Soluble guanylyl cyclase
SHR Spontaneously hypertensive rats
SIRS Systemic inflammatory response syndrome

SOFA Sequential Organ Failure Assessment score
T2DM Type 2 diabetes mellitus
TB Tuberculosis
TNF Tumor necrosis factor
TPN Total parenteral nutrition
UCD Urea cycle disorders

INTRODUCTION

L-Citrulline is a naturally occurring nonessential amino acid (AA), present in mammals and also in each living organism. It is produced by the body naturally and also found naturally in certain foods such as watermelons, cucumbers, pumpkins, muskmelons, bitter melons, squashes, and gourds. Historically, citrulline's (Cit) name was derived from the Latin word for watermelon *Citrullus vulgaris* (Wada, 1930), because it was first isolated from it (Collins et al., 2007). Watermelon is unusually rich in Cit (Kaore et al., 2013).

Cit, made from ornithine and carbamoyl phosphate, is a component of the urea cycle in the liver (Endo et al., 2004). Cit is synthesized from arginine (Arg) and glutamine in the enterocytes. Cit enters into the kidney, vascular endothelium, macrophages, and other tissues and can be readily converted to Arg and nitric oxide (NO). Arg is then made available for utilization by the peripheral tissues (Fig. 60.1).

All three isoforms of nitric oxide synthase (NOS)—neuronal NOS (nNOS), inducible NOS, and endothelial (eNOS)—convert L-arginine to NO and L-citrulline. The Arg/asymmetric dimethylarginine (ADMA) ratio is one of the determinants of NO production. NO activates soluble guanylylcyclase (sGC) in smooth muscles, leading to an increase in intracellular cyclic guanylyl monophosphate (cGMP) and causing vasodilation. This process is essential for endothelial function, hence disturbed NO production in the human endothelium attributes to endothelial dysfunction. Under ischemic
FIGURE 60.1   Schematic representation of synthesis of citrulline and its highlights as biomarker.

conditions, NO is synthesized from nitrite, in acidic conditions, via a nonenzymatic pathway mainly in tissues (Kaore et al., 2013).

Cit is formed exclusively in enterocytes with the liver having only a minimal effect on Cit production. A decrease in the functional mass of enterocytes decreases plasma Cit levels (Oliverius et al., 2010). About 80% of Cit is converted in the kidney to Arg (Luiking et al., 2009; Oliverius et al., 2010), finally converting/recycling Arg to Cit and NO and serving as a potent Arg precursor (Waugh et al., 2001; Flam et al., 2007; Moinard and Cynober, 2007; Luiking et al., 2009) (Fig. 60.1). This is carried out via argininosuccinate synthase (ASS) converting L-citrulline to L-argininosuccinate, which is subsequently converted to Arg by argininosuccinate lyase (ASL) (Fig. 60.1). The importance of the argininosuccinate pathway has been appreciated in the pig for the Cit to Arg conversion in the cerebral vascular endothelium is a constant neuronal source of NO for inducing cerebral vasodilatation (Lee and Yu, 2002). But it is now realized that lack of both, as well as excess NO production, can have very important implications in health and disease. Hence, inhibition of excessive NO production is also a promising future therapeutic target (Kaore et al., 2013) (Box 60.1).

CITRULLINE OR ARGININE SUPPLEMENTATION

To summarize, first, Arg is exposed to more presystemic/systemic degradation than is Cit, making oral delivery very ineffective for Arg. Secondly, Cit is superior to Arg in terms of increased bioavailability. Thirdly, the beneficial effects of Arg do not endure with chronic therapy. Lastly, diseased states such as heart failure, atherosclerosis, diabetic vascular disease, and ischemia-reperfusion injury (as well as Arg supplementation) enhance arginase expression and activity, reducing the effectiveness of Arg therapy. In contrast, Cit inhibits arginase activity. For these obvious reasons, Cit supplementation seems to be a better alternative for supplying Arg than Arg supplementation itself (Kaore et al., 2013).

Cit supplementation holds promise as a therapeutic adjunct in clinical conditions associated with Arg/NO deficiency and/or endothelial dysfunction. Supplementation is likely to benefit clinical conditions such as hypertension, heart failure, atherosclerosis, diabetic vascular disease, and ischemia-reperfusion injury, to name a few. This is likely to be exploited in the future as a therapeutic agent for other clinical conditions, such as sickle cell anemia, hypertension, hyperlipidemia, diabetes, erectile

---

BOX 60.1

SALIENT FEATURES OF CITRULLINE, MAJOR PHARMACOLOGICAL ACTIONS AND ITS CLINICAL APPLICATIONS

Citrulline

Natural sources
- Watermelon (*Citrullis vulgaris*), cucumbers, pumpkins, muskmelons, bitter melons, squashes, gourds

Salient features
- A nonessential amino acid
- Donor of arginine & NO
- Conditionally essential amino acid in intestinal pathology and critically ill

Major pharmacological actions
- Antioxidant
- Vasodilatation
- Decreases leukocyte migration
- Restores nitrogen balance & increases muscle protein content as well as muscle protein synthesis
- Improves endothelial dysfunction

- Increases arginosuccinate synthase (ASS) expression in cancer cells
- Preserves anti-inflammatory mediator response (in sepsis)

Clinical applications
- Alzheimer's Disease
- Multi-Infarct Dementia
- Urea Cycle Disorder
- Diabetes
- Sickle Cell Disease
- Hypertension
- Atherosclerosis
- Intestinal Pathology
- Short Bowel Syndrome
- Villous Atrophy Disease
- Sepsis
- T-cell Dysfunction
- Cancer
- Erectile Dysfunction

dysfunction, sepsis (as an immunomodulator), arginase-associated T-cell dysfunction, short bowel syndrome (SBS) (to restore nitrogen balance), cancer chemotherapy, acute respiratory distress syndrome (ARDS), hyperoxic lung damage, urea cycle disorders (UCDs), Alzheimer's disease (AD), intrauterine growth retardation (IUGR) (amelioration), and multi-infarct dementia (MID). In addition, it has a role in athletic training and in parasitic diseases, such as severe *Falciparum* malaria. Many of these aspects, as well as the basis for therapeutic benefits, are discussed in the following sections.

SALIENT ASPECTS OF NITRIC OXIDE

NO is a free gaseous chemical messenger, which is thought to be involved in a number of physiological processes in the mammalian central nervous system, including memory, respiration, skeletal muscle activity, and cardiovascular homeostasis (Milatovic et al., 2005). Facts about NO as studied in brain reveal a half-life of less than a few seconds. The distance of NO diffusion is 300 μm, which is enough to reach neighboring neurons (Gupta, 2004). Estimates of the half-life of NO in blood range from 0.05 to 1.8 ms, and once it enters the circulation it is not only destroyed quickly but also transported to and interchanges with other compartments (Rassaf et al., 2002).

Growing evidence suggests the role of NO in regulation of insulin sensitivity and oxidation of energy substrates, a key role in the immune response, neurological functions, and hemodynamics in animals and humans. NO released from endothelium is an important regulator of vascular tone and an inhibitor of platelet and leukocyte aggregation and adhesion, as well as an inhibitor of cell proliferation (Kaore et al., 2013). NO undoubtedly plays a crucial role in the regulation of vascular disease. However, as discussed, Cit supplementation is more efficacious and reliable for increasing NO availability as compared to Arg, so Cit is a more promising and successful therapeutic agent. Thus, supplementation with Cit is a novel therapeutic approach in conditions of Arg and NO deficiency (Luiking et al., 2010). Thus, the accompanying rise in Cit levels (also NO/NO synthase and reactive nitrogen species [RNS]) can be used as markers in certain toxicities (Gupta, 2004).

This chapter describes various aspects of Cit: pharmacological perspectives, details about its exploration for therapeutic benefits, and its role as a biomarker, both now and in the future. Another area of interest is the exploration of Cit as a predictor of diseases by detection of the antibody (Ab) to citrullinated peptides. This is due to protein citrullination (i.e., posttranslational modification of Arg; Arg–Cit conversion, deaminated Arg) of

certain body proteins that produce novel epitopes and give rise to autoantibodies, detection of which provides a novel way to diagnose a wide variety of diseases and serves as a marker for monitoring certain clinical conditions. Plasma Cit concentration has been extensively studied in research, and supportive results have established its concentration as a reliable quantitative biomarker of enterocyte absorptive capacity (Papadia et al., 2014), which is used by clinicians to assess functional enterocyte mass in various chronic and acute small bowel pathologies such as SBS (Oliverius et al., 2010). The plasma Cit values can aid in diagnosis and severity of intestinal failure, and possibly also in monitoring bowel function. Thus, decreased plasma Cit concentration reflects a decrease of functional mass of enterocytes provided renal function is normal (Moinard and Cynober, 2007). In addition to being pioneered for intestinal conditions, now it has been explored as a biomarker for rheumatoid arthritis (RA), transplant rejections, IUGR, peripheral arthritis, ornithine-δ-aminotransferase (OAT) deficiency, and congenital anomalies, as well as a marker of inflammation and ARDS.

BIOCHEMICAL ASPECTS

L-Citrulline has a molecular formula of $C_6H_{13}N_3O_3$ (chemical structure shown in Fig. 60.2) and molar mass of 175.19 g/mol. It is an α-AA. Cit exists in two forms: free Cit, which is a product of the NOS enzyme family, and Cit that results from the posttranslational modification of certain proteins at Arg residues, catalyzed by peptidylarginine deiminases (PADs) (Herrera-Esparza et al., 2013). It is considered to be a nonprotein AA in the context that Cit cannot be incorporated into proteins during the translation process (because Cit does not have its own trinucleotide codon). But it is found in some proteins due to posttranslational modification of these proteins and the proteins thus modified are called citrullinated proteins. Interestingly, there is now evidence to suggest that the posttranslational modifications may be responsible for the initial triggering of autoimmunity and the breaking of tolerance (Utz et al., 2002). Research suggests citrullination to be an inflammation-dependent process because it is present in many inflammatory tissues. Citrullination is found to occur with specific proteins, including filaggrin, vimentin, fibrin, fibrinogen, α-enolase, and
FIGURE 60.2   Chemical structure of citrulline.

collagen II, producing novel epitopes that give rise to autoantibodies. Therefore, anticitrullinated protein antibodies (ACPA) are now recognized as specific biomarkers for RA, and assays that use cyclic citrullinated peptide (CCP) as an artificial antigen are showing high specificity and sensitivity (Kaore et al., 2013). Currently, the combination of anti-CCP Abs with rheumatic factor (RF) IgM and RF IgA is recommended either in parallel or for stepwise determination for RA (Conrad et al., 2010), and for erosive arthritis, suggesting that protein citrullination plays a role in the etiology of RA and that PAD inhibitors might be therapeutic (Duskin and Eisenberg, 2010). Its inclusion as a criterion in the 2010 American Rheumatoid Arthritis Classification emphasizes its importance and significance (CDC, 2013). Thus, these Abs could be used as predictors of disease.

Cit is also a posttranslationally modified Arg residue and, surprisingly, is an essential part of the B-cell epitope found in Abs in RA (For more details refer to the later section titled "Anticyclic citrullinated peptide (ACP) antibodies: a novel biomarker of rheumatoid arthritis"). Further exploration may establish Cit as a marker in a variety of disorders in the future.

PHARMACOKINETICS AND PHARMACODYNAMICS OF CITRULLINE

Pharmacodynamics of Citrulline

Citrulline in Sickle Cell Anemia

Cit (0.1 g/kg, p.o. twice daily) in sickle cell disease acts as an Arg precursor in palliative therapy of sickle cell disease, for which it has cleared Phase II trials, decreasing complications and increasing overall well-being of these patients. Arg serves for endogenous nitrovasodilation and vasoprotection (inhibition of adhesion and activation of leukocytes), which forms the basis of vasoprotection by Arg, partly mediated by NO-induced inhibition of endothelial damage and inhibition of adhesion and activation of leukocytes, decreasing the vasoocclusive crisis. With continued treatment with Cit, it causes symptomatic improvement and also maintains nearly normal total leukocyte and neutrophil counts (Waugh et al., 2001). Another study favored L-Arg (100 mg/kg *tid*) for significant and remarkable reduction in total parenteral opioid use by 54%. Lower pain scores at discharge were observed in the treatment arm compared to placebo. Hence Arg therapy represents a novel intervention for painful vasoocclusive episodes; being inexpensive and with narcotic-sparing effects, patients received L-arginine (100 mg/kg *tid*) or placebo for 5 days or until discharge. A significant reduction in total parenteral opioid use by 54% (1.9 ± 2.0 mg/kg *versus*

4.1 ± 4.1 mg/kg, $P = .02$) and lower pain scores at discharge (1.9 ± 2.4 vs. 3.9 ± 2.9, $P = .01$) were observed in the treatment arm compared with the placebo one. There was no significant difference in hospital length of stay (4.1 ± 01.8 vs. 4.8 ± 2.5 days, $P = .34$), although a trend favored the Arg arm, and total opioid use was strongly correlated with the duration of the admission ($r = 0.86$, $P < .0001$). No drug-related adverse events were observed. Arg therapy represents a novel intervention for painful vasoocclusive episodes. A reduction of narcotic use by $>50\%$ is remarkable. Arg is a safe and inexpensive intervention with narcotic-sparing effects that may be a beneficial adjunct to standard therapy for sickle cell−related pain in children. A large multicenter trial is warranted to confirm these observations (Morris et al., 2013). Further studies are needed to confirm these observations.

A recent systematic review showed that Arg (oral, topical or nasal), with or without hydroxyurea (HU), increased NO levels and improved patient clinical condition in sickle cell disease. The parameters shown to be improved were reduction in pain and opioid use [remarkably up to 50% reduction in hospitalizations and emergency visits (Morris et al., 2013)], improvement in heart rate indices, and healing of leg ulcers (topical use of butyrate Arg cured 30% of the patients at 12 weeks and 78% after 3 months). Because it is known that oral HU used for this disorder acts by multiple direct effects such as increasing the synthesis of fetal hemoglobin, reducing infraerythrocytes, and HbS polymerization in deoxygenation conditions, the number of neutrophils is decreased along with erythroid hydration and the expression of adhesion erythrocytes, and the synthesis of NO and its bioavailability is increased. However, being a chemotherapeutic agent HU is both cytotoxic and genotoxic, hence further strategies need to be explored to improve quality of life in these patients (Eleuterio et al., 2016).

Citrulline and Cardiovascular Effects

NO, synthesized by the endothelial cells using Arg as a substrate, contributes to regulation of vascular tone in humans that has been demonstrated by showing that inhibition of its synthesis results in significant vasoconstriction and impaired endothelial regulation of vascular tone in patients with systemic arterial hypertension (Cardillo and Panza, 1998). Thus, increasing Arg availability either by Arg therapy or arginase inhibition may provide therapeutic benefits in future patients with hypertension. NO activates sGC in smooth muscles, leading to an increase in intracellular cGMP, causing vasodilation. This process is essential for endothelial function, and disturbed NO production in the human endothelium is attributed to endothelial dysfunction.

Citrulline in Hypertension

It has been observed that hypertensive patients had a lower Arg−Cit ratio than normotensive patients associated with NO deficiency, oxidative stress, increased ROS, and a disturbed constrictor−dilator balance in the kidneys. Melatonin was found to exert an antihypertensive effect in young spontaneously hypertensive rats (SHRs) because of restoration of the NO pathway by reduction of plasma ADMA, preservation of renal Arg availability, and attenuation of oxidative stress (Kaore et al., 2013).

Studies with both Cit and nitrates consumption significantly decreased diastolic blood pressure, both decreased vascular compliance but had no effect on either pulse pressure or rate-pressure product, whereas Cit also decreased systolic pressure. Cit significantly decreased R−R interval 9% at rest and increased heart rate in addition to significantly decreasing pulse transit duration by 6%. QRS duration decreased by 5% with reduction in R−R interval (this seems to be a direct result of the modest tachycardia caused by Cit). HR augmentation in response to exercise was approximately reduced to half in Cit-treated subjects, without the desensitization observed for glyceryltrinitrate (Alsop and Hauton, 2016). Hence, Cit shows benefit in human subjects for the improvement of oxygen delivery in heart failure.

Another study for effective therapies for infants with forms of pulmonary hypertension that develop or persist beyond the first week of life needs to be worked out. Cit improves NO signaling and ameliorates pulmonary hypertension in newborn animal models. Hence, strategies that increase the supply and transport of Cit merit pursuit as novel approaches to managing infants with chronic, progressive pulmonary hypertension (Cit has proved better than Arg supplementation). More clinical trials are needed for safety and efficacy of Cit therapy in human infants with and at risk of developing chronic, progressive forms of pulmonary hypertension deserve consideration as a novel and potentially cost-effective approach to treat this life-threatening condition in term and preterm infants (Fike et al., 2014).

Therapeutic strategies that increase the transport of L-citrulline may represent a novel approach to the management of pulmonary hypertension in infants.

Another study evaluated Cit in preventing deterioration of pulmonary hypertension and explored combination therapy of tadalafil + Cit versus tadalafil + Arg in 4-week-old rats. Echocardiographical examination suggested that the ratios of RV to LV weight in a tadalafil group and a tadalafil + Cit group were significantly lower than other groups. The estimated pulmonary artery pressure in a Cit and tadalafil + Cit group seem to be lower than those in other groups because of Cit-induced vasodilation that reduces right ventricular function with improved survival rate attributed to tadalafil + Cit group due to low RV to LV ratio and decreased pulmonary artery pressure. The survival rate of tadalafil + Cit was higher than other groups with lower ratio of RV to LV weight (Ishikura et al., 2015).

Preliminary results from a case report clearly indicates that L-citrulline supplemetatation might be a potential therapy for chronic PH in infants with BPD. In this case report, for the first time a premature newborn (study in newborn animals was supporing) was given oral Cit along with sildenafil, hydrocortisone, inhaled nitric oxide. Oral Cit, from beginning of the sixth month of hospitalization, single dose of 150 mg/kg/day was introduced and continued for 70 days; patient was weaned from mechanical ventilation and never intubated again until discharge (Lauterbach et al., 2018).

A study explored and concluded that both NOS-dependent and -independent approaches in the prehypertensive stage toward augmentation of NO can prevent the development of hypertension in young SHRs. The study was done in male SHR and normotensive control rats where Cit was replaced with sodium nitrate. Rats were sacrificed at 12 weeks of age. It is noteworthy that Cit therapy also reduced levels of Arg and ADMA (endogenous inhibitor of NOS) and increased the ARG−ADMA ratio in SHR kidneys, whereas nitrate treatment reduced plasma levels of ARG and ADMA concurrently in SHRs (Chien et al., 2014). This further proves its beneficial effect in hypertension at the molecular level operating in this condition. Hence, Cit is a safer way of delivering Arg for endothelial and immune cells as well as preventing excessive uncontrolled NO production (Cynober et al., 2010) that exerts deleterious effects of its own and is an important coadjuvant in the treatment of stable systolic heart failure patients.

Citrulline in Diabetes

Cit is shown to benefit the underlying endothelial dysfunction (Hecker et al., 1990) of diabetes, in addition to producing a reduction in glucose levels. Watermelon juice exerts beneficial effects by increasing Arg availability, improving glycemic control and vascular dysfunction in type 2 diabetes mellitus through intake of Cit from watermelon (Wu et al., 2007). Cit (50 mg/kg/day, p.o.) and arginase inhibitors are found to be of benefit in endothelial dysfunction and improve impaired vasodilation of coronary arteries in diabetes (Romero et al., 2008).

Thus, studies suggest Cit may be of benefit in diabetes by improving glycemic control and in diabetes and metabolic syndrome by ameliorating underlying endothelial dysfunction. Large-scale clinical trials and mechanistic studies are required to evaluate the therapeutic strategies.

Citrulline as Immunomodulator

Cit production is significantly reduced in sepsis because of diminished de novo conversion of Arg and NO, reducing Cit and Arg availability in septic patients and transgenic mice, in part due to ADMA release. In sepsis, patients are found to have significantly decreased levels of Cit (by 56%), glutamate (by 48%), and Arg (by 47%) in comparison to healthy control subjects. A study in rats revealed that Cit supplementation reduced cell membrane lipid peroxidation and enhanced SOD activities in septic rats. It also decreased the release of TNF-α, IL-6, and IL-1β in early stages of sepsis (Cai et al., 2016). Thus, Cit may be a safe means of immunomodulation that preserves the antiinflammatory mediator response.

The concept of immunonutrition with formulation containing medium dose Arg and high dose Arg (20 g/d) is emerging, which significantly lessens the overall complications, and also improves local wound complications as well as reduces the length of hospital stay in postoperative cancer patients (De Luis et al., 2009; Rodera et al., 2012). This has been supported by another study (containing Arg, zinc, and antioxidants within a high-calorie, high-protein formula) that showed improvement in healing of pressure ulcers (PU) in malnourished patients resulting in greater reduction in PU area at 8 weeks (Cereda et al., 2015).

Citrulline Therapy May Decrease Severity of Sepsis

Sepsis is a major health problem due to its high morbidity and mortality rate and may be considered to be an Arg deficiency state (Luiking et al., 2004). Arg availability is increased in sepsis mainly by protein breakdown, but Arg catabolism is also increased due to its enhanced utilization for NO synthesis and higher arginase activity. Therefore, Arg availability is reduced in sepsis because of lower plasma Arg concentrations and a slower Arg production rate (Luiking et al., 2009). Because of this, Cit production is very low, but because data for Cit in intensive care units are not available, large clinical trials are warranted before any reliable recommendations can be made for Cit-enriched diets in this situation. At least reinforcement can be suggested for Cit supplementation. Its utility as a marker in sepsis or critically ill patients is doubtful because of associated vascular abnormalities, acute renal failure (ARF) and/or multiple organ failure, or comorbid conditions (Cynober, 2013). Further studies are warranted to either prove or disprove the use of Cit therapy as an Arg precursor in this condition.

Citrulline in Arginase-Associated T-Cell Dysfunction

It is interesting to note that T lymphocytes depend on Arg for their proliferation, zeta-chain peptide formation,

T-cell receptor complex expression, and development of memory. This makes it obvious that T-cell abnormalities such as decreased proliferation and loss of zeta chain are observed in cancer and after trauma, and they may provide new insights into T-cell dysfunction (Kaore et al., 2013). Cit may serve as a substitute for arginase-associated T-cell dysfunction, the basis for which is the molecular capability of T-cells to increase Cit membrane transport and upregulate arginosuccinate synthase (ASS) expression and thus convert Cit to Arg in in vitro studies, escaping the ill effects of Arg depletion (Bansal et al., 2004). Cit supplementation can preserve T-cell proliferation and prevent the loss of CD3 zeta chain under conditions of low Arg. New drug targets for improving T-cell associated dysfunction may be explored in the future, and further research may open novel mechanistic insights in this regard.

Citrulline: Role in Dementia of Alzheimer's Disease and in Multi-Infarct Dementia

Cit levels in the cerebrospinal fluid were significantly higher in MID in comparison to a healthy control group (Mochizuki et al., 1996). Further, it was found that there is elevated NOS activity in microvessels of the brain in AD, raising vascular NO production, exerting neurotoxicity, and being responsible for susceptibility to neuronal injury and cell death in AD (Kaore et al., 2013). Some studies contradict this notion and suggest decreased NO production to play a role in neurodegenerative disorders.

Arg fortification with a lysine (Lys)-restricted diet is one of the emerging strategies for a rare autosomal recessive disorder, pyridoxine-dependent epilepsy (PDE), which is resistant to conventional antiepileptic drugs but responsive to pharmacological dosages of pyridoxine (van Karnebeek and Jaggumantri, 2015). Further research may prove or disprove the use of Cit modulators in brain lesions or in PDE.

Citrulline: Can It Improve Aerobic Function/Energy Production?

L-Citrulline malate can develop beneficial effects on the elimination of ammonia in the course of recovery from exhaustive muscular exercise (Sureda and Pons, 2012). Cit is also shown to be a more suitable substrate than Arg to restore NO production in microcirculation during endotoxemia (Wijnands et al., 2012). Cit is shown to enhance protein expression of the myofibrillar constituents (Faure et al., 2013), and protein synthesis occurs through a mechanism of action mediated by the mTOR signaling pathway (Bahri et al., 2013).

Citrulline malate (CM) ingestion significantly reduced fatigue sensation, improved aerobic energy production in muscles, and improved exercise tolerance (Sureda and Pons, 2012), thus greatly enhancing aerobic

performance and prolongation of onset of muscular fatigue (Kaore et al., 2013). CM also limits muscle fatigue or skeletal muscle dysfunction induced by bacterial endotoxins (Kaore et al., 2013). Recent studies show ergogenic effects on Cit supplementation with improvement of muscular contraction efficiency and of athletic performance in mice (Giannesini et al., 2011; Sureda and Pons, 2012). Thus, Cit may be used as an agent to increase exercise capacity for various reasons. However, a recent study found conflicting results where CM supplementation (single 6 g dose preworkout) does not improve the muscle recovery process following a high-intensity resistance exercise session in untrained young adult men (Da Silva et al., 2017).

Citrulline for Urea Cycle Disorders

Cit may be used to treat the inborn errors of metabolism of the urea cycle responsible for removal of ammonia that, fortunately, are quite rare. The first step in the urea cycle is the reaction of ammonia and bicarbonate using ATP, catalyzed by the enzyme carbamoyl phosphate synthetase (CPS) to produce carbamoyl phosphate. The second step is the reaction of carbamoyl phosphate and L-ornithine to produce L-Cit, catalyzed by the enzyme ornithine transcarbamylase. It is interesting to note that deficiencies of either of these two enzymes lead to low serum levels of L-Cit. Treatment is with oral L-Cit. In long-term management, dietary treatment must be individualized (Kaore et al., 2013). Recently, a breakthrough in these disorders has emerged in the form of FDA approval of Cit for certain UCDs.

Citrulline for Acceleration of Wound Healing

NO is an integral part of the inflammatory phase, functioning as a regulatory mechanism to mediate epithelialization, angiogenesis, and collagen deposition crucial to the proliferative phase. NO-induced vasodilatation acted as a host-protective agent by killing pathogens in an in vitro study (Norris et al., 1995) and increasing blood flow to wounds (Stechmiller et al., 2005). This notion is supported by a clinical study in graft patients suggesting that Arg metabolism is involved in tissue repair, including angiogenesis, epithelialization, and collagen formation as increased levels of Cit and other metabolites were found in wound fluid versus plasma (Debats et al., 2009).

Citrulline in Intestinal Pathology

Studies suggest that Cit has a strong potential in total parenteral nutrition after massive intestinal resection (SBS), causing an increase in the Arg pool and acting to restore nitrogen balance. Long-term supplementation of Arg intraduodenally in rats failed to show beneficial results in intestinal ischemia and reperfusion injury (Lee et al., 2012). Cit pretreatment improves integrity of the gut barrier and helps to preserve ileum mucosa in experimental studies, thus reducing bacterial translocation. Similar effects are seen with Arg as well. This understanding of molecular mechanisms may help in developing new strategies that could be extended to malnourished patients with compromised intestinal functions.

Citrulline: Effects of Amino Acids on Hair Strength

Human studies report considerable amounts of Arg deposition on or in hair fibers from coloring agents, whereas a decreased amount of Arg and Cit was found in damaged hairs in users of "relaxers." Decreased Cit has been associated with inflammation. Study reports indicate that when coloring agents were partially replaced with Arg, it decreased the oxidative change in tensile strength of the hair by preventing the undesirable attack by hydrogen peroxide on hair proteins and hair surface lipids. Therefore, prospective studies need to be undertaken to understand whether or how "relaxers" induce inflammation and whether Arg or Cit can substantially reduce hair damage and fragility (Kaore et al., 2013).

Citrulline's Effect on Protein Synthesis

Cit is found to increase protein synthesis during refeeding in rodents with SBS, aging, and malnutrition, and it improves nitrogen balance in healthy humans (Thibault et al., 2011). Cit is a conditionally essential AA in stress, or when intestinal function is compromised. This notion is proved in SBS in rats, where Cit is able to restore nitrogen balance, increase mucosal protein content in the ileum, increase Arg levels, and increase muscle protein content, as well as muscle protein synthesis (+90%) in elderly malnourished rats. Moreover, it also has potential as a supplement for total parenteral nutrition in SBS patients because it additionally prevents muscle atrophy, not seen with Arg supplementation (Osowska et al., 2008; Kaore et al., 2013). Thus, Cit plays a crucial role in maintaining protein homeostasis and improving muscle mass related to malnutrition. Further understanding of molecular mechanisms may help in developing new strategies for malnourished patients with compromised intestinal functions (Box 60.2).

Citrulline as a Biomarker in Diseases

Cit is not involved in protein synthesis or nutrition products, but it may serve as a biomarker in various diseases such as RA, intestinal dysfunction, or sepsis. It is now an established biomarker of enterocyte functional metabolic mass in adults and children, which can be used in assessing the remnant length of small bowel in intestinal diseases such as short bowel, extensive enteropathies, intestinal toxicity of chemotherapy, and radiotherapy. Normal plasma Cit levels range

---

BOX 60.2

THERAPEUTIC APPLICATIONS OF CITRULLINE

Citrulline supplementation exploited for benefits in a variety of conditions

Cardiovascular conditions
- Hypertension
- Right ventricular dysfunction
- Hyperlipidemia

Hematological disorders
- Sickle cell anemia

Metabolic disorders
- Diabetes
- Urea cycle disorders

Neurodegenerative conditions
- Alzheimer's disease
- Multi-infarct dementia

Parasitic infections
- Malaria
- *Trypanosoma cruzi*
- *Toxoplasma gondii*

Others
- Wound healing
- As an antioxidant
- Erectile dysfunction
- Sepsis (as an immunomodulator)
- Arginase associated T-cell dysfunction
- Cancer chemotherapy (in certain tumors)

---

between 30 and 50 μmol/L independent of nutritional status. Levels less than 10 μmol/L may indicate an objective threshold for parenteral nutrition in case of intestinal failure that allows monitoring of intestinal function, except in cases of significant renal failure (Crenn et al., 2011). This reveals that decreased plasma Cit concentration reflects a decrease of functional mass of enterocytes provided renal function is normal (Kaore et al., 2013) (Box 60.3).

Citrulline as a Biomarker in Intestinal Disease

Serum Cit is emerging as an innovative biomarker candidate for assessment of intestinal function. It has been further assessed as a marker of intestinal failure and for monitoring of bowel function. Serial plasma Cit assay helps to monitor residual small bowel adaptation in children. Studies show serum Cit to be significantly lower in SBS patients, and thus it could be accurately taken as a simple, noninvasive biomarker for assessing the severity of intestinal failure. It may prove to be a candidate marker for the gut-trophic effects of bowel rehabilitation therapies. Studies show postabsorptive plasma Cit concentration to be a marker of functional absorptive bowel length that also allows distinction of transient to permanent intestinal failure in SBS patients, and also to be a marker of reduced enterocyte mass in patients with villous atrophy diseases (Kaore et al., 2013). Decreased Cit levels also correlate to the intensity of acute mesenteric ischemia and duration of intestinal damage, for which Cit has a potential future role (Cakmaz et al., 2013).

Plasma Cit is a reliable biomarker of enterocyte functional mass in HIV patients. It can discriminate between protease inhibitor (PI) toxic diarrhea and infectious enteropathy and quantify the functional consequences, which makes it an objective indicator of the need for parenteral nutrition. In HIV enteropathy, Cit concentration <10 μmol/L was associated with a clinical indication for parenteral nutrition. Observations show patients with PI-induced chronic toxic diarrhea had Cit levels in the range of 22−30 μmol/L, whereas in patients with HIV enteropathy Cit levels were <10 μmol/L. This helps to discriminate between PI-induced toxic diarrhea and infectious enteropathy. Further it was observed that 22 μmol/L was a cutoff point with 76% specificity, 95% sensitivity, and 93% negative predictive values (NPV). In addition, Cit levels <10 μmol/L could differentiate patients who needed parenteral nutrition from treatable patients without the need for parenteral nutrition, with 75% specificity, 87% sensitivity, and 87% NPV. Moreover, Cit levels normalized within 2−12 weeks with successful nutritional therapies and treatment for infectious diarrhea (Crenn et al., 2009).

In mice with schistosomiasis, Cit concentrations were reduced and found to be directly correlated with morphometry (height and area) of villi, supporting its role as a biomarker of intestinal function (Siqueira et al., 2010). Interestingly, schistosoma bind to Arg from surrounding tissue and thus escape the immune attack that requires Arg as an NO precursor (Haas et al., 2002).

BOX 60.3

STATUS OF CITRULLINE AS A BIOMARKER

Conditions detected by antibodies to citrullinated peptides as a biomarker
1. Rheumatoid arthritis	ACP antibodies detection
2. Sjögren's syndrome	ACP antibodies detection
3. Brucellosis presenting with peripheral arthritis	ACP antibodies detection

Clinical conditions detected by citrulline as a biomarker
1. Intestinal pathology	
• Short bowel syndrome	Low citrulline levels
• Celiac disease	Low citrulline levels <10 μmol/L
• Total parenteral nutrition (indicator) in HIV patients on protease inhibitor	Low citrulline levels
2. Sepsis	Low citrulline levels <13 μmol/L
3. Acute rejections (transplantations)	Low citrulline levels
4. Critically ill and correlated with severity of inflammation	Low citrulline levels ≈9 μmol/L
5. ARDS (acute respiratory distress syndrome)	Low citrulline levels
6. Polycystic ovary syndrome	Steady increase in citrulline levels preceding injury by about 36
7. Acute kidney injury/ failure	hours (and of creatinine too)
8. IUGR	Low citrulline levels
9. Citrin deficiency	Low citrulline levels
10. Perinatal conditions	
• IUGR	Low citrulline levels
• Congenital anomalies (orofacial cleft)	Low citrulline levels (<8 μmol/L),
• Citrin deficiency	NICCD − Increased citrulline levels
• OAT deficiency	FICCD − Increased citrulline levels
	CTLN2 − Increased citrulline levels
	Low citrulline levels Increased proline/ citrulline ratio

Toxicities for which citrulline acts as a biomarker *(as an indicator of nitrosoxidative stress)*
1. Anticholinesterase poisoning	Increased citrulline levels
2. Kainic acid induced neurotoxicity	Increased citrulline levels

Thus, plasma Cit concentration has been extensively used in research studies with supportive results that establish it as a reliable quantitative biomarker of enterocyte absorptive capacity (Papadia et al., 2014) and also for monitoring of certain intestinal diseases.

Citrulline as a Biomarker in Celiac Disease

Plasma Cit levels are found to be lower in celiac disease, reflecting small bowel involvement. Cit levels increased rapidly after a short period of gluten-free diet (GFD), suggesting Cit to be a sensitive marker of the positive effect of GFD on intestinal repair (Ioannou et al., 2011). Plasma Cit levels were lower in untreated disease and after 1 month of GFD, the levels were significantly higher, and after 3 months of GFD, levels were similar to those of healthy controls. Hence, whole blood Cit concentration may be considered to be a simple biochemical marker for diagnosis and monitoring of enterocyte loss in celiac disease. In Canada self-administered home blood tests or blood-testing kits are available, and patients with positive results should have small intestine endoscopy to confirm the diagnosis before starting a GFD (Rashid et al., 2009).

Citrulline: Is It a Reliable Biomarker in Critically Ill Patients?

Questions have been raised on the acceptability of serum Cit as a biomarker in acute intestinal failure in critically ill patients. These questions need further evaluation because this can be a tricky situation to interpret because of sepsis, vascular abnormalities, and multiple organ failure (Cynober, 2013). On one hand, small bowel ischemia causes acute reduction of enterocyte mass and loss of barrier function. On the other hand, systemic inflammatory response syndrome and sepsis may be linked to an acute dysfunction of enterocytes without enterocyte reduction. As Cit is mainly synthesized by small bowel enterocytes, acute reduction of the enterocyte mass correlates with low plasma Cit concentration. This is exaggerated in shock or critical illness, and thus its utility in this area needs to be evaluated (Piton et al., 2011).

The two studies cited in the preceding paragraph are in accordance regarding a doubtful conclusion that Cit cannot be agreed on as a marker in the critically ill patient, but another recent study refutes this. In this study of critically ill patients, correlation between Cit

levels and various parameters, such as Sequential Organ Failure Assessment (SOFA) score, Acute Physiology and Chronic Health Evaluation II (APACHE II) score, survival, inflammation (C-reactive protein [CRP]), inotrope use, serum levels of prealbumin and albumin, and renal failure in the critically ill patient, was analyzed. Findings revealed that only patients with intestinal dysfunction had significantly low plasma Cit levels <15 µmol/L, whereas there was no correlation between serum levels of CRP, albumin, or prealbumin; renal failure; inotrope use; SOFA score; or APACHE II score and plasma Cit levels (Noordally et al., 2012).

It is of immense importance to note that while both plasma Cit concentrations and glucose absorption were reduced in critical illness, fasting plasma Cit concentrations were not predictive of subsequent glucose absorption. Data suggest that fasting Cit concentration does not appear to be a marker of small intestinal absorptive function in patients who are critically ill (Poole et al., 2015). Hence, because of its metabolism and particular kinetics in the critically ill, plasma Cit concentration might not be as accurate as in stable patients for determining small bowel function. In the recent study, Poole and colleagues found that plasma Cit concentration and glucose absorption were reduced in 20 critically ill patients compared with 15 controls. However, the authors found no correlation between these two variables. Further studies should take into account the type of intestinal failure considered, the particular metabolism of Cit, the time of plasma Cit measurement, and the range of citrullinemia (Piton et al., 2015). Further studies are required to establish Cit as a marker in applicable cases.

Citrulline as a Biomarker to Identify Patients at High Risk of Developing a Catheter-Related Bloodstream Infection

Observations suggest that serum Cit concentration may serve as a useful biomarker to identify patients with intestinal failure who are at high risk of developing a catheter-related bloodstream infection (CRBSI) (Hull et al., 2011). All patients required parenteral nutrition support and had a venous catheter in situ >30 days and were comparable in terms of variables. The patients who developed CRBSIs had lower Cit concentrations (6.7 ± 4.6 µmol/L) than those who did not (11.3 ± 6.4 µmol/L). Cit serves the purpose of being used as a biomarker in this area, and lower Cit concentrations and longer central venous catheter placement are independent factors associated with CRBSI.

Citrulline as a Biomarker for Gastrointestinal Tolerance to Enteral Feeding

Another novel way of using Cit as a biomarker is measuring its urinary levels, which could serve as a noninvasive index of GI tolerance to enteral feeding and nutritional intake in neonates. Studies did not support its role as a biomarker in this condition. This also supports the notion that in neonatal gut, Cit is converted to Arg in situ rather than exported toward the kidneys as observed in adults (Bourdon et al., 2012). Researchers will have to further extrapolate this to measure urinary levels that may help in diagnosing diseases.

Anticyclic Citrullinated Peptide Antibodies: A Novel Biomarker of Rheumatoid Arthritis

Cit may be also considered as a nonprotein AA in that it cannot be incorporated into proteins during the translational process (Cit does not have its own trinucleotide codon), but it is found in some proteins because of posttranslational modification of these proteins. The proteins thus modified are called *citrullinated proteins*. Of interest is recent evidence that suggests the posttranslational modifications to be responsible for the initial triggering of autoimmunity and the breaking of tolerance. Citrullination appears to be an inflammation-dependent process because it is present in many inflammatory tissues (Kaore et al., 2013).

Cit is also a posttranslationally modified Arg residue and, surprisingly, an essential part of the B-cell epitope found in Abs in RA. Citrullination in RA is carried out by PAD, an enzyme that appears to be hormonally controlled. A genetic variation in PAD, PAD4, increases susceptibility to RA due to increased enzymatic activity. Further, the posttranslational protein modification unfolds the protein with a loss of positive charge in Arg residues that alters the antigenicity of self-proteins, leading to autoimmunity and chronic inflammation.

It is now understood that autoantibodies in RA containing the unusual AA Cit are specifically found in serum of RA patients. Antibodies against citrullinated proteins/peptides (filaggrin), i.e., detection of anticyclic citrullinated peptide (ACP) Abs, are highly specific biomarkers in RA. Other biomarkers for RA are RF, antiperinuclear factor, and anti-keratin antibodies (AKA). Moreover, the frequency of false positive results is lower with ACP Ab detection than with RF, so this modern biomarker of diagnostic value needs further evaluation, for early disease detection and for prevention of joint damage and deformity. It also has similar diagnostic value in patients with established or long-duration disease and is a reliable marker of severe erosive disease and in RF seronegative cases. Another related biomarker

equally sensitive to ACP Abs that needs to be analyzed further is antibody to modified citrullinized vimentin, which is significantly correlated with early detection of RA and subclinical atherosclerosis in RA (Kaore et al., 2013). Recently, ACP or ACPA have been found prevalent within the atherosclerotic plaque, which may explain accelerated atherosclerosis in RA (Sokolove et al., 2013) and thus may be associated with increased cardiovascular risks (Cambridge et al., 2013). Results of a recent study also indicated that insulin resistance and anti-CCP may be helpful in the early detection of subclinical atherosclerosis in RA patients (Wahab et al., 2016).

These Cit-containing Abs are detected early, are specific, and are detected well before the appearance of other manifestations of the disease, which may also indicate its role in the autoimmune response and pathogenesis. Citrullinated Ags are expressed in inflamed joints and can be detected early before the manifestation of the disease. ACP-ELISA assays suggest diagnostic sensitivities between 69.6% and 77.5% and specificities between 87.8% and 96.4%. To conclude, an estimation of ACP Abs is highly specific but not absolutely specific in RA, can be exploited as a biomarker for RA, and can be detected early in the course of disease. This may improve the prognostic value in RA patients and new insights in etiology and pathogenesis of the disease may be revealed (Kaore et al., 2013).

ACP Abs provide a better prognostic significance than RF, but whether this will replace RF wholly still remains to be answered. A recent study has raised doubts, because it failed to improve the performance on the American College of Rheumatology (ACR) 1987 criteria in diagnosing early RA in combination with detection of ACP Ab. Future studies may provide an answer to this, or the strategy may be to use RF in combination with ACP Abs for definitive diagnosis of RA. At any rate, the concurrent detection of ACP Ab and RF will surely increase the chances of differentiating RA from other diseases. Further data collection may answer the question of whether the ACP titers might prove to be predictors of efficacy of antitumor necrosis factor (anti-TNF) therapy (Kaore et al., 2013) (Box 60.3).

Good biomarkers serve as an important aspect to guide decisions in the clinical management of RA. A recent study in RA patients documented Abs directed against carbamylated proteins that may predict joint damage and may serve as surrogate prognostic markers. Serum levels of anti-CarP (anti-carbamylated proteins) Abs were found to be much higher in RA patients with joint erosions/deformities than in those without any joint damage, suggesting anti-CarP Abs may have good prognostic value in RA patients with erosions. However, there was no significant correlation between titers of anti-CarP Abs and presence or absence of the rheumatoid factor (Kumar et al., 2017).

First generation of anti-CCP antibodies (anti-CCP1) analysis revealed a higher specificity for RA in comparison to the RF analysis. By the end of 2002, second generation anti-CCP Ab tests were developed with different cyclic peptides and improved performance characteristics, showing an even better specificity for RA. Following anti-CCP2, a third generation anti-CCP test (anti-CCP3) has been developed to increase sensitivity for the detection of patients with RA. Overall, it was observed that both sensitivity and specificity of the anti-CCP tests were significantly higher than those of the RF test (Vos et al., 2017).

Several scholars compared the diagnostic performance of anti-CCP2 and anti-CCP3, but conflicting evidence emerges from these studies. Several studies concluded that the anti-CCP3 test has no apparent diagnostic advantage compared with the anti-CCP2 test, whereas other studies showed a higher sensitivity with anti-CCP3 test. However, it has also been speculated that the reported higher sensitivity of CCP3 may only be found in cohorts with early RA, whereas the sensitivity may be similar in groups with established disease. It was further observed that discrimination between RA and non-RA patients was better using CCP3. The most pronounced difference between CCP2 and CCP3, however, was found in RF-negative patients with a disease duration of ≤ 5 years. In this cohort ($n = 31$), the sensitivity of CCP3 was 51.6% compared to 38.7% for CCP2 (Vos et al., 2017).

Logistic regressions were used to investigate whether the usage of both tests (anti-CCP2 and anti-CCP3) gives a better prediction of RA. At the manufacturer's cutoffs sensitivity and specificity were 79.4% and 61.0% for CCP3 and 80.9% and 69.5% for CCP2. No significant differences could be observed regarding the areas under the curve (AUC) of both ROC curves. The optimal cutoff point for CCP2 was 10.5 U/ml (sensitivity 75.0% and specificity 80.0%) and 5.6 U/ml for CCP3 (sensitivity 86.9% and specificity 61.0%). Binary logistic regressions indicated that the likelihood of having RA is significantly higher when testing positive on both CCP2 and CCP3 compared to CCP2 or CCP3 alone. In our cohort, comparable performance was found between the two CCP assays. Positive results for both CCP2 and CCP3 led to the most specific identification of RA patients. In patients with joint complaints suspected of having RA and with a weakly positive CCP2 (≥ 7 and ≤ 16 U/mL), CCP3 testing could be of additional value for diagnosing RA (Vos et al., 2017).

Although the majority of studies comparing CCP2 and CCP3 detected no advantage of using CCP3 over CCP2, a few studies showed a higher sensitivity of the anti-CCP3 peptide assay compared to anti-CCP2.

Recently, the CCP3 test has been developed for analysis on an automated analyzer, the BIO-FLASH instrument, and this assay may have different properties as compared to ELISA-based assays (Vos et al., 2017).

Future studies may provide an answer to this, or the strategy may be to use RF in combination with ACP Abs for a definitive diagnosis of RA. At any rate, the concurrent detection of ACP Ab and RF will surely increase the chances of differentiating RA from other diseases. Further data collection may answer the question of whether the ACP titers might prove to be predictors of efficacy of anti-TNF therapy (Kaore et al., 2013) (Box 60.3).

Citrulline as a Biomarker in Periodontitis for Presymptomatic Rheumatoid Arthritis?

An interesting study correlated the finding that periodontitis may be a risk factor for RA because the autoantibody response in periodontitis can lead to epitope spreading to citrullinated epitopes, and this may evolve into presymptomatic RA (de Pablo et al., 2014).

Citrulline as a Biomarker in Rheumatoid Arthritis in Patients With Active Tuberculosis

A study validated the utility of anticyclic citrullinated peptide Abs, i.e., second-generation anti-CCP2, as a diagnostic marker for RA in patients with active tuberculosis (TB). The results suggested that the positive rate of anti-CCP2 in patients with newly diagnosed RA was 82.1% (87 of 106 cases), whereas the positive rate in healthy control subjects was 0.4% (one in 237 individuals). As far as the mean level of anti-CCP2 among the RA group, it was 159.3 U/mL versus 15.4 U/mL in the TB group and 0.7 U/mL in the healthy control groups. This supports anti-CCP2 detection being a reliable serological tool for identifying early RA in patients with active TB (Mori et al., 2009). Another recent study supports high sensitivity of anti-CCP and high specificity of both anti-CCP and anti-MCV Abs for RA, even in a population with high incidence of TB. This study concluded that the higher frequency of positive ACPA in TB observed in previous studies may be due to methodological factors (Lima et al., 2013). Thus, ACPA serves as a sensitive diagnostic marker for RA in patients with active TB with 78% sensitivity (confidence interval [CI], 63%—88%) and 97% specificity (CI, 89%—99%), whereas the sensitivity of anti-MCV was 50% (CI, 35%—64%) and specificity was 97% (CI, 89%—99%).

Conditions in Which Citrulline May Prove to Be a Biomarker in the Future

Prospective studies are indicated to develop rational, cost-effective, and risk-stratified guidelines for long-term follow-up of these patients. In addition, specificity and sensitivity needs to be explored in future so that the guidelines may be laid accordingly (Fig. 60.1 and Box 60.3).

Conditions Detected by Anticyclic Citrullinated Peptide

Citrulline as a Biomarker for Brucellosis Presenting With Peripheral Arthritis

The detection of anticyclic citrullinated peptide (anti-CCP) Abs is more specific for RA, but these may be positive in other autoimmune diseases and some infectious diseases. Clinical signs and symptoms of brucellosis (a zoonotic disease) are usually nonspecific and noncharacteristic, and further investigation will definitely aid in differential diagnosis. ACP Abs may serve as a positive biomarker for diagnosing brucellosis presenting with peripheral arthritis (BPA), which is common in children and young adults but which returns to normal values in the follow-up period after brucellosis treatment (Gokhan et al., 2014). It is also observed that the anti-CCP Abs are occasionally present in ankylosing spondylitis, and their presence may be helpful as a serum marker for predicting peripheral arthritis (Kim et al., 2013). Clinicians should be well versed in these findings and should evaluate for the differential diagnosis of BPA.

Citrulline as a Biomarker for Sjögren's Syndrome

The detection of anticyclic citrullinated peptide (anti-CCP) Abs can also be extrapolated to the diagnosis of another autoimmune disease, Sjögren's syndrome (SS). SS is a chronic, slowly progressive, inflammatory, autoimmune disease that is characterized by lymphocytic infiltration of the exocrine glands, characterized by generalized dryness, typically including xerostomia (dry mouth) and keratoconjunctivitis (dry eyes). Observations from a recent study revealed anti-CCP Abs, a weak presence of peptidylargininedeiminase 2 (PAD2) in normal salivary glands, and high expression of PAD2 in primary SS, which suggests the enzyme-dependent posttranslational modification of Cit. Moreover, the coexpression of Abs and PAD2 suggests autoantigen triggering. In a cohort of 134 patients, 7.5% of the serum samples were positive for anti-CCP Abs, whereas 5.2% were positive for AKAs without any radiographic evidence of erosion after a long follow-up. Therefore, ACP Abs may prove to be a diagnostic tool for detection of SS (Herrera-Esparza et al., 2013). Atzeni et al. (2008) documented that ACP Abs in SS may be associated with nonerosive synovitis, but only a minority of patients were ACP positive. Moreover, their coexistence may be a predictor of future progress to RA.

It is noted that ACPA are highly specific of RA, but are also detected in 5%—10% of primary Sjogren's syndrome. Another related recent study documented that

for ACPA-positive patients, clinical and radiological reevaluation was systematically performed after at least 5 years of follow-up found that ACPA-positive patients had more frequent arthritis but not arthralgias and also had more frequent lung involvement. After a median follow-up of 8 (5–10) years, 43.8% patients developed RA, including 31.25% that developed typical RA erosions. Researchers concluded that median term follow-up of ACPA-positive patients with SS showed that almost half of them developed RA, particularly in the presence of elevated of acute phase reactants. These results support the usefulness of a close radiological monitoring of these patients for early detection of erosive change not to delay initiation of effective treatment. Indeed, a number of these patients with ACPA-positive SS may actually have RA and associated SS (Payet et al., 2015).

Another entity introduced, which might tentatively be called ACA-positive limited scleroderma/SS overlap syndrome, is characterized by a benign systemic sclerosis clinical course but poses a high risk of non-Hodgkin's lymphoma. It is noteworthy that the prevalence of non-Hodgkin's lymphoma in the "overlap patients" was higher than in SS (Baldini et al., 2013). There is much scope for further exploration.

Conditions Detected by Citrulline Levels

Citrulline as a Biomarker in Transplants

Intensive chemotherapy is needed to prepare a patient for hematopoietic stem cell therapy, often resulting in gastrointestinal mucositis. The concern therefore is to have a reliable biomarker to decrease the severity of intestinal damage. Findings suggest that Cit may be a more specific and better marker as compared to albumin for inflammation using CRP (van der Velden et al., 2013). This may be due to the supporting fact that Cit correlates better with inflammatory response, showing a strong but inverse relationship (van Waardenburg et al., 2007). After myeloablative regimens, low Cit levels were found to correlate with intestinal damage. Cit-based assessment of intestinal damage has been shown to be an objective and reliable marker in these patients. Cit needs to be evaluated as a biomarker that can have value in diagnosing as well as in clinical decision-making in critical situation. Clinicians should also be aware of findings of significantly lower levels of Cit in patients with intestinal graft versus host disease (GVHD) (Vokurka et al., 2013).

A 3-year study that began in 2004 observed that a cutoff level of Cit <13 μmol/L should alert the clinical team to a serious problem (rejection or infection), as it could be a warning sign of rejection in a previously stable intestinal transplant recipient, whereas levels ≥13 μmol/L practically rule out moderate or severe rejection. For this cutoff point, the sensitivity for detecting moderate or severe ACR and the negative predictive value were high (96.4% and >99%, respectively). Specificity was 54%–74% in children and 83%–88% in adults. Certain other characteristics found to be associated with lower Cit levels were the presence of mild/moderate/severe acute cellular rejection (ACR), the presence of bacteremia or respiratory infection, and pediatric age (David et al., 2007). Cit is thought to be a potent indicator and hence can serve as a danger signal or a marker of ACR in intestinal transplantation. A 16-year-long term study (1995–2011) investigated Cit samples from various transplant patients and found levels to be inversely proportional to the severity of ACR. NPV for any type of ACR (cutoff, 20 μmol/L) and moderate/severe ACR (cutoff, 10 μmol/L) were 95% and 99%, respectively. Moreover, when patients were divided according to graft size, diagnostic accuracy using the same cutoff was identical. Thus, Cit is a potent indicator for ACR, an exclusionary noninvasive biomarker with excellent NPV in the long term after pediatric intestinal/multivisceral transplant (Hibi et al., 2012). It may be emphasized further that time-to-normalization of Cit was delayed by the incidence of rejection, and in some cases with moderate-to-severe rejection, normalization of Cit levels never occurred (Pappas et al., 2004). Dried blood spot (DBS) was then used as a noninvasive method for monitoring graft function following transplantation. Further, an association of lower Cit levels within 30 days of acute rejection was found in patients who had received intestinal transplant (David et al., 2006) and can be taken as a predictive marker. The Cit levels in mild rejection were 15.0 ± 2.3 μmol/L prior to rejection and 18.8 ± 2.4 μmol/L during the rejection-free periods; whereas for moderate/severe rejection the level was 12.4 ± 1.1 μmol/L before rejection and 18.8 ± 2.0 μmol/L during the rejection-free periods (David et al., 2006). Thus, Cit serum levels can be utilized as a biomarker for assessing the grades of rejection. Because of high NPV, a moderate or severe ACR can be ruled out, based exclusively on knowledge of a high value for DBS Cit. It may prove to be a promising noninvasive biomarker for graft monitoring and increasing the success rates of transplants.

A study was done to evaluate correlation of plasma Cit and rejection episodes in intestinal transplantation. Results revealed significantly decreased average serum Cit levels when the patients presented a rejection episode. It is noteworthy that there was no rejection at Cit levels of 17.38 μm/L, mild rejection at 13.05 μm/L, moderate rejection at 7.98 μm/L, and severe rejection at 6.05 μm/L. Cit correlated significantly with the rejection status of the graft such that serial follow-up of the patients using this assay may indicate the possibility of increased alloreactivity and rejection episodes (Ruiz et al., 2010).

Another study to evaluate clinical and biochemical markers of gastrointestinal function in children undergoing hematopoietic cell transplantation (HCT) was done including weekly serum Cit concentrations obtained from 10 days earlier until 30 days after HCT. Mean Cit concentration was found to be statistically lower in patients with severe oral mucositis than in those without severe mucositis. Changes in Cit were not correlated with stool volume, CRP, tumor necrosis factor-α, leptin, or ghrelin in children undergoing HCT. Serum Cit correlates with measures of gastrointestinal function (oral mucositis severity, dietary intake, acute GVHD) and may reflect mucosal injury to the gastrointestinal tract (Gosselin et al., 2014).

Citrulline as a Biomarker in Acute Respiratory Distress Syndrome

It has been observed that in patients with ARDS and severe sepsis, the plasma Cit levels are low. In a study that included patients with severe sepsis, Cit levels were low (6.0 μM) in ARDS as compared with the levels in the group having no ARDS (Ware et al., 2013). The incidence of ARDS was 50% in the group with Cit in the lowest range, and it has been postulated that NOS deficiency may play a pathophysiological role. Thus, Cit can be used as a biomarker in this area, but whether its supplementation could prevent the development of ARDS needs to be determined.

Citrulline as a Biomarker in Polycystic Ovary Syndrome

Patients with polycystic ovary syndrome (PCOS) are found to have a unique metabolomic profile. The profile that helps to differentiate between control and PCOS were AAs (Arg, Lys, proline, glutamate, and histidine), organic acids (citrate), and significantly decreased levels of Cit, Arg, Lys, ornithine, proline, glutamate, acetone, citrate, and histidine in PCOS compared with controls. These findings suggest that Cit is one factor among the metabolomics spectrum that is altered in PCOS (Atiomo and Daykin, 2012), and this lends itself to further investigation in the future.

Citrulline as a Biomarker in Acute Kidney Injury

A need is realized for a biomarker to categorize acute kidney injury (AKI) that could help in the differential diagnosis of prerenal versus intrinsic renal AKI, and for one that might be a better indicator, especially in critically ill patients at risk of AKI (Schiffl and Lang, 2012), and a predictor of long-term kidney outcomes and mortality. Biomarkers for diagnosis of AKI are usually based on blood urea nitrogen (BUN) and serum creatinine and are not very sensitive or specific for the diagnosis of AKI because they are affected by renal and nonrenal factors that are independent of kidney injury or kidney

function. Many new biomarkers are being tried in these patients such as interleukin-18, neutrophil gelatinase-associated lipocalin, and kidney injury molecule-1 (Edelstein, 2008). Decreased Arg levels correlate with renal ischemia-reperfusion injury seen after shock, trauma, and major vascular surgery leading to acute tubular necrosis (Prins et al., 2002).

New metabolomic biomarkers are emerging this area and are currently clinically governed by serum creatinine and BUN, markers with low sensitivity in the early stage of AKI. Cit is found to play the role of a novel indicator for acute kidney failure, shown by an overall direct correlation between Cit and creatinine. A steady increase in Cit levels is anticipated by about 36 h (associated with increased creatinine) along with decreased urine output (Chiarla and Giovannini, 2013). The study revealed that low serum Arg levels could facilitate the diagnosis and determine prognosis of AKI in hospitalized patients (Sun et al., 2012). This might support a role for Cit as an early marker of AKI, but needs further evaluation because some studies refute this (Noordally et al., 2012). Hence, future studies are required to explore this area of concern (Box 60.3).

Homocitrulline as a Biomarker for Renal Failure

A study was done with the aim to evaluate serum homocitrulline (HCit), which results from the carbamylation of ε-amino groups of Lys residues in ARF and to determine if it could be useful for differentiating acute from chronic renal failure (CRF). HCit concentrations increased in ARF correlated with urea concentrations, and serum HCit concentrations were statistically higher in the CRF group when compared to the ARF group. Regarding the predictive value of ARF, it was noted that sensitivity was 83% whereas specificity was 72%. Thus results demonstrate that HCit is a promising biomarker for distinguishing between ARF and CRF patients (Desmons et al., 2016).

Citrulline as a Biomarker in Critically Ill Patients and Correlation With Severity of Inflammation

Critical illness is often associated with a strong inflammatory response that is correlated with increased NO production, increased arginase activity, and decreased renal de novo Arg synthesis. Inflammation could therefore play a key role in Arg depletion and the anticipated need for Arg supplementation in these conditions (van Waardenburg et al., 2007; Luiking et al., 2009). This is due to utilization of Arg (another conditionally essential AA), which is catabolized primarily to Cit and ornithine to generate NO and other polyamines, and thus its nutritional requirements are increased during inflammation (Suh et al., 2012).

A cohort study was done in critically ill children (severity in children was assessed by the Pediatric Risk of Mortality [PRISM] score) having sepsis, trauma, and viral disease, and who were admitted to a pediatric intensive care unit. Findings suggested that plasma Cit and Arg were significantly lower (Arg: 33 ± 4, 37 ± 4, and 69 ± 8 μmol/L, respectively; Cit: 10 ± 1, 14 ± 1, and 23 ± 2 μmol/L, respectively) and correlated strongly and inversely with the severity of inflammation as indicated by raised plasma CRP concentrations (van Waardenburg et al., 2007). Thus, plasma concentrations of Arg and Cit are low during the acute phase of critical illness in children and normalize again during recovery. It is interesting to note that in severe inflammation (sepsis and trauma) and mild inflammation (viral disease), the plasma concentrations of Cit and glutamine (precursors of de novo Arg synthesis) were lower in the former than in the latter condition, whereas CRP was higher in the former than in the latter. Plasma Arg and Cit are strongly correlated to the severity of inflammation (van Waardenburg et al., 2007) and may be exploited as a biomarker in critically ill patients.

Citrulline as a Biomarker in Intrauterine Growth Retardation

Animal studies prove that plasma Cit concentrations are lower in IUGR. In addition, associated hyperammonemia is likely to be a major factor, contributing to high rates of fetal mortality in IUGR fetuses (Lin et al., 2012). Thus, it may gain importance as a promising candidate biomarker of abnormal embryogenesis (Hozyasz et al., 2010).

Citrulline as a Biomarker of Congenital Anomalies

Cleft lip with or without cleft palate is considered to be a very common congenital abnormality in humans. The Centers for Disease Control and Prevention estimates that each year 2651 babies in the United States are born with a cleft palate and 4437 babies are born with a cleft lip with or without a cleft palate. This imposes severe consequences on both physical and psychological development, as well as being a substantial economic and social burden (Parker et al., 2010). Observations suggest Cit as a biomarker in assessment of risk for congenital anomalies such as orofacial cleft, for which further studies are indicated. In addition, it is interesting to note that increased consumption of foods rich in Cit (or supplements) by women of childbearing age may bring down the incidence, indicating that the anomaly may possibly be associated with Cit status. Findings suggest that orofacial cleft incidence was higher in patients having lower concentrations (<8 μmol/L) of Cit, than in those having 8–16 μmol/L or still higher levels. Hence, lower Cit levels during

pregnancy may serve as an indicator for congenital anomalies (Hozyasz et al., 2010) for which further studies need to be carried out.

Citrulline as a Biomarker for OAT Deficiency in Early Infancy

OAT deficiency is a rare congenital metabolic disorder in humans, and early diagnosis is delayed because of the nonspecific character of initial symptoms, into adulthood. Thus, earlier diagnosis will lead to a better prognosis because treatment could be started before the occurrence of irreversible damage. Observations from case reports show that reversed enzymatic flux in early infancy results in borderline low ornithine concentration—evoking urea cycle disturbances—and increased proline. Additionally, plasma Cit was low with an increased proline/Cit ratio in plasma versus controls. Proline concentrations (777 and 1381 μmol/L) were above the 99th percentile (776 μmol/L) of the general population, whereas Cit concentrations (4.5 and 4.9 μmol/L) were only just above the 1st percentile (4.37 μmol/L). Hence, early diagnosis of OAT deficiency can lead to earlier treatment and prevent visual impairment. Further studies are needed to evaluate whether newborns with OAT deficiency leads to metabolic disorders in humans (de Sain-van der Velden et al., 2012).

Further it can be mentioned that in UCDs, patients manifesting severe neonatal hyperammonemia are benefited very little from newborn screening because of poor prognosis. N-acetylglutamate synthase deficiency, carbamoylphosphate synthase 1 deficiency, and ornithine transcarbamylase deficiency are generally not screened for the given instability of glutamine and the low specificity and sensitivity for detection of decreases in Cit levels, while Cit supplementation is of great value in treating acute hyperammonemic decompensation (Cavicchi et al., 2009).

Citrulline as a Biomarker in Citrin Deficiency

Citrin is a mitochondrial aspartate–glutamate carrier primarily expressed in organs such as the liver, heart, and kidney. Citrin deficiency can manifest in newborns as neonatal intrahepatic cholestasis (NICCD), in older children as failure to thrive and dyslipidemia (FTTDCD), and in adults as recurrent hyperammonemia with neuropsychiatric symptoms in citrullinemia type II (CTLN2). Generally, citrin deficiency is characterized by a liking for protein-rich and/or lipid-rich foods and an aversion to carbohydrate-rich foods (Saheki et al., 2004).

In NICCD, the affected neonates have significantly higher blood levels of ornithine and Cit—AAs involved in the urea cycle—than healthy counterparts despite normal plasma ammonia levels. Elevated Cit levels can be considered as a biomarker and, more importantly, can also be a diagnostic marker even in the silent period

(Nagasaka et al., 2009; Treepongkaruna et al., 2012). Affected neonates also have associated hypercholesterolemia and augmented oxidative stress (Nagasaka et al., 2009). FTTDCD is also characterized by elevated Cit levels (Song et al., 2009). In adult-onset CTLN2, elevated plasma Cit and ammonia levels were observed, as shown by case reports (Funabe et al., 2009; Tazawa et al., 2013). Citrin deficiency, a novel cause of failure to thrive (FTTDCD), responds to a high-protein, low-carbohydrate diet. Its other manifestations, such as NICCD or CTLN2, are characterized by higher Cit levels. Thus, estimation of high Cit levels with or without increases in ammonia levels could serve as a biomarker for various manifestations of citrin deficiency.

Citrulline as a Biomarker in Toxicities

Citrulline as a Biomarker of Kainic Acid–Induced Neurotoxicity

It is well established that NO is implicated in various models of neurotoxicity, such as in kainic acid (KA)–induced excitotoxicity in rat brain. Cit has been used as a marker of NO and NOS. A rapid increase in NO occurred 30 min after KA injection, peaked at 2 h, and returned to normal within 24 h (except cortex), manifestations that were well correlated with neuronal damage and death. Vitamin E (an antioxidant) pretreatment prevented the rise in Cit levels and depletion of high-energy phosphates and attenuated the neurodegenerative changes without modifying the seizure activity of KA. This suggests the involvement of NO and peroxynitrite, responsible for mitochondrial dysfunction and neuronal death, for which Cit has been used as a biomarker in KA-induced neurotoxicity (Milatovic et al., 2002; Gupta and Dettbarn, 2003).

Involvement of NO is supported by findings of other studies that evaluated the anticonvulsant effect of 7-nitroindazole, a selective nNOS inhibitor (Gupta and Dettbarn, 2003). These data show that NO is involved in KA-induced neurotoxicity and Cit can be used as a biomarker of NO/NOS.

Citrulline as a Biomarker of Anticholinesterase Poisoning

Organophosphate and carbamate compounds exert their toxicity primarily by virtue of cholinesterase inhibition in the brain and skeletal muscles, commonly referred to as anticholinesterase agents (Gupta, 2006). Cit can serve as a biomarker of anticholinesterase poisoning, where Cit levels correlate well with signs of cholinergic toxicity (Liu et al., 2007). Cit has also been used as a marker of NO/NOS and RNS in assessment of myotoxicity induced by diisopropylphosphorofluoridate (Gupta et al., 2002). Similar findings were also noted with a carbamate compound, carbofuran, which induced skeletal muscle hyperactivity causing RNS and nitrosative stress, where Cit levels were significantly elevated. The increase in RNS was largely prevented by pretreatment with memantine due to prevention of nitrosative stress (Gupta et al., 2002; Milatovic et al., 2005).

Citrulline as a Biomarker of Ammonia Toxicity?

In an experimental study, mice exposed to acute ammonia toxicity showed elevated levels of NO in discrete brain regions, leading to NO-induced toxic effects and corresponding increases in ASS and ASL activities, suggesting effective recycling of Cit to Arg (Swamy et al., 2005). Thus, Cit may serve as a marker of ammonia toxicity.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Cit is a ubiquitous AA in mammals, is strongly related to Arg, and has a scope beyond that normally associated with an AA. Cit has generated tremendous interest and curiosity in the scientific community world due to its plethora of effects. Its role in the urea cycle was realized some time ago. In addition, it has a role in protein homeostasis, and further exploration is opening new horizons for Cit as a supplement as well as biomarker for various diseases and toxicities. To summarize regarding the metabolic pathways in tissues: (1) liver Cit is locally synthesized from OCT and metabolized by ASS to urea; (2) in most tissues, Cit is recycled into Arg and NO via ASS, increasing NO availability; and (3) Cit is synthesized in the gut from glutamine and released into the circulation with 80% being converted back into Arg in the kidneys by ASS made available for utilization by peripheral tissues. Circulating Cit is in fact a masked form of Arg to avoid degradation of Cit in the liver (Cit is readily taken up by liver and degraded). Thus, Cit is actually a better method of getting supplemental Arg into the blood than Arg itself, proving that Cit is a novel therapeutic agent in conditions of Arg and NO deficiencies. Cit supplementation offers an inexpensive, advantageous nutritional therapeutic objective that may prove beneficial in various diseases due to its multiple effects. There may be cardiovascular risk associated with Cit supplementation that needs further evaluation. Research is indicated to prove or disprove whether glutamine supplementation could be used as a precursor for Cit in the future (Lingthart-Melis and Deutz, 2011). Other AAs may also act as a Cit precursor such as glutamate or proline (Cynober, 2002).

Cit supplementation may be (1) highly exploited in therapeutic conditions and situations such as erectile dysfunction, sickle cell anemia, SBS, hyperlipidemia,

cancer chemotherapy, and cardiovascular disease (sustained release preparation), (2) used to increase protein content in malnourished as well as elderly patients, (3) to increase endurance for athletics training, (4) used for the acceleration of wound healing, and (5) used for treatment of AD and MID, as well as many other conditions. Studies support use of Cit supplementation for athletics training due to the capability of oxidative stress reduction after cycling, so Cit may be utilized as an antioxidant in the future. Cit alters the systemic response of mediators and cytokines in sepsis and acts as an immunomodulator. It is also likely to be used as a therapeutic agent (treatment/prevention) in neonates or for childhood conditions such as citrin deficiency, congenital malformations, and IUGR. Moreover, multiple system atrophy is associated with elevated Cit levels, so the role of Cit modulators can be explored in certain brain lesions. Cit has also been tried as an adjunctive therapy in parasitic infections such as toxoplasma, trypanosomiasis, and malaria. Further studies are needed to explore the pleiotropic effects of Cit supplementation in different clinical conditions.

Another area of interest regarding Cit is as an Ab to citrullinated peptides that serve as predictors for diseases, thus serving as biomarkers in various diseases. Protein citrullination (from posttranslational modification of Arg) of certain body proteins produces novel epitopes that give rise to autoantibodies. Their detection provides a novel way to diagnose a variety of diseases and act as a marker for monitoring certain clinical conditions. Until now, Cit has been used on a large scale for diseases such as RA, intestinal pathology, and SBS. In the future, it is likely to emerge as a biomarker for other conditions such as parenteral nutrition in HIV patients, congenital anomalies, acute rejections in transplantations, IUGR, critically ill patients, and acute kidney failure. Its role in toxicities is realized as a biomarker of nitrosative stress (NO/NOS) and RNS in conditions such as anticholinesterase poisoning. In addition, its role as a biomarker is realized in kainic acid−induced neurotoxicity because oxidative stress increases RNS and ROS (when the rate of ATP demand exceeds production), which causes formation of peroxynitrite, a potent inducer of lipid peroxidation and DNA damage.

Much more exploration in this regard is indicated in all aspects mentioned and discussed here and large-scale studies are the need of the hour before Cit is used in therapy with confidence. Similarly, studies are required in the field of its use as a biomarker/predictor of diseases of concern and an effort should be made to determine clear-cut levels in each condition. This is essential in either proving or refuting the role of Cit as a marker and making accurate estimates of sensitivity and specificity. Future studies are indicated in parasitic diseases such as malaria as an adjuvant therapy and as a biomarker for the clinical conditions in question and others such as psoriasis or multiple sclerosis.

Analysis of Toxin- and Toxicant-Induced Biomarker Signatures Using Microarrays

Sadikshya Bhandari, Michael A. Lynes

Molecular and Cell Biology, University of Connecticut, Storrs, CT, United States

BIOMARKERS AND BIOMARKER SIGNATURES IN DISEASE: A VARIETY OF MARKER CLASSES AND POSSIBLE INFERENCES

The National Institutes of Health Biomarkers Definitions Working Group has defined a biomarker as "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention" (Biomarkers Definitions Working, 2001). The assessment of biomarkers can enable the diagnosis of disease, the assessment of disease prognosis, and may facilitate predictions of the response to therapeutic interventions in the disease process. Owing to the variability in baselines of the molecular concentrations of these markers, the wide range of concentrations that may be present in unexposed populations, the variability in both the exposure history of an individual, and the possibility that biomarkers may also be induced by a variety of different xenobiotics, it is often difficult to interpret with certainty the meaning of the appearance of an individual marker. Biomarker signatures are the aggregate of a set of individual biomarkers that together represent a more robust and potentially reliable indicator of exposures and the identity of the toxic agent.

Biomarkers can represent the unique changes in the chemistry of the initially exposed tissue or in tissues where the agent subsequently bioaccumulates. For example, inhaled tobacco smoke is associated with oxidative stress and that process can result in oxidation of deoxyguanosine. One product of DNA oxidation, 8-Oxo-2′-deoxyguanosine (8-Oxo-dG), has been used as a biomarker of other forms of oxidative stress (Pilger and Rudiger, 2006). However, 8-Oxo-dG is rapidly cleared (Hamilton et al., 2001) and has not been found to correlate well with the level of smoking exposures in humans (Azab et al., 2015). As a consequence, downstream biomarkers may be more informative for the characterization of the cellular response to the disease process that arises from xenobiotic exposure.

These downstream biomarkers may include different classes of molecules. Most commonly, a change in protein expression has been used as a hallmark of toxic effects of a xenobiotic or the onset of disease. Malignant and benign melanomas can be differentiated by characterizing the presence of insulin-like growth factor-II messenger RNA-binding protein-3 (IMP-3). The level of IMP-3 is much higher in metastatic melanoma when compared to benign lesions (Pryor et al., 2008). Cytokines, chemokines, and growth factors have been used as an important class of biomarkers in the field of toxicology. One of the biggest challenges in using cytokines as biomarkers is their short half-life in serum as well as a very low basal level expression (Tarrant, 2010). RNAs have been identified as another potential type of biomarkers, specifically plasma microRNAs (miRNAs) and messenger RNAs (mRNAs). Some of the advantages of using RNAs as biomarkers are the tissue-specificity, high level of expression at specific times, and ease of multiplexed assays for RNA measurements (Bartel, 2004).

Biomarkers can include specific changes in gene structure, in epigenetic marks, or to gene activity as indicated by RNA levels. For example, mutation of the fibroblast growth factor receptor gene (FGFR3) is used to predict the severity of urothelial cancer (Chow et al., 2000) and has a potential role as a therapeutic target for that disease process (Knowles, 2007). This kidney disease can result from exposure to agents such as aristolochic acid, melamine, and heavy metals (Chen et al., 2012;

Vervaet et al., 2017), as well as cyclophosphamide, acrolein, and phenacetin.

The immune response is a commonplace target that responds to changes evoked by many classes of xenobiotics. The environmental contaminant mercuric chloride has been shown to affect T cells and predispose to autoimmune phenotypes by shifting from a Th1 to Th2 response (Hemdan et al., 2007). This change to Th2 response includes the shift to production of specific cytokines such as interleukin 4 (IL-4) and IL-10 that can be used as a biomarker for development of autoimmune disease after mercury exposure. However, in the same report, it was found that Th1-polarized responses can be elicited when exposure to mercury occurs in the presence of *Salmonella* antigens. This observation underscores the challenges of interpretation of biomarkers obtained from patients who exist in complex environments that may be populated with multiple xenobiotics, as well as other environmental factors and contemporaneous health issues that can influence the presentation of a biomarker signature.

Rheumatoid arthritis (RAs) is an autoimmune disease associated with inflammation of joints. Meta analysis of a collection of 15 studies identified silica exposure as an important risk factor for RA (Khuder et al., 2002). In addition to the traditional RA biomarkers IL-6, IL-2, and oncostatin M, additional protein markers such as macrophage colony-stimulating factor (M-CSF), TNF receptor superfamily-9, CCL23, transforming growth factor α, and CXCL13 have been shown to identify patients with this disease and were found to be more accurate in defining RA when compared to the traditional set. Additionally, CXCL13 in particular proved to be an important predictor of successful clinical intervention in RA patients (Rioja et al., 2008).

The Predictive Safety Testing Consortium (PSTC) of the Critical Path Institute, US Food and Drug Administration (FDA), along with other federal and international agencies have characterized several biomarkers for detection and quantification of drug-related organ toxicities. For example, albumin, KIM-1 cystatin, β2-macroglobulin, clusterin, and trefoil factor 3 have been evaluated favorably as biomarkers of kidney injury. Markers of drug-induced liver injury include alanine aminotransferase and aspartate aminotransferase, but these markers do not always correlate with the damage observable by histologic evaluation. Other biomarkers such as glutamate dehydrogenase, malate dehydrogenase, paraoxonase/arylesterase 1, purine nucleoside phosphorylase, arginase, sorbitol dehydrogenase, and glutathione S-transferase are under investigation as potential biomarkers for liver injuries. Recent work done to identify more sensitive and specific biomarkers for drug-related skeletal muscle injury has identified skeletal troponins, creatinine kinase protein M, parvalbumin (Pvalb), myosin light chain 3 (Myl3), fatty acid-binding protein 3 (Fabp3), aldolase A (Aldoa), and myoglobin as additional biomarkers (Campion et al., 2013). Similarly, cardiac hormones (natriuretic peptides, NPs) that are synthesized and secreted in response to myofiber stretch are considered to be potential biomarkers for cardiac hypertrophy that can arise from exposure to some drug therapies.

SELECTING SAMPLE SOURCES FOR THE MEASUREMENT OF BIOMARKERS

The most commonly evaluated samples from which biomarkers are measured are blood, serum, saliva, and urine, owing to the minimal invasiveness of sample harvesting techniques. Other sources of samples from which to measure biomarkers include hair (Zhang et al., 2018) and fingernails (Ward et al., 2017), tissue biopsies, interstitial fluid (Samant and Prausnitz, 2018; Zhang et al., 2017), and exhaled breath condensate (Lopez-Sanchez et al., 2017), but these have greater challenges associated with their collection and/or interpretation. In the case of both hair and fingernails, there is some indication that temporal exposure profiles can be interpreted from the spatial location along the length of the hair shaft or fingernail.

Blood samples are one of the most commonly used sources for biomarker as it represents a source of the patient's genetic information (from circulating nucleated leukocytes) as well as physiologically relevant hormones and other regulatory molecules. Moreover, circulating blood passes through all tissues and thus can sample areas where a toxicant may naturally accumulate while being relatively inaccessible to direct sampling. Because collection and processing of blood samples typically requires trained professionals, it is not always cost-effective in large-scale studies. Saliva has proven to be another source of sample material that is readily accessible and contains proteins, lipids, peptides, and other small molecules, as well as sloughed cells and transient cell populations (Molony et al., 2012). Harvests of saliva samples are noninvasive and relatively inexpensive to collect, but the microbial community present in these samples, the nucleases, proteases, and other catabolic enzymes present in this fluid can produce changes in the composition of the sample as it is being collected and processed. Nevertheless, changes in salivary proteins have been shown to be associated with oral cancers as well as other systemic diseases. Higher levels of IgA and amylase are seen in saliva samples from diabetic patients (Aydin, 2007). Posttranslational modifications to proteins have also been identified as a useful class of biomarkers. For example, biomarkers in

cystic fibrosis include a change in the glycosylation pattern of salivary mucin (Shori et al., 2001).

INDIVIDUAL BIOMARKERS AND AGGREGATED BIOMARKER SIGNATURES

Over the past few decades, extensive efforts have led to the identification of a host of biomarkers for different cancers as well as other disease conditions. However, the number of individual biomarkers approved by FDA to refine diagnoses and evaluate treatment efficacy remains small (Fuzery et al., 2013). One of the major reasons behind the failure to transition from biomarker identification to their use in diagnosis and treatment is the inability of biomarkers to go beyond differentiating patients from healthy individuals.

It is possible that biomarker signatures, which evaluate a larger set of molecular and cellular entities, will provide enhanced clinical information (Hanash et al., 2008). For example, detection of prostate cancer that is done by analyzing a set of genetic tumor markers in combination with evaluation of a set of plasma protein markers has proven to be more effective than measurements of prostate surface antigen levels alone (Gronberg et al., 2015). In breast cancer studies, a 21-gene signature was able to identify low-risk patients who had a good outcome even without adjuvant chemotherapy (Sparano et al., 2015). A study done by Pierce et al. identified systemic C-reactive protein and serum amyloid A, circulating markers of inflammation, as potential biomarker signatures to predict long-term survival of breast cancer patients (Pierce et al., 2009). A biomarker signature that includes the detection of multiple chromosomal rearrangements in cell-free circulating tumor DNA was found to be about 93% accurate for postsurgical discrimination of patients who would go on to develop metastatic disease (Olsson et al., 2015). A large study done to distinguish between pancreatic cancer and chronic pancreatitis was based on a metabolic biomarker signature panel with a much higher diagnostic accuracy than that of an individual biomarker (Mayerle et al., 2018). More accurate diagnosis of pancreatic cancer at an early stage can lead to increased patient survival rates of 30 to 40 percent, underscoring the importance of these signatures in health care (Mayerle et al., 2018). In the case of inflammatory bowel disease (IBD), several individual biomarkers have been identified as potential diagnostic tools without much success in the clinical setting. As a consequence, there have been attempts to identify biomarker signatures in the array of circulating proteins and from miRNA profiles isolated from colonic tissues to diagnose and differentiate between the different types and stages of IBD (Wu et al., 2008).

Biomarker signatures may provide information regarding the effectiveness and side effects of treatment at the point of toxicant exposure, or during the subsequent disease process that results from exposure. They may also enable physicians to minimize the use of harsh treatments that have severe side effects in specific individuals. Moreover, it may be possible to identify patient populations most responsive to therapeutic intervention. For example, a plasma inflammatory biomarker signature consisting of CXCL9, CXCL10, sIL-2R, and sCD14 has been identified as a possible marker to understand the effect of combination antiretroviral therapy (cART) for HIV patients (Kamat et al., 2012). In another example, RA patients are heterogeneous in the cytokine expression profile that they present with different individuals showing dramatic differences in the expression of TNF-α. Those RA patients that express little or no TNF-α are likely to be poor responders to treatment with TNF-α antagonists. Similarly, IBD patients can become refractive to treatment with TNF-α antagonists. Hence, ongoing monitoring of the expression profile of inflammatory cytokines may indicate when those changes are occurring and can be useful in selecting other potential biologics with which to treat the ongoing inflammation.

APPROACHES TO BIOMARKER SIGNATURE CHARACTERIZATION

Protocols for the detection and analysis of individual biomarkers are selected on the basis of size, molecular characteristics, and concentration of the biomarker, the influence the sample matrix will have on these measurements, and the specificity and sensitivity necessary to make meaningful measurements. There are advantages and disadvantages to the most commonly used assay systems which include factors such as cost, the requirements for skilled technicians, and an established record of reproducibility. These challenges are compounded for the analysis of biomarker signatures where combinations of different marker classes may multiply the assay requirements for both sample preparations and for successful measurement. The following sections describe some of the most common approaches to these biomarker signature measurements.

MULTIPLEXED HIGH CONTENT SOLID PHASE IMMUNOASSAYS

There are two major formats of multiplexed immunoassays: those done in a planar configuration on a sensor surface and those done in suspension. Planar formats

employ capture ligands that have been immobilized on a solid surface such as a microplate. The enzyme-linked immunosorbent assay (ELISA) is one of the most frequently used immunoassays that enable qualitative as well as quantitative measurements of analytes from a heterogeneous sample mixture. In the most common assay design, ELISAs use a "sandwich" format that is organized as sequential additions of the immobilized capture antibody, analyte, and matched pair antibody—enzyme conjugate, followed by the addition of a chromogenic enzyme substrate. These assays are typically done in 96 well microplates but can be adapted to smaller well formats to economize on reagent use. These standard assays typically measure a single analyte in each well. Multiplexed ELISAs use a similar "sandwich" format but employ chemiluminescent or fluorescently labeled antibodies in the detection phase and can report on multiple analytes in each microplate well. These optical assays can be limited by spectral overlap of the tags used to label each detection antibody, but some multiplex ELISA formats evaluate analytes with capture antibodies that have been immobilized on a glass slide or membrane (e.g., Quantibody Cytokine Arrays) and are reported to be capable of quantifying 400 to 1000 analytes in a single sample volume.

There are other solid phase enzyme immunoassay formats that are also capable of multiplexed analysis. For example, Meso Scale Discovery (MSD) has developed a multiplex immunoassay platform that enables detection of biomarkers such as cytokines and intracellular signaling proteins in a biological sample. MSD assays incorporate electrochemiluminescent labels (SULFO-TAGs) conjugated to detection antibodies, which generate light when stimulated under the appropriate chemical conditions. The use of SULFO-TAG labeling increases the sensitivity and dynamic range as well as reduces the background signal compared to traditional immunoassay techniques like ELISA. In this format, up to 10 analytes can be interrogated in each microwell, and the sensitivity is reportedly two to three logs better than traditional ELISA analysis. The MSD assay has been used to assess proinflammatory cytokines in serum from HIV-infected and noninfected donors in comparison to cytometric microbead assays of the same samples (Dabitao et al., 2011). Studies have suggested that MSD technology's sensitivity in human cytokine profiling is similar to that of microbead assays described in the following section (Chowdhury et al., 2009). These cytometric bead assays represent a suspension immunoassay format that has become commonly used, for example, in the clinical measurement of circulating cytokine levels.

In the suspension format, capture ligands are immobilized on microbeads and are mixed with analytes in liquid samples. This microbead technology can analyze up to 500 analytes per sample. Each individual bead's population is initially labeled internally with a specific fluorescent dye at a unique concentration to create a distinct bead fluorescent profile that is used to identify the specific capture antibody that is subsequently immobilized on the bead surface. Other capture reagents such as aptamers, antigens, oligonucleotides, and receptors that have binding specificity for an individual analyte can be used in place of the immobilized antibody. A mixture of different beads representing different analyte specificities can then be incubated with a biological sample, and individual analytes present in the sample will be captured by the cognate beads in the mixture (Houser, 2012). Subsequent quantification of the analyte concentration is done by incubating the beads with a cocktail of matched-pair fluorescent antibodies with a fluorescent emission profile distinct from the internal fluor profile that will bind to a second epitope on each analyte. Once evaluated by flow cytometry, each individual bead identity is established by the level of internal fluorescence, and the amount of each analyte captured on that bead is determined by the amount of the matched-pair fluorescent antibody that is bound to the captured analyte on that particular bead. This technology is customizable, reproducible, and can be more accurate, sensitive, and economical with sample volume consumption when compared to traditional immunoassays such as ELISA. The most commonly used platforms for this bead-based analysis are the Luminex, Milliplex, and Bio-Rad Bio-Plex analyzer systems.

FLOW CYTOMETRY AND FLUORESCENCE-ACTIVATED CELL SORTING

In addition to its use in microbead analysis, flow cytometry is also used for single cell phenotypic analysis and is most often used to measure biomarkers in the context of intact cells. The level of specific surface markers can, for example, be measured with antibodies or recombinant major histocompatibility complex tetramer/peptide complexes that have been labeled with a specific fluorophore. Internal cytosolic and nuclear antigens can also be detected after fixation and permeabilization of the cell's plasma membrane. As cells bound by the detection reagents pass through the illuminating laser, fluorescent emission characteristics of the fluorophore(s) are detected and quantified. This technique has been used to study biomarkers such as cytokines (Pala et al., 2000) and stress response proteins (Wieten et al., 2009), as well as immunophenotyping of T-cell markers for autoimmune disease (Danke et al., 2005) and vaccine efficacy (He et al., 2008). One of the biggest limitations of flow cytometry in the

measurement of multiple cellular characteristics is that the number of labels used to measure analytes associated with each cell is limited by the spectral overlap of available fluorophores that can limit their optical separation and individual quantification. Multicolor flow cytometry can evaluate as many as 18 fluorescent colors on and in cells passing through the illuminating excitation laser light at rates of 10,000 cells per second. A variant of this technology, mass cytometry, substitutes mass spectroscopy for the fluorescent detection system of a flow cytometer (Bendall et al., 2012; Leipold et al., 2015). In this system, the antibodies used to detect the target cellular analytes are coupled to heavy metal ions that can be readily distinguished from each other as the ions are analyzed in the mass spectrometer. Because the spectrometer can differentiate about three dozen heavy metal ions without spectral overlap, a greater ability to resolve unique cell populations according to their marker profile is possible by mass cytometry than by flow cytometry, but mass cytometry throughput is typically much slower than fluorescence-based cytometry.

Fluorescence-activated cell sorting (FACS) is a variant of flow cytometry that can be used to characterize and subsequently purify an individual subset of cells from a heterogeneous mixture. The cells of interest are identified based on the expressed surface or intracellular molecules that are detected by fluorescently labeled antibodies. Cells with particular characteristics can then be physically separated from the rest of the population. FACS can be used to both characterize the cells that are present in toxin- or toxicant-exposed individuals and subsequently isolate specific subpopulations for additional molecular analysis independent of other cells in the sample that otherwise might serve to dilute the biomarker signals that are associated with exposure.

IMMUNOHISTOCHEMISTRY AND TISSUE MICROARRAYS

Immunohistochemistry (IHC) utilizes antibodies to detect specific antigens on the surface of tissue sections. The tissue sections are processed using a microtome and can be then subsequently probed for different antigens using antibodies which are linked to fluorescent labels or to enzyme, radionuclide, or electron-dense labels for visualization.

The tissue microarray (TMA) is a histologic technique that combines tissue samples from different sources in an assembled array that enables simultaneous analysis of each tissue within the array (Camp et al., 2008). TMAs are made by embedding each tissue, and then producing small diameter cores of each tissue (the cores are as small as 0.6 mm diameter). Each of these cores is then embedded as a spatially encoded array and sectioned to produce slides that represent all of the multiple sections. These TMAs can be processed by IHC or in situ hybridization to study protein markers as well as DNA and RNA expression to determine analyte presence in each tissue section under the same experimental conditions. This technology has been used extensively in clinical studies to compare different types of tumors. The microarray can be used to study different stages of tumors or samples from multiple individuals in a single analysis. It can also be used to screen for novel markers from large groups of tumors (Schoenberg Fejzo and Slamon, 2001). Candidate biomarkers for pancreatic cancer have been identified using TMA (Winter et al., 2012), and TMA approaches were used to explore the association between estrogen and progesterone receptor expression (Hussein et al., 2008) and to create digitized images of kidney and liver from toxicological studies done on rats exposed to different drug candidates (Ryan et al., 2011).

MASS SPECTROMETRY ANALYSIS

In addition to its use in mass cytometry, mass spectrometry (MS) can be used as an analytical technique that generates multiple ions from sample analytes and separates them based on their intrinsic mass to charge ratio (m/z). MS is one of the most commonly used methods to detect, identify, and quantify a relative abundance of molecules within a complex biological sample mixture. Mass spectrometers all have three basic components: ion source, mass analyzer, and ion detector. However, there are differences in the nature of these components that gives rise to different type of mass spectrometers. The use of MS spans several fields such as proteomics, lipidomics, metabolomics, genomics, drug discovery, and structure validation.

MS is one of the most commonly used technologies for toxoproteomics. MS enables accurate measurement and identification of sample composition with sensitivity in the femtomolar (10^{-15}) to attomolar (10^{-18}) range (Mann and Kelleher, 2008). MS has been used to detect toxins from *Clostridium* and *Bacillus* species, for example. Although the most commonly used method to test for *Botulinum* toxins is the mouse lethality bioassay (Dressler et al., 2000), this assay takes several days and can only detect active toxins. MS enables rapid and more sensitive detection of not only the active toxin but also several different components of *Botulinum* neurotoxins (BoNTs) and has been used in clinical settings (Barr et al., 2005; Scarlatos et al., 2008). Additionally, MS-based analytics have been used to identify the enzymatic and biological activities of BoNT and anthrax lethal toxins produced by *Bacillus anthracis* (Kalb et al., 2015). Similarly,

MS techniques such as liquid chromatography—mass spectrometry (LC-MS) and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF) have been used to enhance the detection sensitivity for the plant toxin ricin that is produced by the castor bean plant, *Ricinus communis* (Darby et al., 2001).

MS can detect small molecule analytes such as the uremic toxins indoxyl sulfate and p-cresol sulfate that are involved in some forms of kidney disease (Niwa, 2009). A study done by Williamson et al. utilized MS to perform a comparative study of pertussis toxin (Ptx) and chemically modified toxoid (Ptxd) from licensed vaccines at the peptide sequence level, which could be used to determine how they differentially influence an immune response (Williamson et al., 2010). MS-based analysis has also been used to differentiate between Shiga and Shiga-like toxins that can be present at very low levels in human serum (Silva et al., 2015).

GRATING-COUPLED SURFACE PLASMON RESONANCE MICROARRAY ANALYSIS

Surface plasmons are electron density oscillations that are produced at a metal—dielectric interface (Homola et al., 1999). The generation of these plasmons in the metal (which is typically a thin film of gold) requires the interaction of illuminating light that excites the plasmon generation at the metal surface. To generate these plasmons, the illuminating light must meet three specific requirements (phase velocity, wavelength, and angle of incidence) to be in resonance with the metal electrons. In the most common configuration of an SPR instrument, the phase velocity and wavelength of the illuminating light are fixed at conditions which meet plasmon generation requirements, and the angle of incidence of the illuminating light is varied. Under those conditions, when the angle of the illuminating light does not meet resonance requirements, there is a high degree of reflected light. When in resonance, energy is passed into the metal to create the plasmon, and the reflected light diminishes. Typically, illuminating light is swept through a small series of angles that surround the critical angle at which resonance is maximal, and a U-shaped curve (an SPR curve) of reflected light intensity is produced. The plasmon is influenced by the refractive index very near the metal surface and the SPR phenomenon can be used to measure binding events caused by a molecular interactions that occur at the metal surface that increase the local refractive index (and hence the angle at which plasmon generation occurs). If the rate of change in the SPR curve is measured over time as binding and dissociation events are happening at the sensor chip surface, affinity constants can be calculated from the data produced.

Comparison of preanalyte and postanalyte resonance angles can be used to measure the amount of antigen capture. Typically, the phase velocity of the incident light is matched to the plasmon's requirements using a prism (i.e., a prism-coupled system). This limits the number of simultaneous analyses to the number of prisms and is typically small. In a different embodiment (called grating-coupled surface plasmon resonance, GCSPR), a holographic diffraction grating can be used to establish the required phase velocity, and as a consequence, the metal surface can be imaged and the image computationally divided into separate regions of interest (ROIs) where each SPR curve can be measured independently. If unique capture reagents are immobilized at different ROIs, the change in SPR can be used to indicate increases in refractive index after exposure of the sensor chip surface to the cognate analytes. Using this system, it is possible to measure both molecular and cellular analytes in the same microarray format, and the system is capable of several thousand assays on a single sensor chip (Jin et al., 2006; Unfricht et al., 2005). In a variation of this grating-coupled configuration, the captured analyte can be subsequently interrogated with a fluorescent-matched pair antibody, in a grating-coupled surface plasmon coupled emission (GCSPCE) assay system (Marusov et al., 2012; Molony et al., 2012; Reilly Sr. et al., 2006; Rice et al., 2012; Yuk et al., 2013). This version of the system retains the microarray characteristics, while increasing the limits of detection by almost two logs (to femtogram/ml levels) compared with standard fluorescent microarray immunoassays. Fig. 61.1 is an example of this GCSPCE analysis.

From the data, it is clear that while both patients were diagnosed with RA, the spectrum of cytokines present in each of their sera is substantially different. TNF-α levels, in particular, are different, suggesting that only patient 1 would be responsive to a therapeutic TNF-α antagonist. The technology is also capable of enumerating the capture of whole cells on the sensor chip surface as an indicator of population composition and can assess the functional phenotype (e.g., changes in surface antigen expression or secretion of proteins from the captured cells) over time in this microarray format.

Fig. 61.2 shows the sequence of steps to do functional phenotyping of protein secretion by analysis of immobilized cells in a microarray format. Fig. 61.3 is an example of data from a single set of ROIs in this microarray format. In this example, Jurkat T cells that had been stimulated with the T-cell mitogen phytohemagglutinin (PHA) in bulk culture were subsequently captured on the GCSPCE sensor chip using an immobilized anti-CD3. In some of these ROIs, there was an additional
FIGURE 61.1 GCSPCE microarray analysis of rheumatoid arthritis (RA) patient and control sera. In this study, serum from two patients who meet the RA diagnostic criteria and one control were evaluated for the presence of 17 biomarkers by GCSPEF microarray. Bars indicate average fluorescent intensity values from five regions of interest on the sensor chip surface for each patient sample. Data provided by Dr. James M. Rice, personal communication.
FIGURE 61.2 Capture of viable cells on a GCSPCE microarray and subsequent functional phenotyping. In this graphic representation, a single ROI from an array is shown in expanded detail. In the initial step, the ROI is populated with antibodies specific for a surface marker on the target cell population. After nonspecific binding is blocked, the ROIs in the array are incubated with target cells and are captured on these ROIs. Subsequent culture on the array (in the presence of agonists or antagonists of protein secretion) will produce secreted proteins (e.g., IL-2 cytokine shown in the figure) which will be captured by anti-cytokine antibodies that also populate the same ROI. This capture can subsequently be detected with a matched-pair anti-cytokine antibody that has been labeled with the appropriate fluor (FL).
FIGURE 61.3 Jurkat T cells were prestimulated in culture for 3 h with 10 μg/mL phytohemagglutinin in complete RPMI 1640 at 37°C, 5% CO_2. After stimulation, cells were washed and resuspended in the stimulation media and flowed over the DSP-modified chip printed with capture antibody for 30 min. Unbound cells were washed off and the chip incubated overnight at 37°C, 5% CO_2. Cell capture was determined by SPR and IL-2 secretion was detected with biotinylated anti-IL2 antibody + streptavidin-Alexa fluor 647. One way ANOVA analysis, ****$P < .0001$, ***$P = .0003$.

immobilized anti-IL-2 antibody at one of two different concentrations. Once the cells were captured on the ROIs, they were incubated overnight before biotinylated matched pair anti-IL-2 was passed over the sensor chip followed by streptavidin-alexa fluor. Other ROIs (populated with no capture antibody or with whole mouse IgG) were used as negative controls to determine baseline values.

The data show that these conditions can evaluate cytokine secretion in a system that is versatile and high content capable. By simply employing different fluorescently tagged antibodies, it is also possible to interrogate the functional phenotype of captured cells by evaluating the presence of surface antigens on the cells and the shifts in the expression of those antigens over time as a different indicator of cellular differentiation. Finally, by exposing spatially encoded ROIs of captured cells in the microarray to a diffusing gradient of a toxin, toxicant or pharmaceutical, the different functional phenotype that can characterize cells that experience different exposure profiles according to their spatial location in the gradient will be indicative of how cells may respond to the xenobiotic. Fig. 61.4 is illustrative of this approach, where in a single biosensor chip the individual exposure conditions of multiple individual cell cultures each exposed to a single dose can be rapidly and efficiently modeled. Because a large number of ROIs are available, different kinds of cells captured from a heterogeneous cell suspension (e.g., different leukocytes from a patient's whole blood) at adjacent ROIs can be characterized simultaneously.
FIGURE 61.4 Jurkat T cells captured at spatially encoded ROIs were subsequently exposed to a diffusing gradient of cadmium chloride. Using GCSPCE, there was evidence of increased IL-2 expression by the immobilized cells at a midpoint in the diffusing gradient.

BIOMARKER SIGNATURES IN THE -OMICS ERA

Genomic and Transcriptomic Analyses

The accessibility of genomic sequences as a result of the human genome project has made whole genome data a commonly used approach to analyze complex phenotypes including those that arise from toxin and toxicant exposure. Additionally, genome-wide association studies (GWASs) have provided important information to identify genetic markers that can be used to predict the presence of the disease or the susceptibility to toxic effects of xenobiotic exposure. The use of genomics to identify and characterize biomarkers will enable better opportunities for prognosis, diagnosis, and therapeutic development. DNA microarrays, serial analysis of gene expression, and high-throughput sequencing are some of the most commonly used genomic high content multiplexed assays. DNA microarray analysis of gene expression profiles that are altered by chemicals provides a very effective way to identify biomarkers that can be used for toxicological studies. For example, the toxicity of low dose acetaminophen and subchronic exposures to three halogenated aromatic hydrocarbons was identified using microarray gene expression profiling (Heinloth et al., 2004; Kulkarni et al., 2008). This approach allowed for early detection of toxicity before appearance of a visible phenotype. In some cases, the study of genomics provides reproducible and homogenous data compared to histopathological readings (Heinloth et al., 2007). Studies done by Le Fevre et al. (2007) and Nie et al. (2006) identified marker genes for genotoxic and nongenotoxic carcinogens, which can be used as predictive models for toxicity studies. The two largest databases for toxicogenomics analyses are ArrayExpress and the Gene Expression Omnibus (GEOs).

Transcriptomics was first developed in the late 1990s using Sanger sequencing of concatenated random transcript fragments (Velculescu et al., 1995). The first human transcriptome was published in 1991 for the mRNA sequences of the human brain (Adams et al., 1991). In the past decade, two human transcriptomes consisting of over 16,000 genes have been published (Pan et al., 2008; Sultan et al., 2008). There are now transcriptomes of individuals with specific diseases, of single cells, and of tissues (Kolodziejczyk et al., 2015; Lappalainen et al., 2013; Mele et al., 2015; Sandberg, 2014).

The use of transcriptomics has played a very important role in the clinical field for disease diagnosis and subsequent treatment strategies. Disease association studies have identified regulatory elements as well as

novel splice variants, which are associated with specific disease conditions and disease-associated single-nucleotide polymorphismss (Costa et al., 2013; Khurana et al., 2016). Similarly, RNA-Seq has enabled the transcriptional profiling of T cells and B cells from patients that can be used to study immune-related diseases (Proserpio and Mahata, 2016).

Several genomic studies have identified specific genes that are implicated in the cellular response to toxicant exposure. For example, microarray analysis was used to identify genes that were implicated in the hepatotoxic response to 15 different chemicals (Hamadeh et al., 2002). Transcriptomic data from cardiac biopsies has been used to identify biomarkers associated with cardiomyopathy and myocarditis. miRNA profiling has also been used as a biomarker signature for cardiovascular diseases such as myocardial infarction and hypertension (Li et al., 2009).

Proteomics

Proteomics, "the high-throughput separation, display, and identification of proteins" (Anderson and Anderson, 1998), is one of the most powerful and commonly used tools to study a biological system, as proteins are considered to be the end points of a biological process. Analysis of the proteome uses the many technologies already discussed. Some of the most commonly used tools for proteomic studies for the high-throughput studies are MS techniques such as SELDI (surface-enhanced laser desorption ionization), MALDI (matrix-assisted laser desorption ionization), and antibody microarrays. Numerous posttranslational modifications such as phosphorylation, methylation, glycosylation, S-nitrosylation, and N-acetylation add an additional level of complexity to proteomic analysis.

Proteomic biomarkers that have been used for clinical studies include proteins belonging to classes such as G protein-coupled receptors, enzymes, and components of cellular signaling pathways (Overington et al., 2006). The use of proteomics allows identification of a set of proteins that are associated with a disease or toxicological effect that can be used as potential biomarkers for subsequent studies. For example, a large-scale proteomic screening identified several S100 proteins that were overexpressed in breast cancer tissues, and which can be used as potential biomarkers for cancer progression (Hudler et al., 2014). Proteomics studies have been carried out to create prototype databases to study the effects of toxicological compounds on organs such as the liver (Anderson et al., 1996), kidney (Kennedy, 2001), as well as potential carcinogens in several cases of cancers. Proteomic analysis has also been used to identify biomarkers of acute nephrotoxicity induced by

puromycin aminonucleoside and after exposure to benzene (Cutler et al., 1999; Joo et al., 2003).

Metabolomics

Metabolomics refers to the identification and quantification of small metabolites in a biological system. This branch of "omics" is considered to most closely represent the physiological state of an organism, as metabolites are the direct representation of underlying mechanisms (Gieger et al., 2008). The most commonly used techniques to analyze metabolites on a large scale are nuclear magnetic resonance (NMR) spectroscopy; gas chromatography mass spectrometry (GC-MS); and liquid chromatography MS (LC-MSs). Recent work done by Wishart et al. (2013) estimated over 19,000 metabolites that constitute the human metabolome.

The use of metabolomics in diseases and cancer provides a unique opportunity to identify both gene-derived endogenous biomarkers and environmentally associated exogenous metabolites (Wishart, 2016). Metabolites have been identified as possible biomarkers in diseases such as type 2 diabetes (Wang et al., 2011), pancreatic cancer (Mayers et al., 2014), and memory impairment (Mapstone et al., 2014). Similarly, metabolomic studies have shown that intestinal microbiota metabolism of L-carnitine (a component of red meat) is associated with increased risk of atherosclerosis (Koeth et al., 2013). Precision medicine is a developing area where metabolomics is being extensively used to refine the therapeutic treatments designed for individual patients with cancer (Wishart, 2016). Several studies have investigated the effect of cocaine on the neuronal metabolome of rats (Kaplan et al., 2013; Li et al., 2012).

Lipidomics

Lipidomics is the study of pathways and networks of cellular lipids and their interactions with other molecules within the biological system. The field of lipidomics has been rapidly growing since the early 2000s and this growth is mostly attributed to the development of analytical techniques such as MS and ultra-performance liquid chromatography. Lipidomics has been used to identify potential biomarkers for cardiovascular diseases and inflammatory diseases, as well as neurological disorders such as Alzheimer's and Huntington disease. Similarly, panels of lipids have also been implicated in different cases of breast, prostate, and lung cancers (Yang et al., 2016). For example, a correlation was seen between elevated levels of sphingomyelin and different cases of breast cancer (Nagahashi et al., 2016). Additionally, palmitic amide, oleamide, hexadecanoic acid, octadecanoic

acid, eicosatrienoic acid, myristic acid, and LPC were identified as biomarkers for colorectal cancer and have been used for early diagnosis (Zhao et al., 2014). In the field of toxicology and drug discovery, lipidomic profiling has been used to investigate drug toxicity markers and to do risk assessment characterization. Lipidomic analysis has identified liver damage caused by Ximelagatran, an oral thrombin inhibitor (Sergent et al., 2009). There have been lipidomic profile changes associated with co-exposure to subtoxic doses of benzo [*a*]pyrene and cadmium (Jungnickel et al., 2014).

Genotype—Phenotype Associations

Phenotypes that are observable characteristics above the molecular level are used as the primary identifier of human diseases. Databases such as a Human Phenotype Ontology provide an avenue for annotating and analyzing the phenotypes associated with specific diseases (Robinson et al., 2008). GWASs have discovered over 8900 genetic variants associated with hundreds of human traits and diseases (Hindorff et al., 2009). The efficient cross-referencing of genotypic variants with different phenotypes can open new avenues for understanding biological processes as well as disease conditions. The genotype—phenotype associations enable a comprehensive study of genetic variation, its consequences, and the mechanism of action (Brookes and Robinson, 2015). There are several databases such as PhenoScanner, PhenomicDB, dbGap, and PheGenI that enable efficient cross-referencing of genotype—phenotype associations. These databases enable user-specified comparison and association of phenotypes with the existing GWAS catalogues such as NHGRI-EBI GWAS catalog and data repositories such as dbGaP along with existing genomic resources from the National Center for Biotechnology Information (NCBI). Additionally, PHenotypic Interpretation of Variants in Exomes (PHIVEs) is an algorithm that allows cross species in-depth comparison of human disease phenotypes with genetically modified mouse models (Robinson et al., 2014).

Data Analysis Considerations

High content analysis is capable of producing enormous datasets. It is very important to employ statistical tests that are compatible with high content data. For example, where there are large numbers of markers that are being evaluated in a biomarker signature analysis, there is a higher chance of random correlation between parameters. These correlations need to be adjusted for using statistical methods by using techniques such as "leave-one-out cross-validation". While analyzing multiple biomarkers, independently

calculated P values cannot be used to define the biomarker combination analytical accuracy, as there may be synergistic effects. One method to get the most accurate assessment from multiple biomarkers is by identifying the biomarkers that have the maximum impact and by eliminating the least effective ones by methods such as "Kullback—Leibler divergence" (Borrebaeck, 2017). The Fisher Z test, which is a commonly used statistical method for multiparameter analysis, is another approach to biomarker signature studies. Another way to perform data analysis of biomarker signature datasets is the specific constraint-based local causal discovery algorithm proposed by Lagani et al. (2013). This algorithm incorporates Conditional Independence Tests (CITs) for continuous and multiple categories, thus known as the Multi-Class Conditional Independence Test (MC-CIT). MC-CIT is based on multiple multinomial logistic regressions, which are Generalized Linear Models (GLM) designed for multi-class outcomes. This method has been shown to have better predictive capability for biomarker signatures than the Fisher Z test.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The complexity of the biological system is reflected in the wide array of markers that can be used to infer the consequences of toxin or toxicant exposures. There are a number of different existing and developing technologies that can interrogate biological systems for the composition of individual classes of molecular markers of these exposures and the diseases that result from exposure, and new technologies on the horizon that will enable real-time assessment of multiple classes of markers simultaneously. The data that arise from these experiments will have invaluable benefit for the identification of specific instances of intoxication, for identification of the toxin or toxicant identity, and for our understanding of the molecular mechanisms that attend these exposures. The interpretation of these datasets will require continuing advances in the fields of information management and interpretation, as well as ongoing refinement of the technologies used to detect individual classes of signatures. The opportunities that arise from this work are compelling.

Biomarkers Detection for Toxicity Testing Using Metabolomics

David J. Borts

Department of Veterinary Diagnostic and Production Animal Medicine, College of Veterinary Medicine,
Iowa State University, Ames, IA, United States

INTRODUCTION TO METABOLOMICS

Metabolomics has been defined as the comprehensive and quantitative analysis of all metabolites of a biological system under study (Fiehn, 2001). Metabolomics emerged as a distinct science around the year 2000 and has grown rapidly up until today. While other similar terminologies, including "metabonomics" (Nicholson et al., 1999) and "metabolic profiling," have been used, metabolomics is now the most commonly used term (Robertson et al., 2011).

A typical metabolomics experiment involves measurement, using one or more analytical techniques, of a large number of small molecule metabolites in an extract from a biological fluid or tissue. Biological samples from a number of organisms in each of two or more groups are usually analyzed as part of a study. These groups commonly include at least one group of organisms that has a disease, has been exposed to a drug or toxin, or has been subjected to some other type of stimulus. A control group consisting of healthy organisms or those that have not been exposed to the drug, toxin, or other stimulus is also included. Once the raw analytical data are collected, differential analysis is performed using a variety of statistical and computational methods. The results of these differential analyses reveal metabolites whose concentrations are statistically significantly different between the groups of organisms in the study. These results can be interpreted and applied in a number of different ways, including elucidation of gene function, understanding of underlying mechanisms of disease, and monitoring therapeutic outcomes, among many others. These results can also lead to identification of biomarkers, which can be applied in a variety of ways, such as the diagnosis of disease, prediction of disease susceptibility, and in personalized medicine. Biomarkers identified using metabolomics approaches have also been widely applied in toxicology, including in preclinical and clinical drug development, in ecotoxicology, and to help understand pathways or signatures of toxicity, which can be correlated with specific modes of action (MOA). Several excellent general metabolomics reviews have appeared recently (Beger et al., 2016; Courant et al., 2014; Engskog et al., 2016; Goldansaz et al., 2017; Johnson et al., 2016; Patti et al., 2012; Wang et al., 2015; Wishart, 2016).

METABOLOMICS EXPERIMENTAL OVERVIEW

A typical metabolomics experimental workflow for identification of biomarkers involves the following steps: (1) study design and planning, (2) sample collection and quenching, (3) sample preparation, (4) instrumental analysis, (5) raw data processing, (6) statistical analysis of processed data, (7) identification of putative biomarkers, and (8) biomarker validation. Each of the steps in this workflow will be briefly reviewed.

Study Design and Planning

Study design is a crucial, and frequently overlooked or undervalued, part of a successful metabolomics study. There are myriad considerations necessary when designing metabolomics studies. A partial list of metabolomics study design considerations includes selection of study objective (hypothesis generating, hypothesis testing, biomarker identification, MOA

identification, etc.); subject selection; sample matrix or matrices selection; sample size/statistical power determination; number and timing of biological and/or analytical replicates; identification of appropriate matched control subjects and samples; randomization of sample collection, processing, and analysis; selection of all glass and plastic ware that will contact samples; choice of anticoagulant for blood samples; sample volume requirement; sample collection, quenching, handling, storage, and preparation protocols; selection of quality control samples; selection of analytical technology platform; selection of specific analytical instrumentation within a platform type; and selection of data processing tools and approaches, among many other necessary study design considerations (Dunn et al., 2012a,b; Hernandes et al., 2017).

Sample Collection and Quenching

A wide variety of sample types including biofluids (plasma, serum, urine, amniotic fluid, saliva, cerebrospinal fluid [CSF], etc.), tissues (brain, cardiac, liver, kidney, etc.), and cells (cultured mammalian, fungal, bacterial, etc.) have been used in metabolomics studies. Virtually any type of biological fluid or tissue can be amenable to metabolomics analysis.

Sample collection and quenching are critically important and frequently overlooked steps in a metabolomics study. There are a large number and variety of sample collection and preparation protocols for metabolomics studies of these various sample types (Bando et al., 2010; Chetwynd et al., 2017; Dudzik et al., 2018; Raterink et al., 2014; Vuckovic, 2012). Although these protocols can be quite different depending on sample type, they also have some common elements. One key element is the concept of quenching, defined as steps taken to ensure the cessation of enzymatic activity and metabolite turnover. If enzymatic activity is not stopped very quickly after sampling, continued metabolic turnover will lead to "metabolic pooling." Metabolic pooling will result in a "blurred," if not completely uninterpretable, picture of the system's metabolic state. The main techniques used to ensure enzymatic quenching are low temperature, adjustment of pH, or organic solvents. For example, a common protocol for quenching a blood sample involves rapidly spinning the blood to plasma in a refrigerated centrifuge, immediately freezing small (0.5–1.0 mL) aliquots of the plasma in liquid nitrogen, and quickly transferring the frozen plasma samples to a −80°C freezer for storage.

Examples of other important considerations for sample collection include collection time, anticoagulant selection for blood plasma, and appropriate steps to avoid possible bacterial contamination of samples. Sample collection time should take into account factors such as diurnal variation, fasting time, and time relative to administration of dietary supplements or pharmaceuticals. Common plasma anticoagulants include heparin, EDTA, and citrate. While there is some disagreement as to whether heparin or EDTA is most appropriate for metabolomics studies, citrate is inappropriate because it is also an endogenous metabolite. Bacterial contamination can negatively affect metabolomics results, as bacteria may metabolize and turn over metabolites that are endogenous to the study organism.

Sample Preparation

Sample preparation is another key step in metabolomics protocols and is typically very specific to a particular sample matrix. Sample preparation for urine is frequently a very simple "dilute and shoot" protocol. Sample preparation for plasma or serum typically involves protein precipitation using organic solvent. Sample preparation procedures for tissue samples and cultured cells tend to be more complex and specific for the particular tissue or cell type in question. At this point, sample preparation protocols for metabolomics are not standardized and an array of procedures is in use (Bando et al., 2010; Chetwynd et al., 2017; Dudzik et al., 2018; Raterink et al., 2014; Vuckovic, 2012).

Sample preparation protocols for metabolomics should be as unselective and reproducible as possible. However, the perfect sample preparation and extraction protocol does not exist and the range of metabolites extracted will depend on the protocol used. In some cases, multiple extraction protocols are employed in an attempt to enable the broadest possible metabolite coverage. For example, a common sample preparation protocol for plasma involves two separate extractions with one extract analyzed by liquid chromatography—mass spectrometry (LC-MS) using reversed phase chromatography and the other extract analyzed by LC-MS using HILIC (hydrophilic interaction chromatography).

Instrumental Analysis

A number of different analytical instrumentation platforms have been used for metabolomics analysis. Currently, the most widely used platforms include nuclear magnetic resonance (NMR) spectroscopy, gas chromatography—mass spectrometry (GC-MS), and LC-MS. Each platform possesses strengths and weaknesses relative to the others, and selection of the appropriate analytical instrumentation platform is dependent on several factors including sample matrix type and study objective. NMR's primary strength is that it is inherently quantitative, generally even without any sample preparation, whereas NMR's primary weaknesses

are high cost and poor sensitivity, which result in detection of a limited number of metabolites. The primary strengths of GC-MS include its relatively low cost and the availability of large, well-curated electron ionization spectral library databases. The main weaknesses of GC-MS include limitations on the type and polarity of metabolites that can be made amenable to GC-MS analysis, the necessity to chemically derivatize sample components in many cases, and concerns regarding thermal lability of metabolites during analysis (Fang et al., 2015). The main strength of LC-MS platforms includes the wide metabolite coverage enabled by liquid chromatography separation coupled with electrospray ionization. The main weakness of LC-MS approaches at this point is challenges surrounding metabolite identification. Spectral libraries for LC-MS metabolite identification, while growing, are still significantly limited, and electrospray ionization generates a number of "features" resulting from isotopes, fragments, adducts, multimers, and combinations of these that can be difficult to deconvolve into clear metabolite identifications (a feature, in LC-MS and metabolomics terms, is a molecular entity with a unique m/z and retention time). Despite these challenges and because of the wide metabolite coverage enabled, LC-MS has emerged as the most frequently used analytical technology for metabolomics studies. Currently, the most widely used mass analyzer formats for LC-MS metabolomics work are quadrupole time-of-flight (Q-TOF) and quadrupole orbitrap instruments. These mass spectrometer configurations both provide high resolution and accurate mass capabilities that are beneficial in subsequent metabolomics data processing steps.

Raw Data Processing

There are two fundamentally different approaches to analytical data acquisition and raw data processing in metabolomics: targeted and untargeted metabolomics. Targeted metabolomics is defined as "the measurement of defined groups of chemically characterized and biochemically annotated metabolites," whereas untargeted metabolomics is defined as "the comprehensive analysis of all the measurable analytes in a sample, including chemical unknowns" (Roberts et al., 2012). Targeted and untargeted metabolomics studies require two very different raw data processing procedures. Targeted metabolomics uses a raw data processing workflow similar to typical multianalyte quantitative methods. For targeted metabolomics with GC-MS or LC-MS, analyte peaks are integrated and calibration curves are created using the ratios of peak areas of analytes to those of internal standard compounds. Untargeted metabolomics studies require more specialized raw data processing workflows.

Raw data processing workflows for untargeted metabolomics comprise of four essential steps: (1) identification of features, (2) grouping of the same features between samples, (3) integration of peak areas, and (4) generation of a "peak table," which consists of an array of features and peak areas for each sample. A significant challenge of untargeted metabolomics raw data processing is reduction of a large number of redundant features into an unambiguous entity corresponding to a single metabolite (Mahieu and Patti, 2017). A number of approaches and software tools for untargeted metabolomics raw data processing have been developed (Di Guida et al., 2016; Gowda et al., 2014; Spicer et al., 2017a,b; Tautenhahn et al., 2012; Uppal et al., 2016).

Statistical Analysis of Processed Data

Untargeted metabolomics studies generate large amounts of data. It is common for several thousand features to be measured in a single sample with LC-MS analysis. Multiplied by the dozens, or even hundreds, of samples that are included in a typical metabolomics experiment, data sets can easily contain hundreds of thousands, or even millions, of data points. Statistical analysis methods are necessary to help draw meaning and information from these very large data sets. The most commonly used statistical analysis methods for metabolomics data sets include a group of methods known as multivariate statistical analysis. Principal component analysis (PCA) is a frequently used unsupervised (meaning there is no identification of group membership of samples) statistical analysis tool. PCA allows viewing of groupings of data and can provide an overview of overall data quality. Partial least squares is a supervised (meaning group membership of samples is identified) tool that is frequently used to classify samples into groups and to identify specific metabolites responsible for the groupings (Barnes et al., 2016; Ebbels and De Iorio, 2011; Ren et al., 2015).

There are a number of software options available for statistical analysis of metabolomics data. Most analytical instrumentation vendors offer software packages that include statistical analysis modules. There are some excellent freely available software packages for statistical analysis (Spicer et al., 2017a,b). One freely available statistical analysis software package that is particularly widely used is MetaboAnalyst (Xia et al., 2015; Xia and Wishart, 2016). General commercial statistical software packages such as SIMCA-P, SAS, and Pirouette are also frequently used for metabolomics statistical analysis. Finally, there are many custom software packages for metabolomics statistical analysis, many based on the R programming language (Spicer et al., 2017a,b).

Identification of Putative Biomarkers

Statistical analysis of a processed metabolomics data set may reveal dozens of metabolites that show statistically significant differences in relative abundance between groups tested. However, it is not practical to include dozens of metabolites in a biomarker model. It has been proposed that small groups of 1–10 biomarkers lend themselves to generation of more mathematically robust and practical models (Xia et al., 2013). One common method to reduce the complexity of a biomarker model is to select highly ranked metabolites based on variable importance in projection scores or other selection methods. Multivariate models including selected metabolites are then typically evaluated using cross-validation and permutation testing techniques. Finally, receiver operator characteristic (ROC) curves, which plot one minus specificity (the true negative rate) against sensitivity (the true positive rate), are constructed to evaluate the predictive performance of a biomarker model. The area under the ROC (AUROC) curve represents the predictive performance of the model, with an AUROC value of 1 representing ideal model performance (Nagana Gowda and Raftery, 2013; Xia et al., 2013).

Although it is not necessary to know the identity of a metabolite in order for it to be used as part of a biomarker model, it is certainly desirable. An understanding of the identities of metabolites that make up a biomarker model can help rationalize the metabolites' roles in a particular disease or toxicity state. One of the biggest challenges in untargeted metabolomics has been metabolite identification. In many studies, only a small fraction of the features detected are confidently identified as corresponding to a specific molecular structure. A significant amount of work continues to be devoted to the development of metabolite databases and to approaches to automate and facilitate metabolite identification (Dunn et al., 2012a,b; Vinaixa et al., 2016). The Metabolomics Standards Initiative has developed guidance regarding evaluation and reporting of the level of confidence in metabolite identification that is to be used when publishing results (Sumner et al., 2007).

Biomarker Validation

There are currently no standardized protocols for biomarker validation. However, it is generally acknowledged that validated methods for biomarker measurement should be targeted quantitative methods that measure all of the metabolites in a biomarker set. These methods should make use of appropriate analytical standards, internal standards, and quality control checks as with any other validated quantitative bioanalytical method. These methods should be applied to larger, and more diverse, sample sets compared with those used for preliminary biomarker identification (Nagana Gowda and Raftery, 2013; Xia et al., 2013).

Metabolomics Experimental Overview Conclusions

Although information derived from metabolomics studies can be used in a wide variety of ways in a plethora of applications, the remainder of this chapter will focus on metabolomics studies where specific biomarkers, or sets of biomarkers, have been associated with specific toxins, or systems affected by, or diseases related to specific toxins.

APPLICATIONS OF METABOLOMICS BIOMARKERS IN TOXICITY TESTING

Toxicology was one of the primary application areas of metabolomics in the early 2000s. It has been calculated that 25%–35% of metabolomics publications in the years 2000–02 were related to toxicology (Robertson et al., 2011). Although the percentage of metabolomics publications related to toxicology has decreased over the years to about 10%, the total number of metabolomics publications related to toxicology has continued to grow along with the very rapid growth of metabolomics overall. Following the methodology of Robertson (Robertson et al., 2011), a Scopus search (www.elsevier.com/solutions/scopus) performed in early 2018 reveals that approximately 4000 publications have appeared since 1999, which include the words metabolomics, metabonomics, or metabolic profiling in the title, keywords, or abstract that also contain the root word "toxic." A large fraction of these studies have identified possible biomarkers of toxicity, MOA of toxicity, or pathways of toxicity. By now, metabolomics has been applied to identifying possible biomarkers in virtually every subfield of toxicology. An exhaustive review of these studies is obviously not possible here. A number of excellent reviews of metabolomics applications in toxicology have appeared in recent years (Bouhifd et al., 2013; Nassar et al., 2017; Ramirez et al., 2013; Robertson, 2005; Robertson et al., 2011; Rouquie et al., 2015; Roux et al., 2011). The remainder of this chapter will focus on some of the primary areas in which metabolomics has been applied in toxicology, including hepatotoxicity, renal toxicity, toxicity from chemical agents, neurotoxicity, biotoxins, nanomaterials, and drugs of abuse. Prior to examining each of these topics, a brief overview of a number of larger-scale cooperative efforts to apply metabolomics in toxicology is provided.

Metabolomics in Toxicology Consortia

The Consortium for Metabonomic Toxicology (COMET) was active from 2002 to 2005. This effort was led by Jeremy Nicholson from Imperial College London, UK, and involved five major pharmaceutical companies. The objective of this collaborative effort was to generate a metabolomics database using NMR spectroscopy of rodent urine and blood serum and to build a predictive expert system for target organ toxicity in the rat. This database was delivered to the sponsoring companies at the conclusion of the effort and has been reported as highly successful (Lindon et al., 2005).

BASF's metabolomics program at Metanomics Health, along with a consortium of 12 biopharmaceutical companies, has constructed a metabolomics database covering over 600 chemicals and identifying more than 100 metabolic fingerprints (groups of biomarkers) corresponding to different toxicological MOA. The database was constructed using MS and rat serum. This database is not open access and is available as a commercial product (van Ravenzwaay et al., 2012).

The InnoMed PredTox initiative involved a group of 19 partners, including 14 pharmaceutical companies, 3 universities, and 2 technology providers, and was funded in part by the European Union. The goal of this effort was to identify biomarkers to help predict the toxicity of drug candidates. The approach taken by this group involved the combination of conventional toxicology techniques, proteomics, transcriptomics, and metabolomics using NMR, LC-MS, and GC-MS. The full database resulting from this effort was made publicly available through the European Bioinformatics Institute (Suter et al., 2011).

The Human Toxome Project, funded through the NIH, involved a group comprised of members from government, university, and nonprofit research institutes. The goal of this initiative was to apply transcriptomics and metabolomics to map and annotate "pathways of toxicology" for a defined set of endocrine disruptor compounds. A number of publications have arisen from this effort (Bouhifd et al., 2015).

A recently announced initiative called Metabolomics Standards Initiative in Toxicology (MERIT) has been launched by the European Center for Ecotoxicology and Toxicology of Chemicals (ECETOC). This group includes partners from industry, government agencies, regulators, and academia from across Europe and the United States. Participating members include the US EPA, US FDA, the European Food Safety Authority (EFSA), the UK Health and Safety Laboratory (HSL), BASF, Syngenta, Unilever, Imperial College London, University of Birmingham, UK, VU University Amsterdam, and the Metabolomics Society Data Standards Task Group. The goal of this group is to accelerate the use of metabolomics technology to improve safety assessment of chemicals. The initial focus will be on developing best practice guidelines and minimal reporting standards for the acquisition, processing, and analysis of metabolomics data (Spicer et al., 2017a,b).

Metabolomics Biomarkers in Hepatotoxicity

Hepatotoxicity is frequently observed in the form of drug-induced liver injury (DILI). DILI is a major concern both in the pharmaceutical industry and for public health. DILI is a frequent cause for termination of drug development programs and withdrawal of approved drugs from the market. Worldwide, the estimated annual incidence of DILI is between 14 and 24 per 100,000 people. DILI is one of the leading causes of acute liver failure in the United States, accounting for approximately 13% of cases. A variety of biological mechanisms and a large number of pharmaceutical compounds have been associated with DILI (Araujo et al., 2017).

There are several conventional clinical biomarkers of hepatotoxicity, including total bilirubin, alanine aminotransferase (ALT), aspartate aminotransferase, and alkaline phosphatase, among others. All of these conventional biomarkers of DILI suffer from lack of specificity and sensitivity. These markers are only present at significant levels after extensive liver damage has occurred. Because of these limitations, there has been significant interest in identification of new and more sensitive and specific biomarkers of DILI using metabolomics.

Several authors have used in vitro approaches to assess and classify liver toxicity mechanisms and pathways associated with drug-induced hepatotoxicity (Garcia-Canaveras et al., 2016; Ramirez et al., 2018). For example, Ramirez et al. (2018) treated HepG2 human hepatocyte carcinoma cells with 35 different test substances and performed metabolomics instrumental analysis on cellular extracts using GC-MS and LC-MS. Data analysis revealed concentration-response effects and patterns of metabolome changes consistent with specific liver toxicity mechanisms, including liver enzyme induction/inhibition, liver toxicity, and peroxisome proliferation. Garcia-Canaveras et al. (2016) also used human-derived HepG2 cells exposed to nonhepatotoxic control compounds and to different hepatotoxic drug compounds with known toxicity mechanisms, including steatosis, phospholipidosis, and oxidative stress. Cellular extracts were analyzed using Q-TOF LC-MS in both reversed phase and HILIC chromatography modes. Several dozen metabolites were identified, which were shown to be correlated to each toxicity mechanism. Oxidative stress damage biomarkers were

found in all three mechanisms including altered levels of metabolites associated with glutathione and γ-glutamyl cycle.

Phospholipidosis was characterized by a decreased lysophospholipids to phospholipids ratio, which suggested a phospholipid degradation inhibition. Steatosis was correlated with impaired fatty acids β-oxidation and a subsequent increase in triacylglycerides synthesis. These characteristic metabolite profiles were used to develop predictive models both to discriminate between nontoxic and hepatotoxic drugs and to propose general drug toxicity mechanisms.

Acetaminophen (APAP) is a common cause of acute liver failure, accounting for nearly 50% of cases in the United States. APAP has been considered a model toxicant for DILI, and a number of groups have performed metabolomics studies in an attempt to identify new biomarkers of overdose and acute liver failure. There have recently been several human clinical studies where APAP biomarkers have been identified or tested.

In the first study, Winnike et al. (2010) used ^{1}H NMR in an attempt to identify individuals who were susceptible to DILI caused by APAP. Thirty-five healthy adults received 4 g of APAP per day for 7 days. Urine metabolome profiles obtained 2 days prior to treatment and measured by NMR were not sufficient to predict which subjects were susceptible to development of liver injury. However, metabolomics profiles obtained shortly after APAP treatment, but before ALT elevation, were able to predict subjects that were susceptible ("responders") to liver injury. Levels of cysteine and mercapture conjugates of APAP, glycine, alanine, and acetate were higher in the urine of responders than in nonresponders. This study confirms the use of biomarkers identified using metabolomics to identity subjects at risk for developing DILI soon after initiation of drug treatment and prior to liver injury.

In another study, Kim et al. (2013) used ^{1}H NMR to analyze urine samples from 20 healthy human subjects treated with 3 g of APAP per day for 7 days. Seven endogenous urinary metabolites (trimethylamine N-oxide [TMAO], citrate, 3-chlorotyrosine, phenylalanine, glycine, hippurate, and glutarate) were responsible for the PCA separation of pre- and postdosing urine samples. The authors concluded that NMR measurement of urinary biomarkers could be applied to predict or screen for susceptibility to hepatotoxicity in humans.

Schnackenberg et al. (2017) tested potential biomarkers of APAP DILI, identified in earlier nonclinical metabolomics studies, in children who had suffered an overdose of APAP. Urine samples from the overdose patients were analyzed using a Q-TOF—based LC-MS system. The results identified metabolites from metabolic pathways noted in the previous studies and pathway analysis indicated analogous pathways were significantly altered in both rats and humans after APAP overdose. Metabolites from arginine and proline metabolism, tricarboxylic acid (TCA) cycle, taurine and hypotaurine metabolism, glycine, serine and threonine metabolism, and glutathione metabolism pathways were significant in the APAP overdose group compared with the control group. The authors concluded that a metabolomics approach may enable the discovery of specific, translational biomarkers of drug-induced hepatotoxicity that may aid in the assessment of patients.

Many other studies have used animal models and metabolomics analysis to identify biomarkers of liver hepatotoxicity. Slopianka et al. (2017) used an approach based on LC-MS and a commercially available targeted metabolomics kit to quantitate 20 specific bile acids in plasma and liver tissue from rats that had been dosed the known hepatotoxic drug methapyrilene. These data indicated that cholic acid, chenodeoxycholic acid, glycocholic acid, taurocholic acid, and deoxycholic acid were sensitive biomarkers of hepatocellular/hepatobiliary damage in rats. The bile acid perturbations were observed at earlier time points, indicating better sensitivity than conventional clinical chemistry biomarkers.

In one example with a nondrug hepatotoxin, Bando et al. (2011) used GC-MS to profile plasma and urine from rats that had been dosed with hydrazine. Biomarkers identified included amino acid precursors of glutathione (cysteine, glutamate, and glycine) and 5-oxoproline, a product of glutathione metabolism. In addition, intermediates of the TCA cycle were decreased, while components of the urea cycle and other amino acids were increased. These results confirmed the role of oxidative stress in hydrazine-induced hepatotoxicity.

Metabolomics Biomarkers in Renal Toxicity

Nephrotoxicity (renal toxicity) occurs when kidney-specific detoxification and excretion do not function properly due to damage or destruction of kidney function by toxicants. Nephrotoxicity can be the result of hemodynamic changes, direct injury to cells and tissue, inflammatory tissue injury, and obstruction of renal excretion. Nephrotoxicity is induced by a wide variety of therapeutic drugs (including antibiotics, immunosuppressants, antineoplastic agents, nonsteroidal antiinflammatory drugs, drugs of abuse, and natural medicines) and environmental pollutants (including heavy metals, organic solvents, insecticides, and glycols).

There are a number of conventional clinical biomarkers of nephrotoxicity, including creatinine clearance, serum creatinine (SCr), and blood urea nitrogen

(BUN). These conventional biomarkers of nephrotoxicity suffer from lack of specificity and sensitivity. These markers are only present at significant levels after extensive kidney damage has occurred. Because of these limitations, there has been significant interest in identification of new, more sensitive and specific biomarkers of nephrotoxicity. There is a number of emerging protein biomarkers for nephrotoxicity and there is also significant interest in discovery of potential small molecule biomarkers of nephrotoxicity using metabolomics (Zhao and Lin, 2014).

A number of studies have been performed in attempts to identify biomarkers of nephrotoxicity of antibiotics using metabolomics approaches. For example, one study measured metabolome changes in newborn rat urine following dosing with the aminoglycoside antibiotic gentamicin using GC-MS and LC-MS. A number of putative biomarkers were identified, including tryptophan, kynurenic acid, xanthurenic acid, and hippuric acid. Tryptophan levels were increased following dosing with gentamicin, while kynurenic acid, xanthurenic acid, and hippuric acid levels were decreased. Statistically significant changes in these biomarkers were present 3 days after gentamicin dosing, while significant increases in BUN and SCr were not noted until 7 days following gentamicin dosing (Hanna et al., 2013).

Immunosuppressant drugs are also well-known causes of nephrotoxicity. The calcineurin inhibitor drugs cyclosporine and tacrolimus are the basis for most protocols for the prevention of organ rejection following transplantation. A summary of metabolomics studies to identify biomarkers of immunosuppressant nephrotoxicity has recently appeared (Bonneau et al., 2016). Numerous studies in rat and human urine using NMR have identified candidate biomarker molecules, including glucose, TMAO, citrate, lactate, 15-F_{2t}-isoprostane, hippurate, inositol, creatinine, succinate, α-ketoglutarate, creatine, trimethylamine (TMA), and taurine. A metabolomics study using rat plasma and NMR identified candidate biomarkers, including creatinine, TMAO, and glutathione. A study using human serum from transplant recipients and NMR identified putative biomarkers, including lipids, glucose, hypoxanthine, lactate, succinate, and taurine.

Cisplatin is an antineoplastic agent used to treat a variety of solid tumors. One of the major side effects of cisplatin therapy is nephrotoxicity. Cisplatin nephrotoxicity is related to triggering of reactive oxygen species among several other mechanisms. The conventional nephrotoxicity biomarkers SCr and BUN are used as markers of cisplatin toxicity but these only increase markedly after significant kidney injury. Several candidate biomarkers discovered using genomic and proteomic approaches have proven to be more sensitive than the conventional biomarkers. However, there remains significant interest in identification of metabolomics biomarkers of cisplatin toxicity. In an example study, GC-MS and LC-MS were used to find cisplatin nephrotoxicity biomarkers in rat plasma (Ezaki et al., 2017). GC-MS−derived biomarkers include cysteine and cystine and 3-hydroxybutyrate. LC-MS−derived biomarkers include three acylcarnitines (AC 14:0, AC 18:1, and AC 18:2) and a phosphatidylethanolamine (C18:2-C18:2). Plasma levels of all of the metabolomics identified biomarkers showed significant changes in plasma more quickly after cisplatin administration than the conventional clinical biomarkers SCr and BUN.

Toxicants contained in natural medicines, including traditional Chinese medicines, are also potential sources of nephrotoxicity. Aristolochic acids are a family of potent nephrotoxic acids found primarily in the plant genera *Aristolochia* and *Asarum*. These herbs have been used to relieve symptoms such as cough, arthritic pain, and gastrointestinal problems. In a recent study, the investigators used LC-MS to identify biomarkers of aristolochic acids nephrotoxicity in rat urine. A number of metabolites with significantly changed levels were identified including citrate, aconitate, fumarate, glucose, creatinine, p-cresyl sulfate, indoxyl sulfate, hippuric acid, phenylacetylglycine, kynurenic acid, indole-3-carboxylic acid, spermine, uric acid, allantoin, cholic acid, and taurine. The authors performed KEGG (Kyoto encyclopedia of genes and genomes) pathway mapping to conclude that aristolochic acids nephrotoxicity perturbed biochemical pathways, including the TCA cycle, gut microflora metabolism, amino acid metabolism, purine metabolism, and bile acid biosynthesis (Zhao et al., 2015).

Melamine is a small, nitrogen-rich molecule with a number of industrial uses. It also sometimes added to animal feed and food as an adulterant to increase the apparent protein level in the feed or food when nitrogen-based protein testing is conducted. Melamine is also severely nephrotoxic when it is coadministered with cyanuric acid, a related compound, and can cause acute renal failure. A 2007 pet food recall and a 2008 milk and infant formula scandal in China were both related to nephrotoxicity outbreaks caused by melamine and cyanuric acid contamination. Since these incidents, a number of studies have used metabolomics approaches to identify possible biomarkers of melamine and cyanuric acid nephrotoxicity. A study published in 2012 used NMR to measure alterations of endogenous metabolites in kidney tissue from rats dosed with melamine and cyanuric acid. Over 30 metabolites were observed to have dramatically altered levels compared with normal rat kidney tissue (Kim et al., 2012).

Metabolomics Biomarkers of Toxicity From Chemical Agents

Biomarkers of toxicity for a number of chemical agents have been thoroughly investigated using metabolomics approaches. These chemical agents include synthetic chemicals, such as pesticides and halogenated compounds, metals, solvents, and gases. Representative examples of metabolomics studies yielding candidate biomarkers of toxicity for each of these classes of chemical agents are reviewed in this section.

Organophosphorus and carbamate insecticides are acetylcholinesterase inhibitors with well-known toxic effects and biomarkers of toxicity. Wang et al. studied the effects of the organophosphorus pesticides dichlorvos and malathion, the carbamate pesticide pirimicarb, and their mixtures in subchronic low-level exposures to mice (Wang et al., 2014). Metabolomics analysis was based on NMR spectroscopy with comparison to conventional biochemical assays. Mouse serum analysis showed significant alterations of TMAO, lactate, acetone, very low-density and low-density lipoprotein, and 3-hydroxybutyrate. Mouse liver tissue analysis showed significant alterations of lactate, glucose, choline, glutathione, alanine, glutamine, and isoleucine. Perturbations in these metabolites, along with the conventional biochemical analyses, led the authors to conclude that glucose, fatty acid, and protein metabolism, as well as energy metabolism and oxidative balance, were disturbed by the pesticides tested.

Another study examined toxicity induced by the neonicotinoid pesticide imidacloprid on the central nervous system of the freshwater snail *Lymnaea stagnalis*. This study used a combination of analytical platforms including an LC-MS–targeted metabolomics analysis focused on neurotransmitters, an untargeted LC-MS analysis, and an untargeted GC-MS analysis. Many changes in the metabolome of *L. stagnalis* were observed, including changes in amino acid and nucleotide metabolites tryptophan, proline, phenylalanine, uridine, and guanosine. Many fatty acids levels were decreased and levels of the polyamines, spermidine and putrescine, were increased indicating neuronal cell injury (Tufi et al., 2015).

Toxicity of the herbicide glyphosate has been the subject of much debate and controversy. Mesnage et al. exposed female rats to environmentally relevant low doses of a glyphosate-based herbicide for a period of 2 years (Mesnage et al., 2017). At the end of the study period, rat liver tissues were extracted and metabolomics analysis was performed using GC-MS and LC-MS. Over 50 metabolites were found to be statistically significantly altered. This information, in conjunction with proteomic analysis, was interpreted to be consistent with development of nonalcoholic fatty liver disease and its progression to nonalcoholic steatohepatosis (NASH).

The fungicide vinclozolin has been associated with endocrine disruption and antiandrogenic effects. van Ravenzwaay et al. (2013) used vinclozolin as a model compound and explored metabolomics profiles of plasma from rats dosed with vinclozolin using GC-MS and LC-MS. Results of the metabolome profiling were matched against a proprietary database of metabolome profiles from compounds with known MOA. The best databases matches were with MOA that included liver toxicity and enzyme induction, inhibition of adrenal steroid synthesis, and antiandrogenic effects.

Potential toxicity of the halogenated flame retardants tetrabromobisphenol A (TBBPA) and tetrachlorobisphenol A (TCBPA) was investigated in a study in which embryos of the fish species *Oryzias melastigma* were exposed to environmentally relevant concentrations of the two compounds. Embryo tissue was extracted and analyzed using GC-MS. Lactate and dopa were identified as potential biomarkers of the developmental toxicity and related genetic effects of TBBPA and TCBPA. Moreover, analysis of offspring embryos indicated that disorders of the neural system and disruptions of a number of metabolic pathways induced by TBBPA and TCBPA exposure were heritable (Ye et al., 2016).

Wang et al. used NMR and LC-MS to investigate the effects of another brominated flame retardant, hexabromocyclododecane (HBCD), on the metabolome of mouse urine (Wang et al., 2016). Female mice were dosed with HBCD by oral gavage. Untargeted metabolomics was performed using NMR, whereas targeted metabolic profiling of 20 amino acids was performed using LC-MS. Analysis of NMR data showed perturbed levels of citrate, 2-ketoglutarate, alanine, acetate, formate, TMA, 3-hydroxybutyrate, and malonic acid. LC-MS data showed perturbed levels of alanine, lysine, and phenylalanine. Interpretation of these results led to the conclusion that HBCD exposure caused disturbances in metabolic pathways, including TCA cycle, lipid metabolism, gut microbial metabolism, and homeostasis of amino acids.

Metal toxicity is major concern worldwide. Correspondingly, significant effort has been devoted to metabolomics study and identification of new and sensitive biomarkers of toxic metal exposure. Three example studies involving arsenic, nickel, and thallium are described here.

Arsenic pollution is a serious environmental health risk in many locations, including areas in China where significant dietary and environmental exposure to arsenic is a concern. Zhang et al. (2014) sought to identify dose-dependent biomarkers of arsenic exposure in a Chinese male cohort. Urinary arsenic

species were measured using high-performance liquid chromatography—inductively coupled plasma mass spectrometry. Urinary metabolomics data were acquired using LC-MS. Arsenic-related biomarkers were investigated by comparing results from the first and fifth quintiles of arsenic exposure. Five potential biomarkers related to arsenic exposure were identified: testosterone, guanine, hippurate, acetyl-*N*-formyl-5-methoxykynurenamine, and serine. Interpretation of these biomarkers suggested that oxidative stress and endocrine disruption were associated with increased urinary arsenic levels. Testosterone, guanine, and hippurate could discriminate the first and fifth quintiles of arsenic exposure with AUROC values of 0.89, 0.87, and 0.83, respectively.

Nickel exposure was investigated by measurement of metabolomics changes in rat urine using NMR. Male rats were dosed intraperitoneally with $NiCl_2$ at several levels. Metabolomics profiles showed significant changes in levels of citrate, dimethylamine, creatinine, choline, TMAO, phenylalanine, and hippurate. These biomarkers are consistent with the known mechanism of nickel-induced nephrotoxicity. The authors speculate that this combination of biomarkers could be useful in predicting nickel-induced nephrotoxicity (Tyagi et al., 2012).

The same research group also investigated thallium toxicity by NMR metabolomics measurement in mouse urine. Male mice were injected intraperitoneally with Tl_2SO_4 at three different doses. Metabolic profiles showed significant changes in levels of creatinine, taurine, hippurate, 3-hydroxybutyrate, TMA, and choline. These metabolic perturbations could be seen as soon as 3 h after thallium dosing, indicating that these compounds could potentially serve as rapid and sensitive biomarkers of thallium exposure (Tyagi et al., 2011).

Hydrogen sulfide is an extremely poisonous gas and is a leading cause of workplace gas inhalation deaths worldwide. There are currently no specific, direct tests that can be used to diagnose poisoned patients. In an attempt to identify biomarkers of hydrogen sulfide exposure, a GC-MS metabolomics approach has been used with serum from rats chronically poisoned with hydrogen sulfide (Deng et al., 2015). Adult male Sprague—Dawley rats were exposed to 20 ppm of hydrogen sulfide gas twice per day for 1 h for each exposure. Serum samples were measured after 40 days of twice daily exposures. Alterations in levels of a number of metabolites were observed, including citrate, galactose, lactate, mannose, inositol, urea, phosphate, alanine, valine, and hexadecanoic, linoleic, and arachidonic acids. These changes corresponded to changes in metabolic pathways, including lipid metabolism, energy metabolism, and amino acid metabolism. The authors postulate that the identified candidate biomarkers could

provide a novel means for detection of chronic hydrogen sulfide poisoning.

Carbon tetrachloride is a well-known hepatotoxicant with a number of industrial uses, including as a solvent, cleaning agent, refrigerant, and fire suppression. A number of metabolomics studies with carbon tetrachloride have consistently shown alterations to lipids and bile acids in plasma. Sun et al. (2014) performed a comprehensive study with rats in which clinical chemistry, histopathological, and transcriptomic data were integrated with data from multiple analytical metabolomics platforms including untargeted LC-MS and targeted GC-MS and LC-MS. Metabolomics analysis was performed on plasma and liver tissue extracts. Metabolomics results showed that levels of total fatty acids increased in the liver but decreased in blood. Primary bile acids increased in both liver and blood, whereas secondary and conjugated bile acids decreased in the liver and increased in the blood, indicating that the bile acid conjugation pathway and bile acid uptake by the liver were inhibited by carbon tetrachloride.

Metabolomics Biomarkers in Neurotoxicity

Alzheimer's disease (AD) is the most common neurodegenerative disease worldwide. AD causes approximately 70% of dementia in elderly people and there are currently an estimated 50 million people worldwide with AD. This number is projected to increase to over 130 million by 2050. There are currently no treatments effective at slowing the progression of AD. A number of genetic mutations have been associated with AD; however, approximately 95% of cases are sporadic and without a definitive genetic link. Although there is general consensus around a number of signatures of AD, including deposition of β-amyloid plaques, hyperphosphorylation of tau protein, oxidative stress, inflammation, abnormal metal homeostasis, and others, the underlying molecular mechanisms of AD etiology and development are not well understood. There is tremendous interest in the potential of metabolomics to help identify biomarkers that may be useful for early detection, improved prognosis, and monitoring the progression of AD. There have been hundreds of metabolomics studies with AD performed to date. Recent reviews summarize the current state of this work (Gonzalez-Dominguez et al., 2017; Wilkins and Trushina, 2017).

In one noteworthy study, a targeted metabolomics LC-MS approach was used to analyze serum samples from AD patients and controls. Metabolomics data were correlated with a number of clinical measures of mild cognitive impairment and AD. Results showed that sphingomyelins and ether-containing phosphatidylcholines were perturbed in preclinical biomarker-defined

AD stages, whereas acylcarnitines and amines, including valine and α-aminoadipic acid, were perturbed in clinical AD stages (Toledo et al., 2017).

Parkinson's disease (PD) is the second most common neurodegenerative disease worldwide. An estimated 10 million people worldwide suffer from PD. PD is characterized by loss of dopaminergic neurons and by the time of clinical manifestation of disease, 60%–80% of the dopaminergic neurons are lost in the striatum. Currently, there is no way to definitively diagnose PD at its early stages. Extensive metabolomics studies have been undertaken with PD in hopes of identifying biomarkers which may lead to early diagnosis, improved prognosis, and monitoring the progression of PD. Recent reviews provide an overview of metabolomics studies of PD (Gill et al., 2018; Havelund et al., 2017).

In one example study, untargeted LC-MS was used to measure plasma and CSF metabolite profiles from early-stage PD patients. A total of 20 candidate biomarkers were identified in plasma and 14 were identified in CSF. These candidate biomarkers were used to successfully differentiate the test set from a control set with AUROC values of 0.8 for plasma and 0.9 for CSF (Stoessel et al., 2018).

Metabolomics Biomarkers of Biotoxins

Biotoxins are toxic substances that have a biological origin. Biotoxins include mycotoxins, made by fungi, and cyanotoxins, made by cyanobacteria (blue-green algae). Mycotoxins are typically associated with fungi that colonize crops and are capable of causing disease and death in both humans and animals. Cyanotoxins are produced in highest concentrations where cyanobacteria reproduce exponentially to form blooms. Cyanotoxins can cause poisoning and death in both humans and animals. Examples of applications of metabolomics to identify biomarkers of toxicity from mycotoxin and cyanotoxin exposure are described here.

Liu et al. used NMR to study the effects of zearalenone (ZEN) intragastric dosing on the urine and plasma metabolome of rats (Liu et al., 2013). In plasma, levels of glucose, lactate, N-acetyl glycoprotein, O-acetyl glycoprotein, and propionate were elevated, whereas levels of tyrosine, branched chain amino acids, and choline were reduced. In urine, levels of allantoin, choline, N-methylnicotinamide, 1-methylhistidine, acetoacetate, acetone, and indoxyl sulfate were elevated, whereas levels of butyrate, lactate, and nicotinate were reduced. The authors concluded that ZEN exposure caused oxidative stress and changed systemic metabolic processes, including cell membrane metabolism, protein biosynthesis, glycolysis, and gut microbiota metabolism.

Another study examined the combined toxic effects of ZEN and deoxynivalenol (DON) in liver and serum of mice. Mice were treated with ZEN only, DON only, or a combination of ZEN and DON. Histopathological and serum biochemical measurements were collected and metabolomics profiling was performed with GC-MS. A number of metabolomics biomarkers were identified for each treatment group. Interestingly, all data indicated that the combination ZEN + DON treatment had slightly weaker toxicity than the individual ZEN and DON treatments. The authors concluded that combined ZEN + DON treatment had an antagonistic toxicity effect in mice (Ji et al., 2017).

De Pascali et al. (2017) used NMR metabolomics to investigate the effects of a single bolus dose of a combination of five mycotoxins on piglet urine. Dosed mycotoxins included ZEN, DON, ochratoxin A, and fumonisin $B_1 + B_2$ ($FB_1 + FB_2$). Dosed mycotoxin levels were close to the established maximum guidance levels for animal feed. Perturbed urine levels of creatinine, p-cresol glucuronide, phenyl acetate glycine, betaine, and TMAO were detected. The postulated reason for these changes was alteration of the gut microbiome. Interestingly, the changes in metabolite levels persisted for at least a week after bolus dosing suggesting a sustained impact on gut microbiota.

The metabolomics of rats and mice exposed to microcystin-LR has been investigated using NMR profiling. Microcystin-LR is a cyclic heptapeptide that has been shown to have acute hepatotoxic effects. In a study published in 2013, rat urine metabolite levels of citrate, 2-oxoglutarate, succinate, hippurate, betaine, taurine, creatine, guanidinoacetate, dimethylglycine, urocanic acid, and bile acids were found to be altered. The extent of alteration of metabolites levels was correlated with the severity of histopathological findings (Cantor et al., 2013). A more recent study combined proteomics and NMR metabolomics data from liver and serum of mice exposed to chronic low doses of microcystin-LR. A large number of metabolite levels were found to be altered in both liver tissue and serum. Interpretation of these alterations, along with histopathological data, led to the assessment that chronic microcystin-LR dosing led to hepatic inflammation resulting in NASH disease (He et al., 2017).

Metabolomics Biomarkers of Nanomaterials

Nanoparticles are particles between 1 and 100 nanometers (nm) in size. Nanoparticles are of interest because of their small size and high surface to volume ratio. Nanoparticles frequently exhibit unique physical and chemical properties that are not observed with bulk material of the same composition. Nanoparticles are made from a variety of substances, including

fullerenes, metals, ceramics, polymers, lipids, and others. Nanoparticles are used in applications including catalysis, imaging, energy research, environmental applications, and consumer and medical products. The unique properties of nanoparticles can also lead to toxicity that is unique compared with bulk material of the same composition. Because of their small size, nanoparticles can be readily inhaled, ingested, and absorbed through the skin (Hobson et al., 2016). As awareness of and interest in nanotoxicology has grown over the last several years, so has interest in applying systems biology approaches (including metabolomics) in an effort to develop a comprehensive understanding of the toxicological mechanisms of these materials. Costa and Fadeel (2016) have reviewed systems biology approaches in the context of nanotoxicology.

Titanium dioxide is a whitening agent that is used in many industrial and consumer products including toothpaste. While titanium dioxide nanoparticles are not typically used in toothpaste, they are used in dental cements to improve mechanical and antibacterial properties. Garcia-Contreras et al. (2015) examined the alteration of metabolomics profiles caused by titanium dioxide (TiO_2) nanoparticles in human gingival fibroblast (HGF) cells. HGF cells were treated with TiO_2, extracted, and metabolomics analysis performed using capillary electrophoresis—mass spectrometry. Results showed that the TiO_2 nanoparticles augmented metabolic changes in a number of pathways, including amino acid, urea cycle, polyamine, S-adenosylmethionine, and glutathione synthesis.

Hadrup et al. compared the effects of selenium nanoparticles and equimolar bulk sodium selenite administered by oral gavage on the rat urine metabolome using LC-MS (Hadrup et al., 2016) Evaluation of all significantly changed metabolites showed that selenium nanoparticles and sodium selenite induced similar dose-dependent changes in the metabolite pattern. Altered metabolites included decenedioic acid and hydroxydecanedioic acid for both selenium formulations, whereas dipeptides were altered only for sodium selenite. The authors concluded that these effects may reflect altered fatty acid and protein metabolism.

Silver nanoparticles are widely used in consumer and biomedical products. Due to their antimicrobial properties, they are used in medical products such as wound dressings, implants, and catheters. A study used NMR metabolomics, combined with conventional clinical chemistry and histological examination, to characterize organ and systemic response in mice (Jarak et al., 2017). Mice were intravenously dosed with silver nanoparticles and serum and tissues were analyzed by NMR. In serum, significant changes were observed in glucose, lactate, pyruvate, lysine, and phosphocreatine. These changes were interpreted as possibly related to oxidative stress caused by the silver nanoparticles.

Metabolomics Biomarkers of Drugs of Abuse

Metabolomics has also been applied to study acute and chronic toxic effects of drugs of abuse, including stimulants, opioids, and designer drugs. Metabolomics has not only assisted in understanding the molecular mechanisms behind drug dependence but can also be applied to elucidate the mechanism(s) of toxicity of new and emerging designer drugs. Examples of metabolomics applications to discern mechanisms of toxicity and identify related biomarkers for a stimulant (methamphetamine [MA]), an opioid (heroin), and a designer drug (MAM-2201) are described next (Zaitsu et al., 2016).

MA is an illegal stimulant drug of abuse with serious negative health consequences, including cardiovascular disease, psychosis, depression, and dental pathology. A study by McClay et al. examined the metabolomics of single and repeated exposures of MA in male mouse brain tissue extracts using GC-MS and LC-MS (McClay et al., 2013). Mice were dosed intraperitoneally with either a single dose of MA or with daily dosing of MA over a period of 5 days. After a single MA exposure, levels of compounds, including lactate, malate, succinate, fumarate, tryptophan, and 2-hydroxyglutarate, were altered significantly. After repeated, 5 days, MA exposure, additional specific compound alterations included phosphocholine and ergothioneine. The authors concluded that these data confirmed and extended existing models of MA action in the brain, in which an initial increase in energy metabolism gives way to disruption of mitochondria and phospholipid metabolism pathways and increased endogenous antioxidant response.

Heroin is the most widely used opioid in the world. Repeated heroin use changes the physical structure and physiology of the brain, creating long-term imbalances in neuronal and hormonal systems, which are not easily reversed. Li et al. (2017) investigated the metabolomics of repeated daily dosing and withdrawal of heroin in male mouse brain tissue extracts using LC-MS. Mice in the heroin-treated group were dosed intraperitoneally with heroin twice per day for 12 consecutive days. Mice in a heroin-withdrawal group were dosed twice per day for 10 consecutive days followed by a 2-day withdrawal period. Perturbed metabolites in the heroin-treated group included amino acids, TCA cycle intermediates, neurotransmitters, and nucleotides. In the heroin-withdrawal group, a marked reduction in histidine, increases in phenylalanine and tryptophan, and a decrease of catecholamines to baseline levels were measured. Melatonin was significantly

decreased in the heroin-treated group, while N-acetylserotonin, a precursor of melatonin, was increased in the heroin-withdrawal group. The authors interpreted these results as an indication that heroin disrupts not only energy metabolism but also the biosynthesis of both catecholamines and melatonin in the mouse brain.

MAM-2201 is a synthetic cannabinoid that has recently been used as a designer drug and has been reported to show acute toxicity in humans. Zaitsu et al. (2015) studied the disruption of the metabolome of the male rat cerebrum using GC-MS. Mice were dosed intraperitoneally with a single dose of MAM-2201 at either a high- or low-dose level. The levels of 12 metabolites were significantly changed in a dose-dependent manner compared with the control group. Altered metabolites included creatinine, fructose, gluconic acid, glutamic acid, psicose, malic acid, phenylalanine, sorbitol, sorbose, succinic acid, tagatose, and valine. These results indicated that MAM-2201 disrupted energy metabolism in the rat cerebrum and also glutamatergic neurotransmission.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Metabolomics is a maturing science that is now nearly 20 years old. Metabolomics has been widely applied in toxicology with over 4000 publications in the field. Many of these publications have identified putative or candidate biomarkers correlated with susceptibility, exposure, and/or effects of toxicants. All of these studies demonstrate that metabolomics approaches for the identification of small molecule endogenous biomarkers of toxicity are extremely promising. However, while some areas, such as hepatotoxicity of drugs, have seen sufficient work that reproducible patterns of biomarkers have emerged, many of these studies have been very preliminary and their results are not validated. Many barriers and challenges exist to establishing validated metabolomics-derived biomarkers of toxicity. For example, there are currently no standardized study design, analytical instrumental analysis, or data analysis and reporting protocols for metabolomics. Indeed, the literature abounds with metabolomics studies, in which similar toxicants, species, and biological specimens are examined, but very different sets of putative biomarkers have been identified (Poste, 2011). In spite of the successes of metabolomics, there are currently no FDA-approved biomarkers for clinical use, which have been discovered with metabolomics approaches (Trivedi et al., 2017).

For biomarkers of toxicity discovered using metabolomics to become more practically useful, they must be validated. For these biomarkers to become validated, they must be quantitated more accurately and precisely and measured in larger groups of subjects. More accurate quantitation can be accomplished using targeted metabolomics approaches with appropriate internal standards and quality control samples, similar to conventional validated bioanalytical methods. An obvious barrier to performing larger-scale trials is the cost involved. To overcome this barrier, adequate funding for such trials must exist and, more than likely, government-industry partnerships will need to be formed. If this can be accomplished, and if these candidate biomarkers can become rigorously validated, then the great potential for application of small endogenous molecule biomarkers of toxicity identified using metabolomics may be realized.

Transcriptomic Biomarkers in Safety and Risk Assessment of Chemicals

David T. Szabo[1], Amy A. Devlin[2]

[1]PPG Industries Incorporated, Pittsburgh, PA, United States; [2]US Food and Drug Administration, Silver Spring, MD, United States

INTRODUCTION

Identification and use of transcriptomic biomarkers to distinguish physiological conditions or clinical stages is an emerging field that has advanced substantially this decade. This is partly due to several national and international agencies' recommendations to incorporate advanced technologies in the safety and risk assessment process. Transcriptomics is recognized as an unbiased, sensitive, and personalized approach with the potential to reveal new predictive biomarkers of disease and ultimately improve the decision-making process. When performed in a dose–response format, the observed transcriptional changes can provide both quantitative and qualitative information on the dose at which cellular processes are affected. Transcriptomic approaches have transformed the way in which physicians approach diagnosis, prognosis, and treatment and in which regulators approach risk assessment. This chapter provides fundamental insights into the promising technology of transcriptomics with multiple applications in both regulatory science and clinical research, where it can be used to discover novel biomarkers potentially useful for human safety and risk assessment (Fig. 63.1).

Transcriptomics

The transcriptome of an organism includes the total of all its RNA transcripts at one point in time. The term "transcriptome" was first used in the 1990s (Piétu et al., 1999; Velculescu et al., 1997). Although transcripts originate from less than 5% of the genome in humans and other mammals, each gene (locus of expressed DNA) may produce a variety of messenger RNA (mRNA) molecules using the process of alternative splicing. Therefore, the transcriptome has a level of complexity greater than the genome that encodes it. Modern transcriptomics is regarded as a high-throughput technology concerned with determining how the transcriptome changes with respect to various factors at a certain time point and at a given biological state. Regulation of gene expression is highly complex and underlies many fundamental biological processes such as growth, differentiation, and disease pathogenesis with the ability to adapt rapidly with tremendous variability in different tissues and in response to stimuli (Sandvik et al., 2006). Transcriptomics and global gene expression are powerful tools used in the field of toxicology and, as in most cases, toxicity is not expected to occur without alterations at the transcriptional level (Eun et al., 2008; Gibb et al., 2011). A common application of transcriptomics in toxicology is to compare gene expression in samples following chemical administration from exposed and nonexposed animals to provide a list of genes that demonstrate altered expression in the diseased group. Such findings not only advance our understanding of disease pathogenesis but they also reveal transcripts that can be qualitatively or quantitatively assessed as new biomarkers.

Within the National Institutes of Health, the term biomarker is defined as follows: a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention (Ilyin et al., 2004). Although a single biomarker can be easily understood, transcriptomic studies have uncovered aggregate measures composed of multiple genes as informative biomarkers of complex disease. Efforts in transcriptomic biomarker development are not restricted to medical diagnostics but include environmental chemical risk assessment and determination of exposure to
FIGURE 63.1   Chapter overview on the use of transcriptomic biomarkers for safety and risk assessment.

microbes or chemical residues in food (Riedmaier et al., 2009a,b,c; Pinel et al., 2010).

Transcriptomic Methods

There are three commonly used methods for assessing transcriptomes: quantitative real-time polymerase chain reaction (qPCR), microarrays, and RNA sequencing (RNA-Seq). Each method has advantages and disadvantages.

qPCR is a targeted method that involves the reverse transcription of mRNA to cDNA followed by the use of short DNA sequences called primers to anneal and amplify known genes from a biological sample. Rapid quantitation of hundreds of transcripts using qPCR is relatively inexpensive, but knowledge of sequences of the candidate transcripts is required.

Microarrays and RNA-Seq were developed more recently, within the last 30 years, with further advancements made in the 21st century (Wang et al., 2009; Nelson, 2001). Microarrays were the preferred method of transcriptional profiling until the late 2000s when the use of RNA-Seq increased (Medline trend, 2017; Nelson, 2001). Microarrays consist of probes, which are short nucleotide oligomers, arranged on a solid substrate, such as glass (Romanov et al., 2014). Relative transcriptional expression is determined by hybridization of fluorescently labeled transcripts to array probes. At each probe location, fluorescence intensity on the array signals transcript abundance for each probe sequence (Barbulovic-Nad et al., 2006). Unlike RNA-Seq, microarrays do require some knowledge of the organism of interest, such as its annotated genome sequence, that can be used to create probes for the array. Microarrays can be further subdivided into low-density spotted arrays or high-density short probe arrays (Heller, 2002). Single- or dual-channel detection of fluorescent tags can be used to record transcript presence. Low-density spotted arrays generally use a range of picoliter amounts of purified cDNAs arrayed on the surface of a glass slide (Auburn et al., 2005). Probes used are longer than those of high-density arrays, often lacking the transcript resolution of high-density arrays. Different fluorophores are used for exposed and nonexposed samples in spotted

arrays; the ratio of fluorescence is used to determine a relative calculation of abundance (Shalon et al., 1996). High-density arrays, popularized by Affymetrix GeneChip array (Santa Clara, CA), quantify transcripts using several short 25-mer probes (Irizarry et al., 2003).

RNA-Seq combines high-throughput sequencing methodology with computational methods to assess and quantify transcripts present in an RNA extract (Ozsolak and Milos, 2011). As previously indicated, RNA-Seq usage exceeded the use of microarrays as the dominant transcriptomics technique in 2015 (Medline trend, 2017). Typical nucleotide sequences generated are approximately 100 base pairs (bp) in length, with a range of 30 bp to over 10,000 bp dependent on sequencing method used. RNA-Seq couples deep sampling of the transcriptome with many short fragments from a transcriptome to permit computational assembly of the original RNA transcript by aligning reads to a reference genome or to each other, the latter referred to as de novo assembly (Wang et al., 2009). RNA-Seq has a typical dynamic range of five orders of magnitude over microarray transcriptomes; additionally, input RNA quantities are much lower for RNA-Seq (nanogram quantity) compared with microarrays (microgram quantity). This allows more detailed examination of cellular structures down to single cells when used with linear amplification of cDNA (Hashimshony et al., 2012). Background signal is very low for 100 bp reads in nonrepetitive regions, and, in theory, there is no upper limit of quantification in RNA-Seq (Ozsolak and Milos, 2011). RNA-Seq can be used to identify genes within a genome or identify what genes are upregulated or downregulated at a specific point in time. Read counts and a simple quantitation approach allowing for the comparison across data sets can be used to correctly model relative gene expression.

These three methods of assessing the transcriptome all have their benefits and challenges when compared with one another, and each method's utility is dependent on the application and/or function of the study and outcome. Although RNA-Seq has already begun to replace microarrays in basic research, clinical studies will likely use both approaches depending on scientific goals, sample size, and cost. Looking forward, it is clear that advances in our fundamental understanding of gene transcription

and rapidly advancing techniques for transcriptome assessment will have a continued impact on biomarker development. However, one hurdle in the field is to establish better platforms for the reproducibility and predictive accuracy between sites (Fielden et al., 2008).

Types of Transcriptomic Biomarkers

There are two frequently used types of transcriptomic biomarkers: mRNA and micro RNA (miRNA). Two other transcriptomic biomarkers less commonly used are noncoding RNA and circular RNA (circRNA).

mRNA biomarkers are already an established method in several scientific fields. Diseased tissue can be distinguished from nondiseased tissue by analyzing the expression of specific genes. Use of mRNA gene expression analysis is helpful when validating differentiation of types or stages of diseases. miRNAs are endogenous noncoding RNA of approximately 19−22 nt in length (Krol et al., 2010). Transcription of miRNAs occurs via RNA polymerase II, resulting in primary miRNA with 500−−3000 nucleotides (Benz et al., 2016). Primary miRNA is next cleaved into premature miRNA of 70−80 nucleotides in length by the "microprocessor complex," consisting of RNase III Drosha enzyme and the DiGeorge syndrome critical region 8 (DGCR8) protein (Lee et al., 2003). Premature miRNA is exported into the cytoplasm with aid of the nuclear export transporter, exportin 5, processing about 22 nucleotides by interacting with RNase III endonuclease Dicer protein and the cofounder double-stranded transactivation-responsive RNA-binding protein (Lund et al., 2004). This duplex is integrated into the "RNA-induced silencing complex" following binding to the argonaute protein and a glycine tryptophan repeat-containing protein, where they bind to partial or total complimentary sequences in the 3′ or 5′ untranslated region of the target mRNA (Ha and Kim, 2014; MacFarlane and Murphy, 2010). miRNAs are involved in posttranscriptional processing of mRNA. In this way, they are able to regulate physiological pathways and metabolic processes and therefore impact the entire cellular physiology, organ development, and tissue differentiation. The expression of miRNAs can be measured in cell culture samples. These miRNAs are also present in body fluids, such as urine, blood, and breast milk (Laterza et al., 2009; Kosaka et al., 2010; Kroh et al., 2010). Identification of single biomarkers on the mRNA or the miRNA level is not possible in most pathological disorders. In such cases, a set of multiple biomarkers must be present to distinguish between specific disease types, disease states, or applied treatments. Bioinformatics is one approach that can be used to integrate the data analysis of multiple biomarker levels of different types of RNA. This could help to generate an integrative gene expression pattern (Molloy et al., 2011). To achieve this goal, different multivariate analysis methods are available which are used for biomarker selection and validation, namely hierarchical cluster analysis and principal components analysis.

Noncoding RNAs can be subdivided into small noncoding RNAs, which are shorter in length than 200 nucleotides (nt), and long noncoding RNAs (lncRNA), which are greater than 200 nt in length (Gibb et al., 2011). LncRNA transcripts do not code for proteins; there are greater than 60,000 members of the lncRNA family that have been catalogued (Volders et al., 2012, 2014). While the primary sequence of lncRNAs is not well conserved, it can be partially compensated through a high level of structural conservation (Johnsson et al., 2014). LncRNAs can be transcribed from conserved genomic regions (Boon et al., 2016) and back-splicing of exons, also capable of forming circRNAs (Jeck et al., 2013; Memczak et al., 2013). LncRNAs play an important role in the pathogenesis of several diseases as they are involved in cell functioning, including roles in chromatin rearrangement, histone modification, modification of alternative splicing genes, and regulation of gene expression (Hu et al., 2017; Fan et al., 2017). CircRNAs have recently been demonstrated to be widespread and abundant within transcriptomes (Jeck et al., 2013; Memczak et al., 2013; Jeck and Sharpless, 2014). CircRNAs are not formed by the usual model of RNA splicing but primarily from the exons of protein-coding genes (Salzman et al., 2012). CircRNAs are characterized by covalently closed loop structures through joining the 3′ and 5′ ends together via exon or intron circularization (Jeck and Sharpless, 2014; Zheng et al., 2016). Formation of circRNAs occurs through two varied mechanisms of exon circularization: intron-pairing-driven circularization and lariat-driven circularization (Jeck et al., 2013). When introns between exons form circular structures, they are removed or retained to form exon-only circRNA or intron-retaining circRNA known as ElciRNA (Jeck et al., 2013; Li et al., 2015). CircRNAs can also be formed by the circularization of two flanking intronic sequences (Conn et al., 2015; Ashwal-Fluss et al., 2014). To date, several circRNAs have been identified in organs or tissues, with some linked to disease, indicating that circRNAs have a role beyond being by-products of mis-splicing or splicing errors (Wang et al., 2016; Zheng et al., 2016). Many circRNAs have been found to behave as "miRNA sponges" to regulate gene expression (Memczak et al., 2013; Zheng et al., 2016; Hansen et al., 2013).

TRANSCRIPTOMICS IN BIOMARKER DISCOVERY

Transcriptomic approaches have been used by various researchers to identify novel biomarkers, which

are beginning to influence both clinical practice and environmental chemical risk assessment. This section focuses on biomarkers of cardiovascular disease and hepatotoxicity, exposure to infectious agents, tobacco products, anabolic steroids, beta-agonists, and use of biomarkers in pathway analysis for quantitative environmental chemical risk assessment.

Cardiovascular Biomarkers

Cardiovascular disorders are responsible for high morbidity and mortality and can lead to a substantial economic burden at the individual, institutional, and national levels. The use of the human cardiac transcriptome as a biomarker to improve clinical diagnosis is slow to develop, mostly due to risks and complications associated with endomyocardial biopsies (Zhang et al., 2003). However, recent transcriptomic experiments using human cardiac biopsies have been conducted and used to identify specific causes of cardiomyopathy (Farazi et al., 2011) including subtypes of myocarditis (Soga et al., 2002). The ST2 protein, encoded by the IL1RL1 gene, is markedly elevated in patients with heart failure and exists in a soluble form that can be measured in peripheral blood. ST2 was first identified as a potential biomarker upregulated in an in vitro transcriptomics study involving myocardial stretch. Follow-up studies in animals have suggested ST2 is part of a cardioprotective paracrine signaling axis between cardiac fibroblasts and myocytes (Sanada et al., 2007; Kakkar and Lee, 2008). ST2 signals the presence and severity of adverse cardiac remodeling and tissue fibrosis, which routinely occurs in response to myocardial infarction, acute coronary syndrome, or worsening heart failure. ST2 use as a biomarker has considerable prognostic value and is used as an aid for risk stratification in identifying patients who are either at high risk of mortality or need rehospitalization. As a result of these biomarker discovery studies, a commercial-grade soluble ST2 assay for use in assessing prognoses of chronic heart failure has been cleared by the United States Food and Drug Administration (US FDA) (Presage, Critical Diagnostics, San Diego, CA). Although the ST2 immunoassay measures protein levels in the blood, the use of transcriptomics was vital in its discovery. The initial findings of the transcriptomic screens have led to both a novel cardiac biomarker and therapeutic target for heart failure.

The use of miRNAs as a cardiovascular disease biomarker is promising across several endpoints. They are considered to be involved in fibroblasts proliferation, collagen synthesis, and connective tissue growth factor signaling (Angelini et al., 2015). The implication of miRNAs in heart failure was also demonstrated; its increased expression can depress cardiac function (Wahlquist et al., 2014). Other associations between miRNAs and cardiovascular endpoints include cardiac hypertrophy (Care et al., 2007; Bang et al., 2014), acute coronary syndrome (Widera et al., 2011), acute myocardial infarction (Ji et al., 2009; Wang et al., 2009; Corsten et al., 2010; D'Alessandra et al., 2010), hypertension (Li et al., 2011), and heart failure (Latronico et al., 2007; Tijsen et al., 2010). Above all, there are a large number of detectable miRNAs, but only a few that may currently provide valuable information. This area remains largely under investigation for cardiovascular endpoints.

Hepatic Biomarkers

Several studies have used transcriptomics to identify biomarkers of hepatotoxicity and to determine their mechanism of action (Kussmann et al., 2006; Mutlib et al., 2006; Nie et al., 2006; Tugendreich et al., 2006; Fielden et al., 2007; Eun et al., 2008). Liver gene expression profiling by microarray technology was used to develop biomarkers for nongenotoxic hepatocarcinogens (Fielden et al., 2007). Fielden et al. (2007) collected hepatic gene expression data from rats treated for 5 days with 47 test chemicals. They observed that this short-term in vivo rodent model was more sensitive, more accurate, and provided quicker results when compared with the traditional models for risk assessment of nongenotoxic carcinogens. qPCR has also been used for the identification of biomarkers of toxicity (Ellinger Ziegelbauer et al., 2009). These studies demonstrate that transcriptomic technologies are valuable sensitive tools for screening hepatotoxic and hepatocarcinogenic potential of suspected test agents, although their biomarkers and mechanisms of action may be different.

Liver transplantation is a surgical procedure in which a liver that no longer functions properly is removed and replaced with a healthy liver from a living or deceased donor. The unique characteristics of the liver transplant present opportunities to decipher the immunological mechanisms underlying allograft survival and to develop therapeutic targets aimed toward tolerance strategies. RNA-Seq is beginning to be capitalized on to provide insights into normal, pathological, and pharmacological processes (Mastoridis et al., 2016). The integration of clinical and molecular data becomes essential to the pursuit of advancing the field of transplantation and developing personalized therapy.

Biomarkers of Anabolic Agents

Screening for anabolic agents such as steroid hormones (testosterone or estrogen) and beta-agonists in meat-producing animals demonstrates an application of transcriptomics for use in safety and regulatory monitoring. In agricultural meat-producing animals, the myotropic, growth-promoting properties of steroid

hormones and beta-agonists are beneficial because of increased productivity and reduced costs with weight gain and feed efficiency (Chwalibog et al., 1996). As a consequence, hormone and drug residues in meat are increased and adverse side effects to the consumer occur (Daxenburger et al., 2001; Lange et al., 2001; Maume et al., 2001; Swan et al., 2007). Questions and controversy over the impacts of these added hormones on human development and health have lingered for decades. The use of growth promoters is approved in the United States, Canada, Mexico, Australia, and South Africa, and although the US FDA does not currently regulate their use in cattle, these drugs are prohibited for over-the-counter use by humans. The European Union (EU) forbids the use of these substances, including the importation of meat from animals treated with these substances. To enforce the EU rules, the monitoring of anabolic agents in meat is necessary. Current methods to uncover the abuse of anabolic agents in animal residues are limited to immune assays or chromatographical methods (Mayer et al., 1991, 2011) which can only detect known substances. The use of transcriptomics is a promising approach to develop a biomarker pattern based on physiological changes that result after illegal application of anabolic agents. Discovery of a single transcription biomarker in cattle for a particular organ or tissue is challenging; therefore, gene expression profiles, the measurement of several genes at one time, is used (Riedmaier et al., 2009a,b,c). Promising candidate genes and gene profiles for the development of a biomarker screening method in cattle include insulin-like growth factor 1 in liver and muscle (Johnson et al., 1998; Pfaffl et al., 2002; Reiter et al., 2007), steroid hormone receptors in the liver, muscle, uterus, gastrointestinal tract, kidney, prostate and blood cells (Pfaffl et al., 2002; Toffolatti et al., 2006; Reiter et al., 2007; Riedmaier et al., 2009a,b,c), and various inflammatory, apoptotic and proliferative genes in blood cells (Chang et al., 2004; Cantiello et al., 2007; Riedmaier et al., 2009a,b,c). Agonists for the beta adrenergic receptor are known to effect mRNA expression of different muscle proteins, such as α-actin, myosin, or calpastatin in cattle. Overall, the use of transcriptomics and other omics technologies can be used to develop new screening methods for the detection of the misuse of anabolic steroids and beta-agonists for public health protection.

Infectious Agents and Sepsis

One of the most common causes of mortality among hospitalized patients in the intensive care unit (ICU) is sepsis. Sepsis can be challenging to diagnose among patients in the ICU due to multiple comorbidities and underlying conditions (Novosad et al., 2016; Vincent et al., 2009). In 2016, after 25 years of no change in definition,

the Sepsis-3 conference redefined sepsis as a "life-threatening organ dysfunction caused by a deregulated host response to infection," and septic shock as a "subset of sepsis in which underlying circulatory and cellular/metabolic abnormalities are profound enough to substantially increase mortality" (Singer et al., 2016). Laboratory biochemical, microbiological, and hematological testing is fundamental in the diagnosis of sepsis. Because culture-based diagnosis is lengthy, considerable effort has been made to uncover biomarkers that allow early diagnosis of sepsis. Currently, biomarkers alone are not sufficient for diagnosis of sepsis and should accompany thoughtful clinical assessment and other supportive laboratory data (Faix, 2013; Vincent, 2016).

Most frequently in sepsis, serum protein inflammatory biomarkers are used. Sepsis can be separated into two successive phases, the initial hyperinflammatory phase, which may resolve or come before the secondary immunosuppressive phase, generally characterized by organ dysfunction. Markers are available for both phases but biomarkers of the hyperinflammatory phase predominate and include procalcitonin (PCT) and C reactive protein (CRP). The second immunosuppressive phase contains biomarkers such as human leukocyte antigen-D related (HLA-DR).

CRP is an acute-phase protein often manufactured in the liver and can rapidly rise in a few hours after exposure. Peripheral blood mononuclear cells have demonstrated upregulation of CRP mRNA in response to endotoxin, the most common cause of sepsis (Haider et al., 2006). CRP plasma concentration appears to reflect sepsis severity (Miglietta et al., 2015). Although CRP does not differentiate sepsis from other diseases, it is particularly useful to screen for early onset neonatal sepsis (Hofer et al., 2012) and to monitor patients after surgery (Watt et al., 2015). PCT is generally considered the most useful biomarker of sepsis (Riedel et al., 2011). Its production is stimulated similarly to that of CRP. PCT can discriminate between infectious and noninfectious systemic inflammation in critically ill patients (Harbarth et al., 2001) and may be able to differentiate between viral and bacterial infections (Ahn et al., 2011). PCT mRNA expression is elevated in septic tissues versus nonseptic tissues in the hamster model (Domenech et al., 2001).

HLA-DR expression on the cell surface is a key indicator of immune response due to its vital role in antigen presentation. Expression of HLA-DR is lower in septic patients than in nonseptic patients, but its expression may also be low due to other causes of a weakened immune system (Das, 2014). Reduced HLA-DR expression in septic patients has also been determined transcriptionally (Winkler et al., 2017). Biomarkers of organ dysfunction include the following: lactate, venous to arterial

carbon dioxide pressure difference, proadrenomedullin (MR-proADM), and cell-free DNA (cf-DNA). Hyperlactatemia, high blood lactate level, is considered a severe sepsis marker of organ dysfunction, as it indicates poor tissue perfusion (Rello et al., 2017). Levels of CO_2 in the blood above 6 mmHg within the first 24 h in critically ill patients are correlated with higher mortality (He et al., 2016). Higher levels of MR-proADM are associated with greater mortality, and investigations demonstrate that it has also been observed transcriptionally (Becker et al., 2004). Cf-DNA levels are greater in sepsis patients than in healthy individuals, but cf-DNA is found after cell death.

Sepsis is a major public health concern due to its high mortality and morbidity. Protein biomarkers are commonly used in the diagnosis of sepsis, but several studies utilizing precursor biomarker mRNA are promising in the pursuit of more rapid diagnostics. Combinations of biomarkers are likely needed for sepsis diagnosis and treatment due to its high complexity in the patient. Combinatorial biomarker assessments can likely be performed more rapidly using transcriptional analyses in the future.

Tobacco and Risk Continuum

Since 2009, the US FDA Center for Tobacco Products has had authority to regulate the manufacture, distribution, and marketing of tobacco products with the goal of reducing death/disease from consumer use. Biomarkers could play an important role, including transcriptomics, across a number of FDA regulatory activities, including assessing new and modified risk tobacco products and identifying and evaluating potential product standards. The concept that not all tobacco and nicotine products present the same risks to human health is not a novel concept as there is clearly a large difference in the health risks associated with cigarette smoking when compared to medicinal nicotine products. There have been attempts to describe a "risk continuum" placing various nicotine product categories within a paradigm (Fig. 63.2). On July 28, 2017, FDA noted, "A key piece of the FDA's approach is demonstrating a greater awareness that nicotine — while highly addictive — is delivered through products that represent a continuum of risk and is most harmful when delivered through smoke particles in combustible cigarettes" (FDA, 2017).

Smoking is a major risk factor for developing oral squamous cell carcinoma, but less attention has been paid to the effects of smokeless tobacco products. Using oral cell lines, potential biomarkers distinguishing biological effects of combustible tobacco products from
FIGURE 63.2 Hypothetical example of a tobacco product risk continuum.

those of noncombustible tobacco products have been identified (Woo et al., 2017). Microarrays revealed xenobiotic metabolism and steroid biosynthesis as two pathways upregulated by combustible but not by noncombustible products. Notably, aldo-keto reductase genes, *AKR1C1* and *AKR1C2*, were the genes in the top enriched pathways and were statistically upregulated more than eightfold by combustibles. *AKR1C1* was further supported by qPCR as a potential biomarker for differentiating the biological effects of combustible from noncombustible tobacco products.

Electronic Nicotine Delivery Systems (ENDS, electronic cigarettes or vapor products) are gaining in global popularity and generate a heated aerosol comprised of purified nicotine and generally recognized as safe ingredients. An expert review concludes that e-cigarettes are around 95% safer than smoked tobacco and they can help smokers to quit (Public Health England, 2015). RNA-Seq analysis has been used to examine the transcriptomes of differentiated human bronchial epithelial cells exposed to air, tobacco smoke, and ENDS aerosol in an in vitro air—liquid interface model for cellular exposure. Results indicate that ENDS do not elicit many of the cell toxicity responses observed from combustible cigarette smoke exposure. These transcriptomic studies establish a baseline for future analysis that can better inform the FDA of the risks and future regulation of these products while comparing them to the greater health-risk combustible cigarettes. Currently, there is a lack of systematic effort or FDA guidance by the Center for Tobacco Products to identify transcriptomic biomarkers that would have utility and validity for evaluating tobacco products. Omics research could further strengthen the

applicability for tobacco regulatory science to better understand the risk continuum for overall public health protection.

Environmental Chemical Risk Assessment

The US EPA, the National Toxicology Program (NTP), and the National Research Council recommend the use of pathway analysis as a basis for toxicity testing and chemical risk assessment (Collins, 2008; Thomas et al., 2012). To date, transcriptomics have not yet translated to a toxicity value derivation for regulatory purposes. Transcriptomic data in risk assessment have focused on supportive roles, elucidating a chemical's mechanism or mode of action (Thomas et al., 2012) that underlies chemically induced noncancer and cancer endpoints. Female B6C3F1 mice were previously exposed to multiple concentrations of five chemicals (1,4-dichlorobenzene, propylene glycol mono-t-butyl ether, 1,2,3-trichloropropane, methylene chloride, and naphthalene) that had tested positive for lung or liver tumor formation in 2-year rodent cancer bioassays conducted by the NTP (Thomas et al., 2011). The dose—response changes in gene expression were analyzed using a standard benchmark dose modeling (BMD) approach and then grouped based on cellular/biological processes. The transcriptional points of departure for the five chemicals were compared with both cancer and noncancer points of departure based on apical endpoints. Overall, the transcriptomic responses corresponded closely with both noncancer and cancer apical responses as a function of dose, and their use as a point of departure is beginning to look promising.

As the field continues to evolve, additional studies have demonstrated that transcriptional points of departure correlate with those derived from apical endpoint changes, resulting in a suitable transcriptomic biomarker; however, there is currently no consensus on the process. Eleven approaches have been identified from apical data showing promise for chemical risk assessment (Farmahin et al., 2017). This was accomplished using published microarray data from dose—response studies across several chemicals in rats exposed orally for up to 90 days. It is promising for this field that transcriptional BMD values for all approaches aligned well with corresponding apical points of departure.

Cancer risk assessment from exposure to environmental chemicals has also benefited from transcriptomic biomarkers. Positive genotoxicity findings are a major challenge to industry and regulatory agencies when these tests produce irrelevant positive findings (i.e., positive results in vitro that are not relevant to human cancer hazard). In vitro transcriptomic biomarker-based approaches have also been developed that provide biological relevance to positive genotoxicity assay data, particularly for in vitro chromosome damage assays (Li et al., 2017).

Transcriptomic changes in canonical pathways are a promising approach to identify biomarkers to estimate the noncancer and cancer points of departure for use in quantitative risk assessments. The high correlation between these pathways and rodent toxicity indicates the need for further investigation of their role in these endpoints and examination of their relevance to human responses. If they are relevant, these pathways could be considered toxicity pathways and used as the basis for future high-throughput toxicity screen.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Transcriptomics as a discipline is still evolving, and although there are no clearly defined methods for the discovery of biomarkers using gene expression technologies, the potential of this new field seems promising. There is a growing demand for transcriptional biomarker development in a variety of applications, including the following: clinical diagnosis, pathological processes, biomarkers for environmental chemical exposure or response, and safety evaluation. The discovery of predictive markers that precede pathology should be able to lessen the adverse impact to health. Because gene transcription is a very dynamic process able to adapt rapidly to environmental, physiological, or pathological changes, the transcriptome is a preferred data set for the identification of sensitive and predictive biomarkers. It is conceivable that both a single biomarker and the concept of multimarker panels will become the standard in biomarker research (Ky et al., 2011). To validate an identified transcribed biomarker set with high significance, the application of bioinformatics is necessary. Considering that there are different levels at which biomarkers can be measured and evaluated, and as technologies advance, new categories of transcriptomic biomarkers will continue to emerge and offer opportunities to significantly improve risk assessment while reducing cost.

Percellome Toxicogenomics Project as a Source of Biomarkers of Chemical Toxicity

Jun Kanno

Japan Bioassay Research Center, Japan Organization of Occupational Health and Safety, Hadano, Japan

INTRODUCTION

Toxicology is a field of science to study interaction of the living organisms and the chemicals or xenobiotics, and its aim is to ensure human safety. For this aim, chemicals to which we encounter daily are tested by experimental animals, and the toxicity data thereof are extrapolated to humans. This classical approach is based on an assumption that experimental animals and humans should respond similarly to an exogenous chemical. And this approach has been apparently robust for nonspecific toxicity targets such as respiratory chain disruption, DNA damage, and radical oxygen species generation. However, thalidomide showed us that this classical approach has a serious blind spot. Incorporating the recent achievements of the basic biology, new molecular toxicology deals with various kinds of toxicological phenomena via a specific receptor or transcription factor, or modifying epigenetic regulation systems. These targets are often related to delayed adverse effect when exposed to an organism in phases of development and maturation. New pharmaceuticals are also molecular targeted and drug evaluation authorities are in need of molecular biology-based toxicology.

Although "first in human" has been a trend in the field of drug development, the incidence of TGN1412 still reminds us that there are issues to be studied for species differences and similarities at molecular level. There are other factors that human is difficult to use for toxicity assessment. One example is the assessment of combined exposure of a chemical to drugs and quasi-drugs, supplements, and health foods. Another example is the embryo and child to which voluntary clinical trials are often difficult to conduct.

To modernize the experimental animal toxicity studies, we initiated a project to draw the comprehensive and dynamic changes in gene network of the liver and other organs induced by exogenous chemicals. By compiling the drawings into a database, we attempted to build a systems toxicology for the mechanism-based prediction of toxicity of both old and new chemicals. For this purpose, we developed a standardization method designated "Percellome method" (Kanno et al., 2006; Kanno, 2015). This method generates absolute copy number of mRNA in a per one cell bases as an average of a test organ or tissue. The standard animal study was designed to monitor time course and dose response at once, and to plot the gene expression data in a single 3-dimensional surface graph with dose levels in X-axis, time in Y-axis, and mRNA in copy number in Z-axis (Fig. 64.1). A series of homemade algorithms and software programs are prepared for handling and analyzing the 3D surface data. More than 140 chemicals (Table 64.1) chosen for various characteristics were tested for liver and other organs including lung, kidney, heart, hippocampus, etc., in more than 370 studies (one study consist of four time points and four dose levels with organ samples in triplicate). The variation in protocol includes single oral gavage with 2, 4, 8, and 24-h sampling, repeated dosing, and others. More than one organ is sampled in most studies up to six in special studies. The data represent the average of the sampled organs.

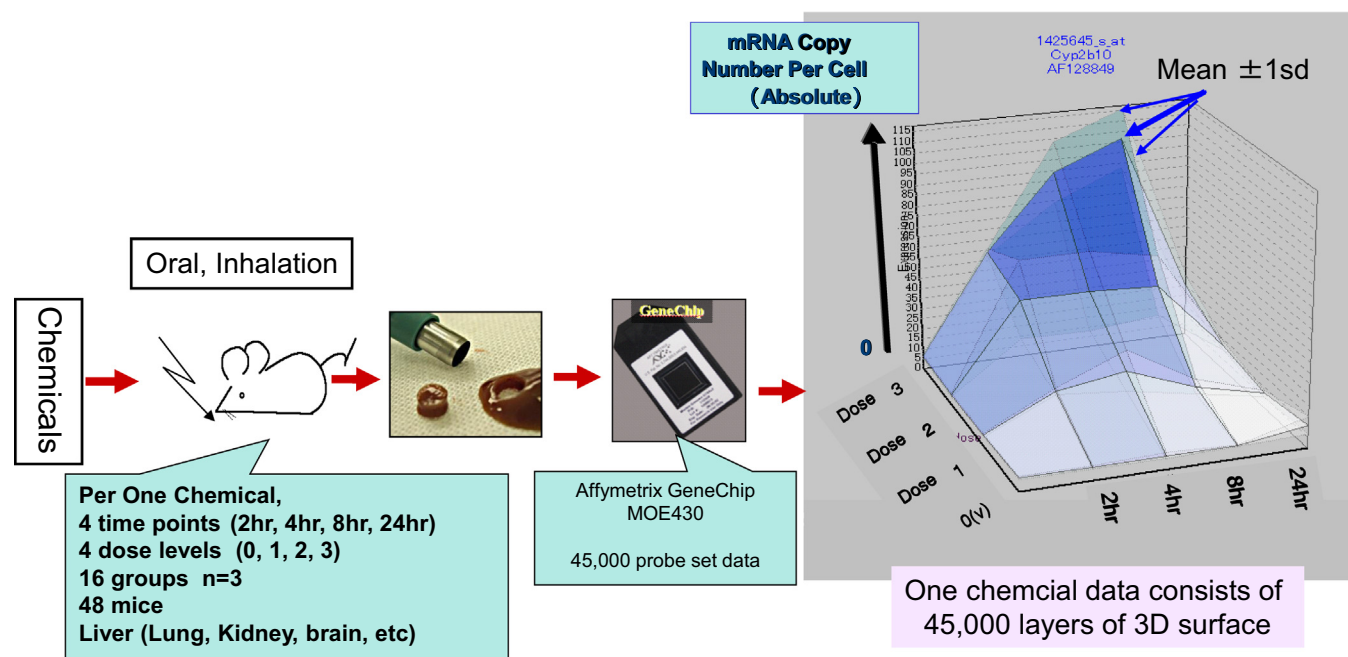
During the process of preparing the project, we found that the quality of gene expression data is highly dependent on the level of control over the animals' husbandry. The most important factor was the circadian change of the mRNA; some genes show 10-fold changes only by the time of day. After knowing the phenomenon, the light—dark cycle of the animal facility has been strictly controlled, and the treatment and sampling is conducted swiftly at the fixed clock time.


FIGURE 64.1   Standard experimental protocol of Percellome Project and 3-dimensional surface graph for visualization of the gene expression data.

We are still on the way to develop the fully operational systems toxicology. The high-resolution gene expression data are similar to the electron microscopy. When invented, the images first seen were new to anybody. Until the text book or the atlas is complied, many photographs are taken under a standardized sampling and staining method. The concept of data analysis is shown in Fig. 64.2. A chemical is considered as a stone thrown into a water surface of gene network, and Percellome project monitors the ripples by unsupervised clustering of the genes according to the shape of the 3D surface. The limitation is clear that the transcriptome monitors only the gene expression and misses the protein reaction. However, as shown below, we believe that at least some of the protein reactions are monitored by transcriptomics as a shadowgraph. The power of large database consisting of standardized data of similar quality would be demonstrated by cross-referring the individual data. As illustrated in Fig. 64.3, the gene network as a sphere of water is probed by multiple chemicals, and the data of each intersection are becoming available at high precision by our software programs.

Nevertheless, at this stage, we would like to show two examples of our analysis that new confirmative information is generated for chemicals near us. We show that proteins known to be controlled by phosphorylation, which is impossible to directly monitor by mRNA transcriptome, was monitored as upregulation of the relevant gene as a shadowgraph. At the end, joining the rat toxicogenomics data to mouse Percellome data and an ongoing analysis of the New repeated dosing

experiments and Garuda Platform to facilitate data handling are briefly demonstrated.

By publicizing the Percellome database along with the homemade analysis tools for 3D surface data via the Garuda project, we hope the data analysis will be accelerated by the help of toxicologists and bioinformaticians worldwide.

MATERIALS AND METHODS FOR PERCELLOME DATA GENERATION AND EXAMPLE STUDIES

Experimental animals and dose setting

Male C57BL/6 Cr Slc (SLC, Hamamatsu, Japan) or male C57BL/6J (Charles River, Japan) mice (48 mice per study) maintained in a barrier system with a 12-h photoperiod (starts at 8:00) were given a single oral dosage (between 10:00 and 10:20) of test chemicals at a ratio of 0, 1, 3, and 10 and the liver was sampled at 2, 4, 8, and 24 h postgavage (three animals from each dosages groups). The top dose for each chemical is set, referring to the dose-setting preliminary study, as the maximum dose that is negative for treatment-related symptoms and for macroscopic and microscopic changes in target organs such as liver and lung in 24 h after single gavage. In general, the maximal doses in the Percellome studies are 10- to 100-fold lower than the reported maximum tolerated doses (MTDs). To minimize the effect of circadian oscillations in the transcriptome, 12 animals were processed at each time point

at a speed of 2.5 min per mouse from initiation of anesthesia to immersion of the organ samples into RNAlater solution, keeping the total elapsed time within 30 min.

Microarray data generation

As reported previously (Kanno et al., 2006), tissue blocks soaked in RNAlater (Ambion Inc., TX) were kept overnight at 4°C until use. RNAlater was replaced with RLT buffer (Qiagen GmbH., Germany) and

homogenized. A small aliquot of the homogenate was treated with DNAse-free RNase A and Proteinase K, and the DNA concentration was measured by PicoGreen fluorescent dye (Molecular Probes Inc., USA). In proportion to the DNA contents, each sample homogenates were spiked with the grade-dosed spike cocktail (GSC; cocktail of five *Bacillus subtilis* RNA sequences selected from the gene list of Affymetrix GeneChip arrays AFFX-ThrX-3_at, AFFX-LysX-3_at, AFFX-PheX-3_at, AFFX-DapX-3_at, and AFFX-TrpnX-3_at) and then processed by the Affymetrix Standard protocol to apply to Mouse 430 2.0 GeneChip. The raw readouts were converted to Percellome data. The mean value (m) with standard deviation (sd) was calculated for all of the probesets (PSs) for each dose time points. To better visualize the changes in 2 h, 2-h vehicle value was used for putative 0-h data and drawn a 5×4 surface graph with X-axis for dose, Y for time, and Z for expression, in which thick colored mean surface and two thin blue-colored $\pm 1sd$ surfaces are overlaid (Fig. 64.1). The mean surface is rainbow-colored from blue, green, red, to yellow according to its peak values (cf. http://toxicomics.nihs.go.jp/db/).

COMPREHENSIVE SELECTION OF RESPONDING mRNAs

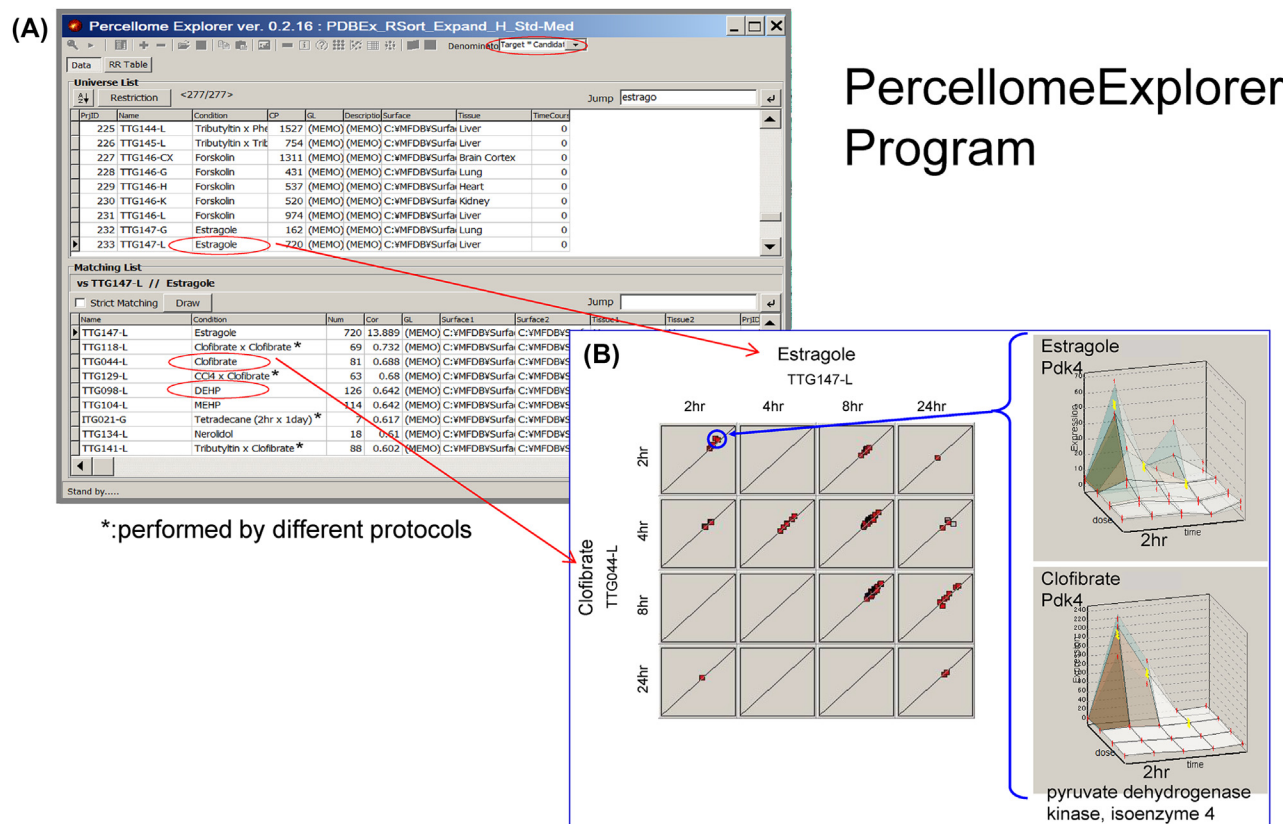
A homemade software program named RSort was used for automatic selection of treatment-responding mRNAs. This program firstly sorts the PSs based on


FIGURE 64.4 Finding chemicals sharing similar gene expression profile by PE software. Data automatically generated by RSort program are used in this program. (A) The lower window shows the result of search that the most similar chemical to estragole by the same protocol was clofibrate followed by DEHP. (B) A sub window generated by this software indicating the numbers of PSs with the peak time. One plot can be visually checked by several clicks as shown in the right-hand side for Pdk4 gene.

the roughness of the 3D surface; it calculates the numbers of peaks (upward and downward) in each surface and sort the surface by the number of the peaks (1−8 peaks in 4×4 grid). Secondly, it filters the PSs by the roughness (normally surface with more than three peaks are discarded) and several parameters such as maximum expression level (detection level of GeneChip, 1 copy per cell for liver samples), P values between vehicle and top dose groups ($P < .05$ or $P < .01$). In this study, RSort program selected surfaces with the number of peaks three or less, with first or second peaks in high doses (at any time) or with first or second peak in middle doses if its mean values are statistically insignificant to that of the neighboring high-dose peak at $P < .01$ by student's t-test, and the mean value of the selected highest or lowest peaks is significantly different from that of vehicle control at $P < .05$ by student's t-test. These auto-selected PSs were visually checked for its surface shape, eliminating noise data, and subdivide into those showed initial changes at 2, 4, 8, and 24 h. Another program named Percellome Explorer (PE) was used to select a list of chemicals that share PSs with a particular chemical of interest. The PE contains the gene lists automatically selected by the RSort of all data in our

Percellome Project (341 datasets for liver samples, 200 for all samples), and automatically sorts out the chemicals sharing same PSs by its number (cf. Fig. 64.4). The automatically selected gene lists (product sets) were visually checked to remove noise surfaces.

ESTRAGOLE STUDY

The flavor compound estragole (1-allyl-4-methoxybenzene) (CAS No.: 140-67-0) is a major component of tarragon, as well as of oils obtained from basil and other plants. Estragole (98%) from Sigma−Aldrich (Catalog No. A29208-25G, lot No.: 05202AH) at a dose of 100 mg/kg caused no observable effects after 24 h in dose finding study. Percellome study was conducted at doses of 0, 10, 30, and 100 mg/kg dissolved in corn oil (Sigma−Aldrich, C8267) and delivered by gavage (Kanno et al., 2012).

PENTACHLOROPHENOL STUDY

The pesticide pentachlorophenol (PCP) (CAS No.: 87-86-5) at a dose of 100 mg/kg caused no observable

effects after 24 h in dose finding study. Percellome study was conducted at doses of 0, 10, 30, and 100 mg/kg dissolved in 0.5% methyl cellulose (Shin-Etsu Chemical Co., Ltd. Tokyo, Japan) and delivered by oral gavage (Kanno et al., 2013).

MERGING OF TGP DATA TO PERCELLOME DATABASE

A government—private sector joint research project, Toxicogenomics Project, so-called TGP (2002—2011), was initiated by the National Institute of Health Sciences (NIHS) and an alliance of 17 Japanese pharmaceutical companies. Rat liver was chosen as a primary target because the member companies already had their own rat data. The project adopted the Percellome method and was set up by a group of scientists in the NIHS. Up to 150 chemicals were monitored for rat liver transcriptome on acute phase (3, 6, 9, and 24 h after single gavage), and repeated phase (3, 7, 14, and 28 days during repeated oral dosage) with four dosage levels (Affymetrix GeneChip, Rat Expression 230A, Rat Genome 230 2.0 Array and Human Genome U133 Plus 2.0 Array). In 2005, the whole project was moved from NIHS to the National Institute of Biomedical Innovation (NIBIO) in Osaka, Japan. The data (non-Percellome, 75 percentile global normalization) are available at TG-GATEs homepage (http://toxico.nibio.go.jp/english/datalist.html). As the raw data of TGP contain Percellome spike data, we started to transform TGP data into absolute values using Percellome method and developed a method to combine the rat TGP data and mouse Percellome data using the ortholog-based concatenated ID allowing many-to-many correspondence. Here, examples on clofibrate (CAS No.: 37-07-0) and phenobarbital (CAS No.: 57-30-7) are briefly shown. Doses of clofibrate were 0, 10, 30, and 100 mg/kg dissolved in MC 0.5% with DMSO 0.1% to mouse (http://percellome.nihs.go.jp/PercellomeWeb.dll/EXEC) and 0, 30, 100, 300 mg/kg dissolved in corn oil to rat, and phenobarbital was 0, 15, 30, 150 mg/kg in MC 0.5% to mouse and 0, 100, 150, 300 mg/kg in MC 0.5% to rat.

NEW REPEATED DOSING STUDY

All 48 mice were pretreated with 5.0 mg/kg of carbon tetrachloride (CCl$_4$) for 14 days and on the 15th day, 0, 0.7, 2.0, and 7.0 mg/kg of CCl$_4$ was given to 12 mice each and then sampled at 2, 4, 8, and 24 h (n = 3). Gene expression data were obtained as described above. The expression profile was compared to the single dose study performed at the same dose levels without any pretreatment, i.e., the study performed by the standard Percellome single exposure protocol (cf. Figs. 64.1 and Fig. 64.12).

RESULTS AND DISCUSSION

Estragole Study

As previously reported (Kanno et al., 2012), 1214 upregulated and 244 downregulated PSs were automatically selected and 167 of those were selected visually as biologically feasible. Among those upregulated PSs, Ingenuity Pathway Analysis (IPA) highlighted a certain number of genes encoding proteins associated with the PPAR-alpha. The metabolic enzymes upregulated were Cyp4a10, Cyp4a14, and Cyp4a31, reported to be regulated by PPAR-alpha (Bumpus and Johnson, 2011). The upregulated transporters Slc16a5, Slc25a20, and Slc27a1 are also considered to be regulated by PPAR-alpha. A limited number of genes were related to oxidative stress, apoptosis, and cell proliferation. The genes downregulated could not be assigned to any known pathway by IPA or by searching the literature.

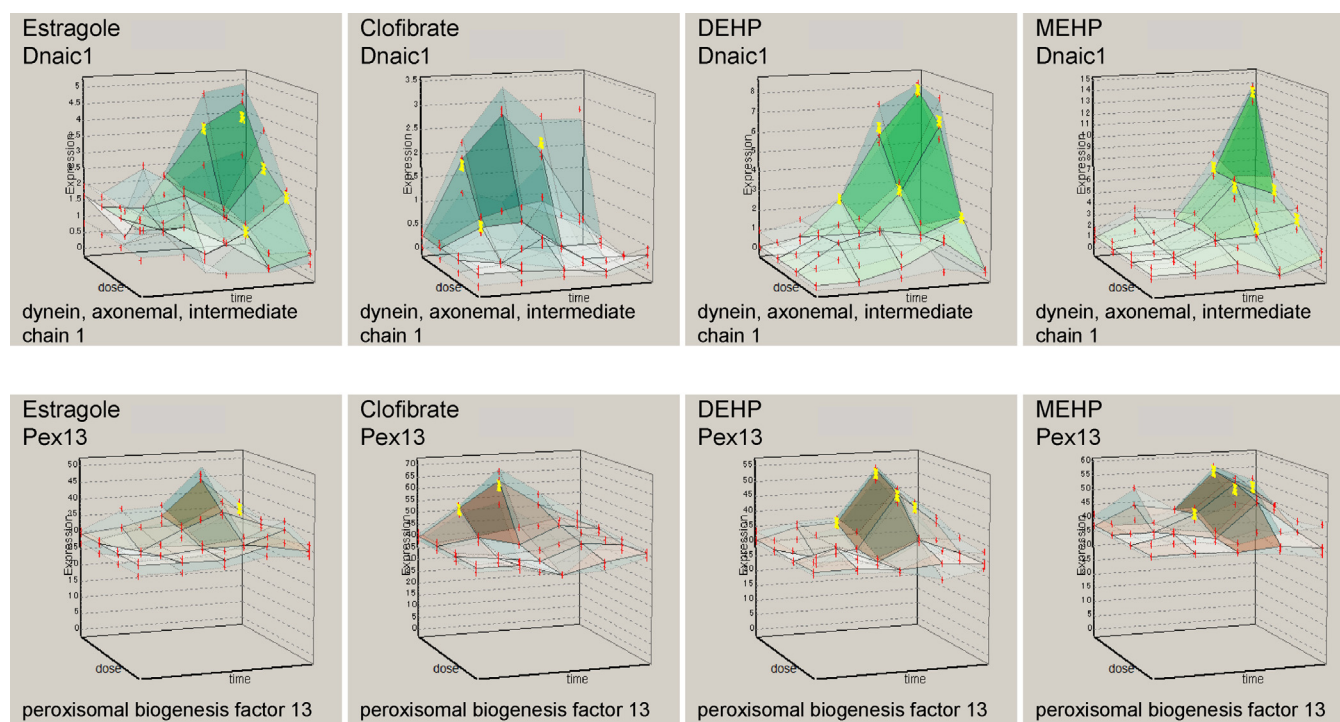
To confirm the result, we scanned the Percellome database by the PE program, which automatically compares the PS lists with all the studies performed. As a result, PE identified clofibrate (81 PSs), followed by di(2-ethylhexyl)phthalate (DEHP) (126 PSs) as the two chemicals most similar to estragole under the same experimental protocol (Fig. 64.4). Clofibrate and DEHP (Lee et al., 1995; Yu et al., 2001) are known as PPAR alpha agonists. The PE program also showed that the time course in induction of PSs is slightly slower in estragole than clofibrate but considerably similar (Fig. 64.4B). Fig. 64.4B also shows that genes commonly induced at 2 h contained isozyme 4 of pyruvate dehydrogenase kinase (Pdk4). Such early-responding genes are considered to be located immediately downstream of the receptor. Dynein, axonemal and intermediate chain 1 (Dnaic1) is induced 8 and 4 h after administration of estragole and clofibrate, respectively, as well as by DEHP, and its metabolite mono-(2-ethylhexyl) phthalate (MEHP) at later time points (Fig. 64.5). Dnaic1 appears to play an important role in peroxisome biogenesis (Brocard et al., 2005; Kural et al., 2005). This delayed induction compared to that of early-response genes, such as Pdk4, might indicate that several mediators are located between PPAR-alpha and this gene. The nature of the pathway, together with a literature search indicate that HNF4A and PEX13 (Odom et al., 2004) may be involved, since the latter is induced slightly by estragole (not significantly) and clearly by clofibrate, DEHP, and MEHP (Fig. 64.5).


FIGURE 64.5   Dnaic1 and Pex13 induction by estragole, clofibrate, DEHP, and its metabolite MEHP. Dnaic1 and PEX13 appear to play an important role in peroxisome biogenesis.

Among the isozymes of cytochrome P-450, Cyp4a10, Cyp4a14, and Cyp4a31 are induced significantly by estragole, as well as by clofibrate and DEHP. On the other hand, Cyp1a2 which is induced slightly by Phenobarbital was not upregulated by estragole. All three of these Cyp4a's are considered to be regulated by PPAR alpha. Whereas DEHP also induces Cyp2b10 and Cyp51, estragole and clofibrate do not. Phenobarbital also induces Cyp2b10 and Cyp51, but not Cyp4a's. Thus, the present Percellome analysis indicates (Fig. 64.6) that DEHP activates two receptors, PPAR-alpha and constitutive androstane receptor (NR1I3 or CAR), which regulates Cyp2b (Ren et al., 2010) and probably Cyp51 (Dekeyser et al., 2011; Xu et al., 2005). In contrast, estragole and clofibrate activate PPAR-alpha, but not CAR.

Expression of the drug and/or metal transporters Slc12a7, Slc14a2, Slc16a1, Slc16a5, Slc22a5, Slc23a2, Slc25a20, Slc25a42, Slc27a1, and Slc29a3 appeared here to be altered by estragole. Again, PE analysis reveals that most of these Slc are also induced by DEHP and clofibrate (not shown). Among these, only Slc27a1 (Francis et al., 2003; Lemoine et al., 2009) has so far been reported to be regulated by PPAR-alpha. However, expression of most of these Slc's including Slc27a1 peaked after 8 h, indicating that these genes may be activated indirectly.

Our novel finding that estragole activates PPAR-alpha signaling may help elucidate the mechanism(s) of its hepatocarcinogenicity, i.e., peroxisome proliferation. Indeed, estragole increases liver weight at a dose lower than the carcinogenic dose (Sixty-Ninth Meeting of the Joint FAO/WHO, 2009). Although recent reports on estragole carcinogenicity suggest involvement of its metabolites (Ishii et al., 2011) or glucocorticoid pathways (Kaledin et al., 2009), our Percellome data did not support the involvement of such pathways or its genotoxicity which can be monitored indirectly as an enhancement in DNA repair and responses to oxidative stress. Interestingly, DEHP and Wyeth 14,643, well-characterized nongenotoxic rodent hepatocarcinogens that evoke tumors through peroxisome proliferation, gave mutation in Lac Z transgenic mice (Boerrigter, 2004).

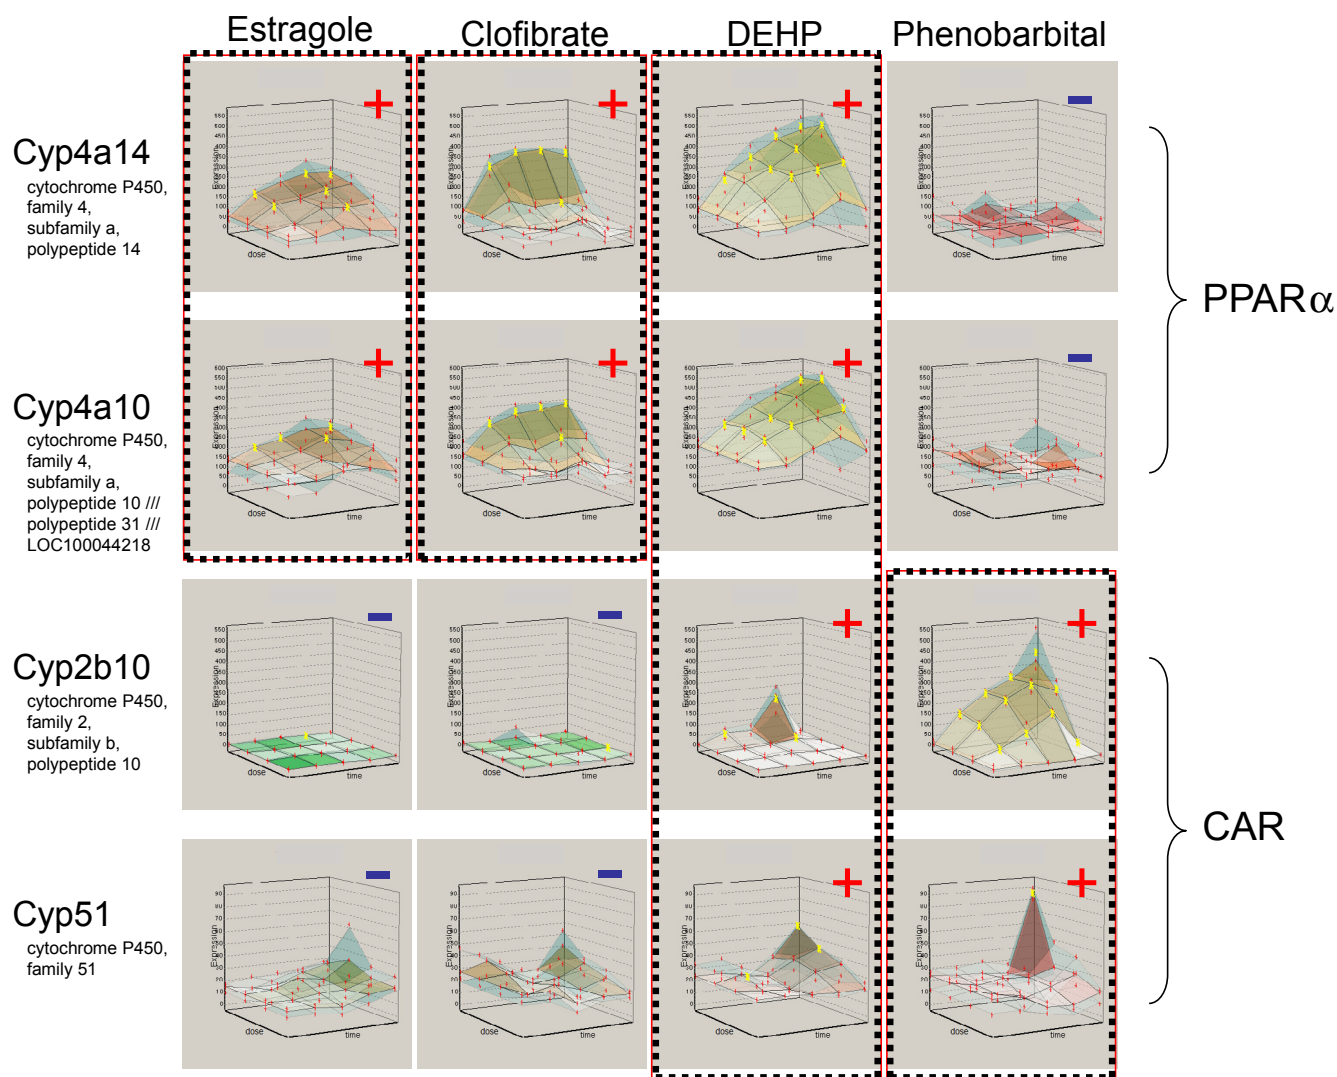
An important advantage of determining the actual average number of mRNA molecule per cell is that the responses obtained in different studies can be compared directly. Estragole was comparable to clofibrate in copy numbers of mRNAs induced, and the studies were conducted at the same dose (i.e., 0, 10, 30, and 100 mg/kg). Therefore, these data strongly suggest that estragole appears to be as potent as clofibrate in activating PPAR-alpha signaling in per body weight basis.


FIGURE 64.6 A summary of the pathways shared with estragole, clofibrate, DEHP, and MEHP illustrated by the responses of Cyp4a14, Cyp4a10, Cyp2b10, and Cyp51; the former two are PPAR-alpha-driven, and the latter two are CAR-driven.

PCP Study

The numbers of PSs that started to change their expression at 2, 4, 8, and 24 h were 98, 55, 127, and 1192, respectively (Kanno et al., 2013). Among 168 liver gene expression studies registered in Percellome database, chemicals that shared the PS list with PCP are listed in Table 64.2. The chemicals that shared the PSs with the 2-hr list of PCP was sodium dihydroacetate (TTG154-L); 51 PSs, followed by acephate (TTG109-L); 24 PSs, down to 5-fluorouracil (TTG160-L); 4 PSs. The sum set (union of the PS lists) from TTG154-L through TTG160-L was 75 (upregulated (Up) 59, downregulated (D) 16). Likewise, the sum set of the 4 h PS lists was 31 (Up 22, D 9), 8 h was 46 (Up 23, D 23), and 24 h 636 (all Up). The PS list unique to PCP (Unique list) at each time point was 23, 24, 81, and 556, respectively.

The PS list common to PCP and other related chemicals (Common list) at 2 h contained Gluconeo-genesis Pathway of PGC-1A (PPARGC1A)/Foxo1/HNF4 (Fig. 64.7) (Puigserver et al., 2003). This finding is in concordance with the report in experimental animals that PCP acutely induces hyperglycemia (Deichman et al., 1942). PPARGC1A is reported to increase the expression of Lpin1 (Finck et al., 2006), which is also the case with the Common list.

A small set of genes of metabolic enzymes are induced during the first 8 h, including Cyp2a4, Cyp4f16, Cyp7a1, Cyp17a1, Cyp39a1, Fmo2, Fmo5, and Sult1d1. IPA indicated that they are likely to be induced by Nr1i3 (CAR), Nr1i2 (PXR/SXR), or Nr5a1. Although our RSort program with current parameter setting did not pick up those nuclear receptors, manual search showed, among the three receptors, PXR/SXR was

induced by PCP. This series of change was not unique to PCP. Downregulation of Junb and Fos at 2, 4, and 8 h were uniquely found in PCP gene list.

The list of PSs induced at 24 h contained well-known networks. About half of the PSs were in the common list and assigned, by IPA, to NRF2-mediated Oxidative Stress Response accompanying clear induction of Keap1, and phase I and II metabolic pathways. The other half was unique to PCP and was assigned to interferon pathways (Figs. 64.8 and 64.9). Other networks were not effectively searched by the IPA.

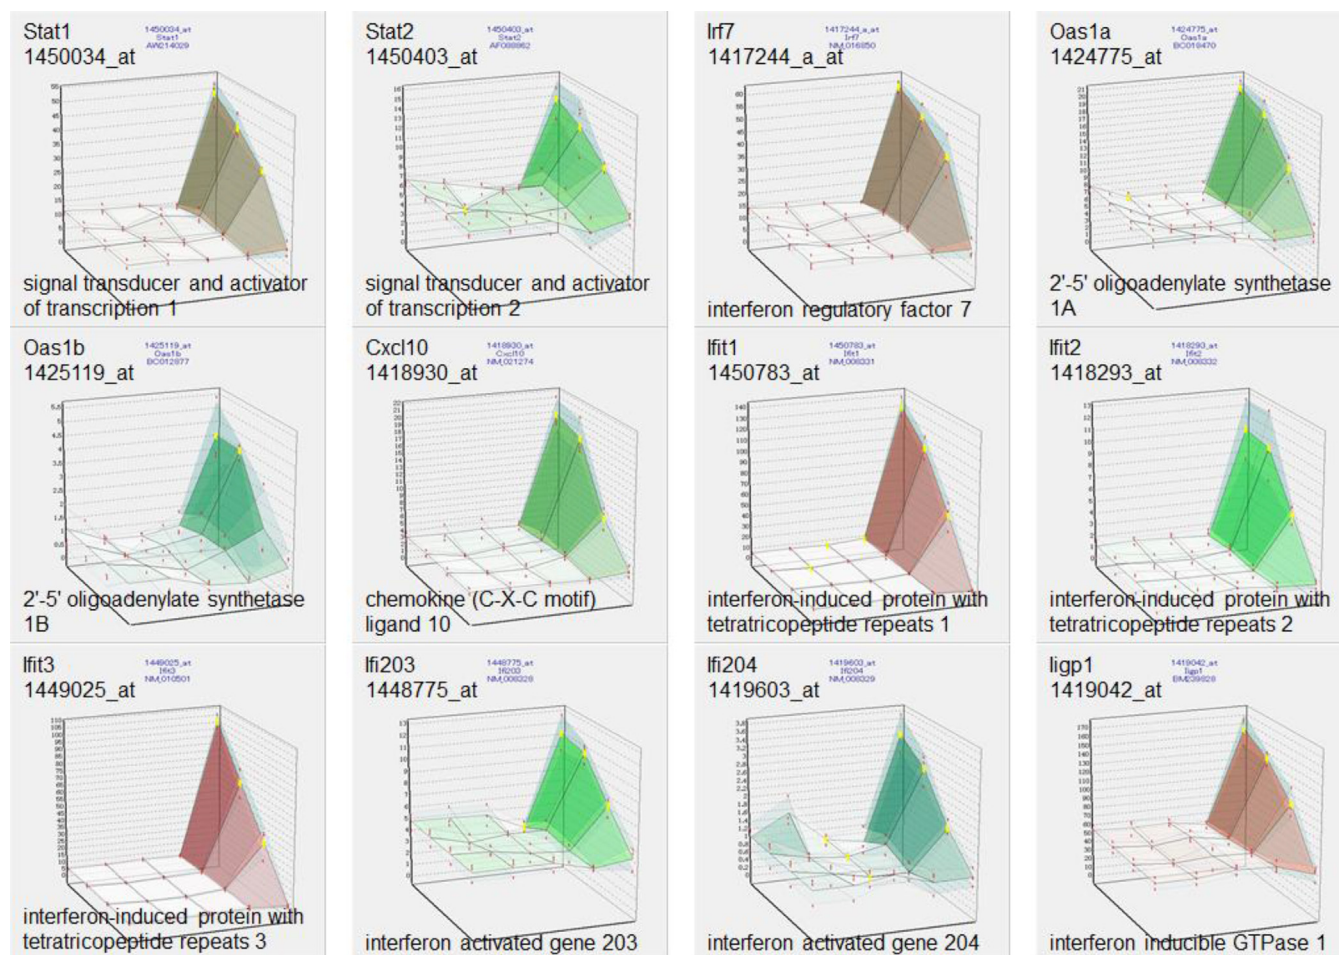
Among the chemicals tested in the Percellome project, PCP is relatively a slow starter in induction of genes, i.e., less than 100 PSs are induced at 2, 4, 8 h and increases to 1200 at 24 h. It would be plausible to consider that metabolite(s) of PCP was generated during the first 8 h and the metabolite(s) induced the 24 h burst in genes of Nrf2 and interferon networks. Some metabolizing


FIGURE 64.8 Representative illustration of PCP-induced interferon network genes. All of these genes are induced at 24 h in a dose-dependent manner. *From Kanno et al., 2013, with permission.*
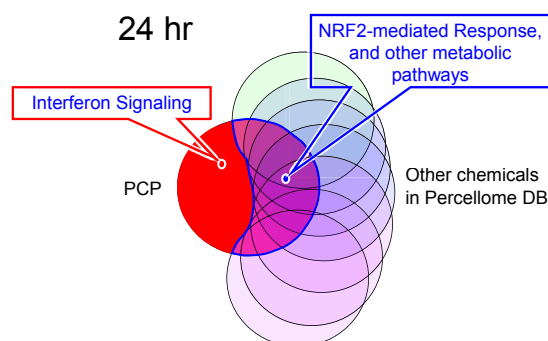

FIGURE 64.9 Venn diagram illustration of the uniqueness of PCP in terms of inducing interferon signaling shown by the PE results. Among 168 liver study data registered in the Percellome database, approximately 10 chemicals shared the list with PCP at 24 h. Intersection (purple) of the PCP and the Sum of the list (Common list in text) contained Nrf2-mediated response genes and those of other metabolic pathways. The rest of the list of PCP (red: PCP NOT Sum) are almost exclusively made of interferon signaling and related genes.

enzymes known to be located downstream of PXR/SXR are induced by 8 h. These enzymes might have metabolized PCP. IPA analysis indicated a possible activation of CAR and PXR/SXR. This finding may explain the engagement of DEHP to the top chemical list in Table 64.2. Weak signal to CAR and PXRSXR may have been transduced by PCP and cyp2a4 and other metabolic enzymes were turned on, which leads to PCP metabolism, and triggered Nrf2 network.

It is of an interest whether PCP or its metabolite(s) can be a ligand to PXR/SXR. Metabolites known are tetrachloro-p(o)-hydroquinone (TCpHQ and TCoHQ) and tetrachloro-p-benzoquinone (chloranil, TCpBQ). Furthermore, TCpHQ is reported to be metabolized, generating hydroxyl radicals with a help of H_2O_2 without Fenton reaction, to trichloro-hydroperoxyl-1,4-benzoquinone (TrCBQ-OOH) and trichloro-hydroxy-1,4-benzoquinone (TrCBQ-OH) (Zhu and Shan, 2009).

We have no Percellome data on those metabolites. To date there is no report on the interaction of PCP and its metabolites with the PXR/SXR. Since 8OH-dG, a type of DNA adduct was monitored in PCP-treated animal liver, mechanism for the hepatocarcinogenicity by PCP has been attributed to the hydroxyl radical formation during metabolism of PCP. The common list supports this mechanism.

It is reported that TLR4-mediated lipopolysaccharide-induced activation of the IFN-beta promoter was inhibited by PCP in a Myd88-independent way (Ohnishi et al., 2008). On the other hand, PCP was considered to trigger TLR4 via the induction of hydroxyl radicals (Lucas and Maes, 2013). Our data show that PCP had significantly upregulated Myd88, Irak1, Traf6, Tlr2, Tlr3, Tlr5, Tlr9, and although not significantly, Tlr4. Irf 3, Irf7, and Irf9 are also induced. This finding indicates that PCP might have triggered the TLR system via modifying the proteins in the cytoplasm either by itself, its metabolites, or hydroxyl radicals. TLRs or the pattern recognition receptors in the endosomes or on the cell surface may have sensed modified proteins. As Irf 3, 7, 9, and interferon alpha are increased, it would be possible that Irf mediated autocrine or paracrine of the interferon receptor ligand, i.e., interferon alpha is induced, and subsequent burst in interferon network had followed (Sato et al., 2000). It is noted that, although Myd88 is induced, NF-κB, TNF, IL12, and CD40 were not. This result might indicate that there may be a switch toward inflammatory cytokine production that was not triggered by PCP. There is a recent report that isopropanol impaired the AP-1 activation in TLR4-mediated lipopolysaccharide effect on TNF-alpha in monocytes (Carignan et al., 2011). The downregulation of Fos/Junb induced by PCP might be related to this switching; further analysis is needed for elucidating relation between suppression of Fos/Junb gene expression and segregation of the inflammatory cytokine pathway from the interferon pathway.

There is a relatively new low-molecular weight compound "imiquimod" sold as a TLR7 agonist for treatment of skin viral infection (Hemmi et al., 2002). A poly fluoromethylated compound, 8-(1, 3,4-oxadiazol-2-yl)-2, 4-bis (trifluoromethyl) imidazo [1, 2-a] [1, 8] naphthyridine (RO4948191) is reported as an orally available low-molecular weight interferon receptor agonist (Konishi et al., 2012) and shown to induce a set of genes similar to those induced by PCP, such as OAS1, Adar, Bst1, Stat1, Ifit3, Usp18, Osg15, Herc6, and CXCL10. These two reports suggested that synthetic (halogenated) hydrocarbons can be ligands to both TLR(s) and interferon receptor(s) and directly trigger the interferon responses. Further analyses on interaction of the PCP and related chemical(s) with those receptors are essential for the clarification of the mechanism of triggering interferon gene networks.

Merging the TGP Data to Percellome Database

A mouse Percellome data of clofibrate (TTG044-L) and a rat TGP data of clofibrate (TGP0098-L), both oral single gavage studies, are shown as example. The probe IDs were concatenated according to ortholog, and PE database was rebuilt for 323 projects consisting of 293 (liver 171) Percellome projects and 30 TGP project data (liver only) as a trial. The coverage of the PSs is about 55% for both species.

Clofibrate induced a large number of ortholog genes commonly found in both species. The PE graph indicated that rat is responding slightly slower; many genes induced at 4 and 8 h in mice are induced at 24 h in rat. For this chemical, which is known to hit a single target PPAR-alpha, it seems that the direct matching at ortholog level is effective in analyzing the response interspecies-wise (Fig. 64.10).

Phenobarbital induced less number of ortholog genes commonly found in both species. It is known that, for example, P450 genes are not the same, at least in its numbering. Therefore, for listing up the responding Cyp PSs needs a search at the level closer to Gene Ontology (Fig. 64.11).

In the Percellome database, using PE as a tool, there is no boundary between different organs and different study protocols in terms of searching common PS lists. However, between mouse and rat, because of the differences in annotation and differences in the numbers of PSs per one annotation makes the borderless search a challenge. The ortholog-based concatenated ID approach is effective in certain cases, but apparently not enough for more universal use. A tiered approach, i.e., ortholog level, gene ontology level, and probably more relevant binders between species based on the gene sequences will be considered in the near future for better performance in interspecies gene expression analysis.

New Repeated Dosing Study

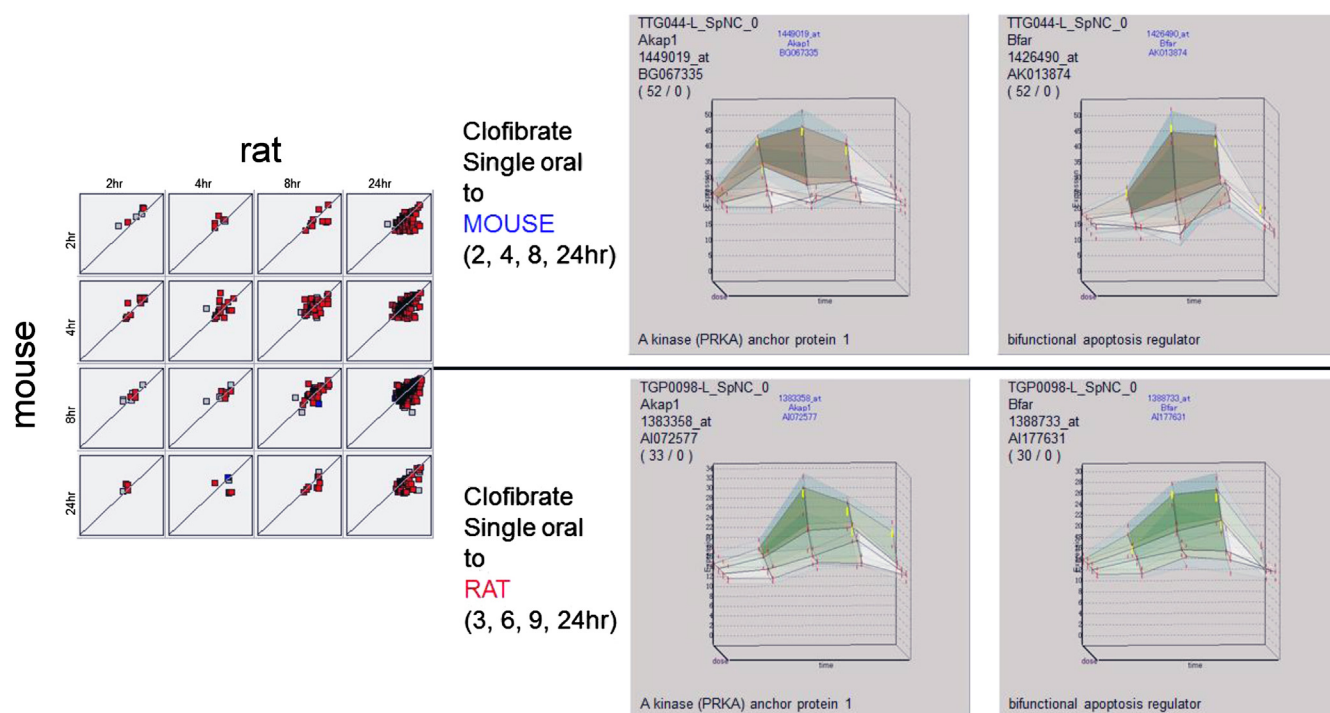
This study design is a derivative of a study on gene knockout mouse. Instead of using knockout mouse, this new method starts with a process of creating a mouse in the "chemically induced transgenic state" by giving repeated dose of a chemical before applying the single dose Percellome standard protocol. The idea is that repeated daily dosing should gradually alter the


FIGURE 64.10 A few representative genes from the mouse Percellome data of clofibrate (TTG044-L) and a rat TGP data of clofibrate (TGP0098-L). Ortholog-based search was effective for clofibrate data.

gene network and eventually induce a new steady state where at least some part of the whole gene network is different from that of the untreated mice. Therefore, the gene expression profile generated by the single challenge on the next day of the last daily dosing contains the information of altered gene network of the chemically induced transgenic state caused by repeated dosing of a chemical (Fig. 64.12) just like we observe the effect of knocked out gene. Fourteen days of repeated dosing of CCl_4 at the dose of 5 mg/kg resulted in a suppression of responses to the final challenge of CCl_4 in almost all of the genes that showed clear response in the standard single dosing experiment. We found that there was a tendency in the suppressed genes that the baseline copy number of mRNA was also suppressed in such genes. A few genes that the response to the final challenge was enhanced showed a tendency that the baseline was elevated. Further analysis suggested that the effect of 14-day pretreatment can be assessed by the combination of two responses, i.e., the change in the "Transient Response (TR)" and the "Baseline Response (BR)." TR is a quick response that is monitored within the 24 h after the single dosing. BR is a gradual response that is monitored as a change in expression level of vehicle control groups caused by the repeated dosing (Fig. 64.12). In case of CCl_4, the result can be summarized as "there were many genes that showed diminished TR with lowering of the BR.

A small number of genes showed enhanced TR with higher BR." The duration of pretreatment was shortened up to 4 days, and the effect of repeated dosing on both TR and BR was found to be similar to those by 14 day pretreatment. By the end of March of 2018, this New Repeated Dose Study protocol (4 days of repeated dosing and final challenge) was applied to CCl_4, valproic acid sodium salt, clofibrate, tributyltin, N,N-diethyl-3-methylbenzamide (Deet), acetaminophen, phenobarbital sodium, thalidomide, 5-fluorouracil, acephate, and pentachlorophenol. The effect of repeated dosing on the TR and BR was various among those chemicals. For example, CCl_4 was the most potent chemical to suppress the TR and BR of the genes. In contrast, valproic acid sodium salt was the extreme case that showed least effect on both TR and BR. Phenobarbital showed a tendency to boost the TR in many genes.

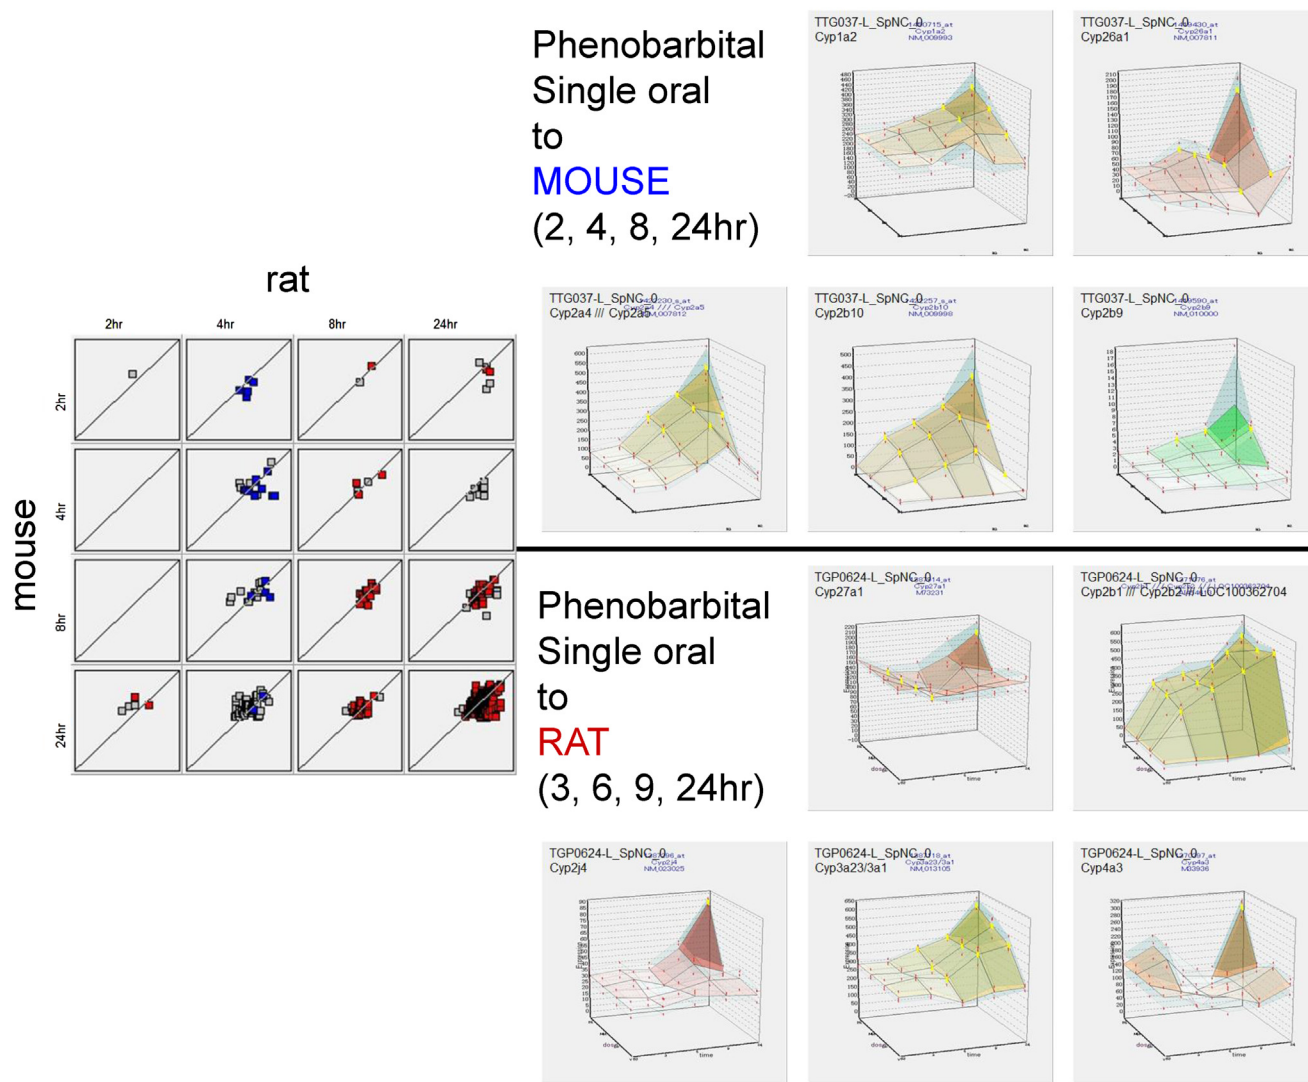
Comparison of the Percellome data between the single dose experiment data and the New Repeated Dose study data is generating a database on the relation between TR and BR in molecular basis. Again, Percellome analysis tools can list up a group of genes by the pattern of TR and BR and search for, for example, the upstream and downstream of the gene networks by checking the enhancer–promoter sequences for common transcription factor and the relevant binding sites. Detailed analysis is underway with a plan to test more


FIGURE 64.11   A few representative genes from the mouse Percellome data of phenobarbital (TTG037-L) and a rat TGP data of phenobarbital (TGP0624-L). Ortholog-base search was less effective for phenobarbital data and needed more broad level of matching list.

chemicals in different categories and to advance epigenetic search using whole genome bisulfite sequencing for DNA methylation analysis and ChIP-Seq study (using anti-H3K4me3, -H3K27Ac, -H3K27me3, and -H3K9me3) for histone modification analysis.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

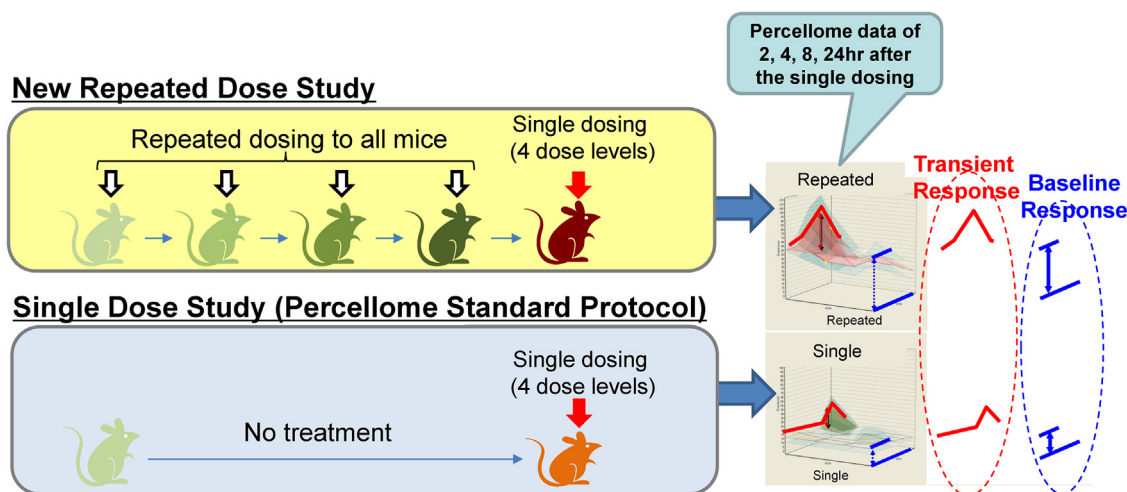
The Percellome Project for the mouse transcriptome had started from the fiscal year 2003, 1 year after the initiation of the TGP project. The TGP project was designed, launched, and maintained by us until the alliance members took over the project. The data structure of both projects is identical and therefore Percellome method can be applied. In the first 3 years, the Percellome project generated 90 chemicals database on mouse liver acute response, i.e., 2, 4, 8, and 24 h after single oral exposure of three dose levels (n = 3 for each point of data). From 2005, the second subproject, Inhalation Toxicogenomics project was launched for collecting lung and liver transcriptome data from mice exposed to a very low concentration of gases comparable to the so-called "sick building syndrome." From 2006, the second stage of Percellome Project was launched for repeated exposure studies and multiorgan relation studies. Fetus (developmental) Percellome and


FIGURE 64.12 New Repeated Dose Study. The study is a modification of single dose study using gene knockout mice. In case of gene knockout study, shifts in gene networks caused by knocking out a gene can be evaluated by comparing the Percellome data of wild-type mice and the gene knockout mice challenged by a same chemical. The new repeated dose study is based on a hypothesis that pretreatment will create a "chemically induced transgenic state" in the repeatedly dosed mice. The response within 24 h triggered by the last single dosing is defined as "transient response (TR)". The shift in the expression level of vehicle control group, representing the slow response to the repeated dosing, is defined as the "baseline response (BR)."

FIGURE 64.13 Garuda alliance. A project to publicize the Percellome data and analysis tools including our homemade software through the Garuda platform (http://ww.garuda-alliance.org/) is in progress.

Brain-behavior Percellome projects are also launched. Up to now (May 2018), the Percellome database contains a total of nearly 400 datasets (one dataset is 4×4, triplicate, one organ, total of 48 GeneChip data) tested on about 150 kinds of chemicals over multiple organs, such as liver, lung, kidney, thymus, testis, and brain (hippocampus, cortex).

The absolutized mRNA expression data were easy to handle and therefore greatly facilitated the data analysis including developing the softwares. And the 3-D graph (time x dose x mRNA in copies per cell) made the whole process biologist-friendly. At any time, the data quality and the biological plausibility of the response can be visually checked by the eyes of biologists.

The final goal of the project is to develop a simulation method of virtual mice and virtual human *in silico* to perform toxicity testing. It may take many years until the "Star Trek" era. The practical interim goal is to develop the method to instantly draw a comprehensive and dynamic gene network of each test chemical and construct a systems toxicology for molecular mechanism-based predictive toxicology. Combined effects of two or more chemicals, cross-interaction among organs in a body, and species differences are expected to be logically handled by the Percellome systems toxicology.

Examples shown here, especially the PCP data, indicated that, at least some of the regulation mediated by the protein phosphorylation can be considered as "monitored indirectly," like a shadowgraph, by the transcriptome, i.e., Stat1 and Stat2. Therefore, we believe that precise transcriptome can cover signaling network driven by protein-modification up to a certain degree.

The toxicology of repeated dosing is now gathered to the Percellome Project. New Repeated Dosing Protocol turns out to be very promising to characterize the molecular basis of the shift of response of an organism against repeated chemical exposure by comparing the response to the single dose exposure by dissecting the response to two factors, i.e., the transient response (TR) and the baseline response (BR) of each genes. CCl₄ New Repeated Dosing study instantly indicated the involvement of ER stress (eIF2 and Xbp1 pathway involved, data not shown).

The joining of two large databases, TGP (publicized as TG-GATEs) and Percellome database (now equal in data size to TGP), by Percellome method has been planned. The analysis tools including our homemade software through the Garuda platform (Fig. 64.13) will facilitate the process. We hope to have all data analyzed by many toxicologist and biologists worldwide for drawing the entire dynamic gene network activated in toxicological conditions of a living organism.

Proteomics in Biomarkers of Chemical Toxicity

Christina Wilson-Frank

Purdue University, College of Veterinary Medicine, Animal Disease Diagnostic Laboratory, Department of Comparative Pathobiology, West Lafayette, IN, United States

INTRODUCTION

Toxicoproteomics is emerging as an important tool in elucidating biochemical pathways of chemical toxicity and identifying potential biomarkers for establishing risk assessment, level of concern, and early detection of toxicant exposure. Proteomic analyses allow global simultaneous, high-throughput monitoring of proteins following exposure to chemical toxicants and provides an effective strategy to identifying useful biomarkers indicative of toxicity.

One of the major challenges in proteomics research, particularly when probing biological samples for biomarkers of chemical toxicity, is the inherent complexity of the proteome. However, advancements in sample preparation (to reduce sample complexity), analytical instrumentation, and automated sequence database searching have enabled for simplified and improved, high-throughput analysis and more accurate protein identification. When evaluating the proteome in complex biological samples, the proteomics platforms commonly employed include a technology that globally separates proteins, combined with the use of mass spectrometry for protein identification. To achieve global separation of proteins from complex samples, gel-based technologies are more commonly used in proteomics studies for chemical toxicity, such as 1-dimensional gel electrophoresis (1-DE), 2-dimensional gel electrophoresis (2-DE), and 2-dimensional-difference gel electrophoresis (2-DGE).

Recently, advances in analytical instrumentation have increased the separating capacity and resolution of chromatographic systems; therefore, the use of high-performance liquid chromatography (HPLC) and ultrahigh-performance liquid chromatography are emerging as popular platforms for high-throughput, complex protein separations. The most common analytical platforms used for protein sequencing and identification are matrix-assisted laser desorption/time-of-flight mass spectrometry (MALDI-TOF MS) and tandem mass spectrometry (MS/MS) which can include time-of-flight (TOF), quadrupole (Q), or ion trap mass spectrometry.

Using these technologies, researchers have been able to measure qualitative and quantitative changes in proteins in samples such as serum/plasma, blood, brain, liver, and kidney samples to distinguish unique biomarkers of chemical toxicity. Much of the proteomics research conducted to elucidate candidate biomarkers of chemical toxicity predominantly involves recognizing quantitative changes in proteins after biological systems or cells are subjected to acute or chronic exposure to toxicants. However, an alternative approach to defining potential, candidate biomarkers of toxicity involves using protein network building tools, such as MetaCore or Ingenuity Pathways Analysis software (Wang et al., 2013; Huang and Huang, 2011). Proteins that are differentially expressed in chemical toxicity studies can be subject to protein interaction network analysis, which predicts protein–protein interactions and highlights which molecular pathways in which those proteins play a key role. Not only does this highlight probable molecular mechanisms of toxicity but also may allow investigators to focus on a specific group of proteins or protein in that pathway to evaluate as prospective biomarkers.

Pesticides, herbicides, heavy metals, and most organic contaminants are well-studied chemical toxicants that are known to be potential occupational or environmental health hazards. This chapter describes proteomics investigations conducted in these biological samples that identify potential, predictive biomarkers of chemical toxicity and lead to an improved understanding of mechanisms of toxicity of these chemicals. The potential biomarkers identified in these investigations have been reported to be a result of either cause acute or chronic chemical toxicity and have been

recognized as environmental contaminants or have a high risk of occupational exposure.

HEAVY METALS

Arsenic

Arsenic is a carcinogenic metalloid and is recognized as one of the most toxic heavy metals (Tokar et al., 2013). Environmental exposure to arsenic primarily occurs via arsenic-contaminated drinking water, because trivalent and pentavalent forms of the heavy metal are widely distributed in the environment. Because arsenicals are used in the smelting industry and in the manufacturing of pesticides, herbicides, and products used in wood preservation, occupational exposure to arsenic is also a concern (Tokar et al., 2013). Individuals exposed to arsenic are at risk for developing cancer, hyperkeratosis, cardiovascular disease, and kidney and liver damage. For most of these cases, chronic exposure to arsenic is implicated. Due to the lack of adequate biomarkers to assess exposure to arsenic in these cases, various proteomics methodologies have been used to help reveal candidate biomarkers for early diagnosis of arsenic-induced diseases.

Arsenic-induced hyperkeratosis has been associated with skin cancer and other internal cancers and is endemic in parts of the world in which individuals are chronically exposed to arsenic in drinking water (Hong et al., 2017; Hsu et al., 2013). To identify useful biomarkers for early diagnosis of arsenic-induced, hyperkeratosis in exposed individuals, a proteomic study was conducted using skin samples from the palms and feet of individuals who had skin lesions who resided in an arsenic-contaminated area in Shanyin, China (Guo et al., 2016). One protein, DSG1 (desmoglein 1), was significantly suppressed in the skin from arsenic-exposed individuals. DSG1 is a cadherin-like protein that promotes anchoring of the keratin cytoskeleton to the cell membrane; therefore, suppression of this protein can result in abnormal epidermal cell differentiation. Proteins that were present in increased concentrations in affected individuals were FABP5 (fatty acid-binding protein 5) and KRT6C (keratin 6C). KRT6C and other keratins are responsible for maintaining epidermal cell-to-cell adhesion, and mutations in these proteins have been linked to other types of skin abnormalities (Guo et al., 2016). FABP5 plays an integral role in fatty acid metabolism and is known to be upregulated in various forms of human cancers, possibly promoting tumor development (Chen et al., 2011; Levi et al., 2013; Ogawa et al., 2008).

Cardiotoxicity can also occur with chronic arsenic exposure, as it causes cardiac arrhythmias and can alter myocardial depolarization (Chen and Karagas, 2013). To evaluate the mechanism of arsenic cardiotoxicity, rats were given sodium arsenate and changes in the proteomic profiles of heart tissue from treated rats were evaluated (Huang et al., 2017). Eighty-one proteins changed with arsenic exposure and 14 of the proteins were associated with cardiovascular function and development. Proteins that were upregulated included cardiac troponin T and creatinine kinase. Cardiac troponin T is present in cardiomyocytes and is responsible for myocardial contractility. It is a known, specific biomarker for acute cardiotoxicity and concentrations will increase after myocardial injury. Other proteins involved in cardiac contractility were also identified and were downregulated with arsenic exposure. These proteins include myosins, tropomyosin alpha-1 chain, and galectin-1. Other proteins identified that may serve as potential biomarkers include talin 1 and vinculin, both cytoskeletal proteins important for myocardium morphogenesis, and vimentin (filament protein important for enhancing protective effects on myocardial ischemic injury).

Cadmium

In addition to occurring naturally in the environment, cadmium is also a major environmental contaminant due to being widely used in the production of textiles, plastics, batteries, and fertilizers (Hulla, 2014). Because tobacco plants are known to accumulate cadmium from the soil, individuals smoking tobacco are known to have increased levels of cadmium in their blood and kidneys (Satarug and Moore, 2004). Prolonged exposure to cadmium can lead to accumulation in the proximal tubule epithelial cells and glomerulus, ultimately leading to nephrotoxicity (Pari et al., 2007). Measuring blood urea nitrogen and creatinine are the traditional biomarkers used to assess kidney damage; however, when high levels of these biomarkers are detected, significant kidney damage has already occurred. In an effort to identify early biomarkers of nephrotoxicity, researchers have used proteomics to investigate the effects of cadmium on renal cells. In one study using 2D-gel electrophoresis/MALDI-TOF MS and SILAC/LC-MS, HK-2 human kidney epithelial cells were treated with cadmium chloride (Kim et al., 2015). Of the several proteins identified in this study, HSPA8 (heat shock protein) and ENO1 (alpha-enolase) increased in the treated cells. The increase in ENO1 and HSPA8 was suggested to be due to cadmium-induced cell death through oxidative stress.

Another study investigating cadmium nephrotoxicity in human renal cells identified 27 proteins effected by cadmium exposure (Galano et al., 2014). Fifty percent of the proteins identified are involved in apoptosis, whereas others identified were found to be important

for protein synthesis and cytoskeleton formation. Similar to the previous study, this group of investigators also identified an increase in ENO1. It is important to note that HSPA8 (and other heat shock proteins) and ENO1 are also increased when human kidney cells are damaged by other toxic agents (Kim et al., 2015). Therefore, these proteins may be candidates for biomarkers of early kidney damage as opposed to specific biomarkers for cadmium-induced nephrotoxicity.

Chromium (VI)

Hexavalent chromium (Cr (VI)) is a toxic, heavy metal commonly used as an oxidizing agent for stainless steel production, welding, chrome pigment production, and chromium plating (Ashley et al., 2003). Due to its widespread industrial use, concerns regarding environmental contamination and occupational exposure to Cr (VI) have been raised due to its proven toxicity to ecosystems and also because it is a known human carcinogen (Tokar et al., 2013). Recently, investigators have imposed the use of comparative proteomics and serum protein expression profiling to identify biomarkers of occupational exposure and also to gain a better understanding of the mechanism of carcinogenesis of Cr (VI).

In an attempt to identify novel serum proteins that change with occupational exposure to Cr (VI), blood samples were collected from 107 chromate workers and were analyzed using nano-flow HPLC/MS and critical proteins of interest that were identified were verified using ELISA (Hu et al., 2017). When compared with the control group, there were 44 differentially expressed serum proteins found in occupational Cr (VI) exposure, all involved in 16 important signaling pathways associated with the immune system, C-reactive protein (CRP), sonic hedgehog protein (SHH), and calcium. Although more studies need to be conducted to garner an understanding of the noted regulatory proteins and mechanisms involved in Cr (VI) exposure, the investigators concluded that CRP and SHH might be potential, novel biomarkers as higher levels of SHH and lower levels of CRP were noted in all of the workers exposed to Cr(VI).

Lead

Lead is a major, toxic heavy metal that has been historically used in variety of products including paints, batteries, pesticides, gasoline, and ammunition (Thompson, 2018; Tokar et al., 2013). Although workplace exposure to lead has been progressively reduced, environmental exposure to lead still remains a toxicological concern. Most exposures to lead are through contaminated food or water sources or lead-containing paint chips (Tokar et al., 2013). In mammals, the toxic effect of lead exposure can be widespread ranging from liver or kidney damage

and neurotoxicity to hematologic effects (Tokar et al., 2013). Proteomic responses to lead neurotoxicity and hepatotoxicity have been conducted that identify possible biomarkers of exposure and also define metabolic pathways involved in lead-induced cell injury.

In addition to exposure via inhalation or orally, dermal exposure to lead (e.g., lead acetate) is also a concern (Cohen and Roe, 1991). One group evaluated the hepatotoxic risk caused by derma exposure to lead acetate using 2-DE and MALDI-TOF MS (Fang et al., 2014). In this study, dermal application of lead acetate was applied every 24 h to the back of nude mice and the harvested livers subjected to proteomic analysis and Western blots. The proteins that changed significantly with lead exposure were proteins associated with protein folding, ER stress, apoptosis, and oxidative stress. Specifically, the proteins GRP75 (mortalin) and GRP78 (glucose-regulated protein 78 kDa) were increased by 4.5-fold and 2.0-fold (respectively) with dermal lead exposure. These proteins are responsible for protein folding and targeting misfolded proteins for degradation and also are important indicators of oxidative stress. The investigators suggested that oxidative stress and proapoptotic signals from the ER as a result of lead toxicity were responsible for these proteins being elevated. Other proteins that increased in a dose-dependent manner with lead exposure were ATF6 (activated transcription factor 6), 1RE1α (inositol requiring enzyme), and PERK (protein kinase R-like endoplasmic reticulum kinase). Increased expression of these proteins would lead to cleavage of poly (ADP-ribose) polymerase ultimately resulting in apoptosis of hepatocytes. The investigators also noted that AST and ALT levels were elevated in this study, further confirming liver damage. This study concluded that dermal exposure to lead acetate leads to generation of reactive oxygen species culminating in hepatotoxicosis due to necrosis and apoptosis of hepatocytes.

In addition to lead hepatotoxicity, one group investigated the neurotoxic effects of lead exposure by identifying differentially expressed proteins in the hippocampus of juvenile mice given lead acetate in drinking water. Six proteins were upregulated and three proteins were downregulated in lead-exposed mice. Pdhb1 (pyruvate dehydrogenase E1β) and ATPase (proteins involved in cell energy metabolism), Hspd1 and Hspa8 (heat shock proteins involved in cell stress response), and Dpysl2 and Spna2 (proteins involved in protein binding and cytoskeleton development) all increased with oral lead exposure. There were three proteins that decreased with lead neurotoxicity, NADH dehydrogenase, Aars (alanyl tRNA synthetase), and Grb (growth factor receptor protein). The investigators surmised that the increase in ATPase in this study may be compensatory to the decrease in NADH dehydrogenase due to the increased demand for energy by the cells after

lead toxicity. This group also conducted object recognition tests which revealed that lead administration reduced the memory ability and vertical activity of affected mice to show the biological responses to lead neurotoxicosis induced in these mice.

Mercury

Because of its ubiquitous presence in the environment and its propensity to bioaccumulate, mercury poses a significant health hazard to aquatic species and humans. Depending on the form of mercury, it can cause toxicity to the central nervous system, gastrointestinal tract, liver, and kidneys (Gupta et al., 2018a). There have been several studies conducted using proteomics technologies to help elucidate key pathways or biomarkers that may lead to an earlier assessment of exposure risk and to gain an understanding of the mechanism of toxicity of mercury in these organ systems.

Proteins involved in mercury neurotoxicity and hepatotoxicity have been studied in medaka fish (*Oryzias melastigma*). In both studies, chronic exposure to mercury chloride was investigated and potential biomarkers elucidated using 2D-gel electrophoresis/MALDI-TOF MS. Following mercury chloride exposure, there were 33 proteins identified in liver samples from medaka fish of which several proteins significantly changed in the treated fish versus the controls (Wang et al., 2013). Protein markers that increased significantly with mercury exposure included cathepsin D, peroxiredoxin-1 and 2, and natural killer enhancing factor. These proteins are involved in cellular responses to oxidative stress or mediate apoptosis of damaged hepatocytes, highlighting that chronic mercury exposure causes oxidative stress in the liver.

Keratin 15 and novel protein similar to vertebrate (PLEC), proteins involved in cytoskeleton assembly, decreased in the treatment group. Mercury has been previously shown to disrupt the cytoskeleton, particularly in cases of acute toxicosis (Wang et al., 2011). Studies investigating the neurotoxicity of mercury in medaka fish revealed similar results. Sixteen proteins were significantly different in the treatment group when compared to controls. As was observed in the chronic hepatotoxicity study, the proteins that changed were important in responses to oxidative stress, cytoskeletal assembly, and metabolic disorders (Wang et al., 2015).

The protein markers that increased were cathepsin D, peroxiredoxin-1 and 2, and natural killer enhancing factor. Whereas the proteins that decreased were keratin 15, formimidoyltransferase cyclodeaminase (FTCD), and novel protein similar to vertebrate (PLEC). Novel biomarkers for acute and chronic mercury nephrotoxicity were evaluated in vivo in Sprague—Dawley rats orally dosed with mercury chloride and also in vitro in rat kidney proximal tubular cells (Shin et al., 2017). Proteomic analyses revealed two key biomarkers to be considered for mercury-induced nephrotoxicity. Aldo-keto reductase (AKR7A1) and glutathione-S-transferase (GSTP1) were significantly elevated, in a dose-dependent manner, in the kidney and proximal tubular cells. Interestingly, these proteins were notably increased in the absence of detectable increases in BUN and creatinine. AKR7A1 is a protein that is integral in detoxifying metabolites, and GSTP1 is important in protecting cells from oxidative stress. To further corroborate these findings, the investigators were able to show that generation of reactive oxygen species in vitro was increased by mercury in a dose-dependent manner. The authors mention that it is not clear these proteins can serve as noninvasive biomarkers (measured in blood or urine); however, they may serve as biomarker candidates for early stages of nephrotoxicity. Collectively, in the aforementioned proteomic studies, the biomarkers identified for hepatotoxicity, neurotoxicity, and nephrotoxicity allude to mercury causing oxidative stress as a mechanism of toxicity in these organ systems.

In addition to tissue proteomics, there has been a study conducted to identify serum biomarkers for organic methylmercury toxicity. One group of researchers dosed mice with organic methylmercury, enriched for serum glycoproteins and analyzed the samples using nano-UPLC/MS/MS (Kim et al., 2013a). Although 21 proteins were differentially expressed in the organic methylmercury-treated mice, two serum protein biomarkers were identified and validated using Western blot analysis and immunohistochemistry. Amyloid P component (SAP) and inter-alpha-trypsin inhibitor heavy chain 4 (ITI-H4) were upregulated. SAP, a protein that exists in amyloid deposits and stabilized chromatin, was the protein that increased the most. ITI-H4 increased more than twofold and is responsible for regulating inflammatory conditions and acute phase response in cells. The authors note that previous proteomic investigations in serum from children with high levels of mercury in their blood (due to eating contaminated fish) also have detectable ITI-H4 (Gump et al., 2012).

PESTICIDES AND HERBICIDES

Methyl Parathion

Methyl parathion is an organophosphorus pesticide and is classified by the Environmental Protection Agency as a class I toxicant. Due to its widespread use in agriculture, occupational exposure in humans often occurs via inhalation or dermally. Environmental exposure occurs due to contamination of soil and water or due to runoff from sources where methyl parathion

has been applied. The primary mechanism of toxicity of this organophosphate insecticide is through inhibition of acetylcholinesterase in the central nervous system and at the neuromuscular junction (Gupta and Kadel, 1990; Gupta et al., 2018b). Some studies have also shown that methyl parathion can cause DNA damage and induce oxidative stress in a variety of organ systems (Bartoli et al., 1991; Hai et al., 1997).

A group of researchers in China have taken an interest in studying changes in cell membrane proteomes to investigate the neurologic and oxidative effects of methyl parathion in brain and other organ systems to establish candidate biomarkers of methyl parathion in those tissues and gain a better understanding of the mechanisms of methyl parathion toxicity. Using 1-DE and 2-DE to separate the membrane proteins and MALDI-TOF MS/MS to sequence the peptides, candidate biomarkers for methyl parathion toxicity were evaluated in zebrafish (*Danio rerio*) brain and liver, pleural-pedal ganglia from sea slugs (*Aplysia juliana*), and kidney from scallops (*Mizuhopecten yessoensis*) (Huang and Huang, 2011, 2012a,b; Chen et al., 2014). The proteins that were identified to be upregulated or downregulated were further validated and confirmed using Western blots and real-time polymerase chain reaction (RT-PCR). Common in all of these proteomic studies, the cell membrane proteins that changed significantly with methyl parathion treatment play a role in oxidative stress, mitochondrial function, energy/cell metabolism, signal transduction, protein synthesis, and degradation and intracellular transport. A list of the membrane proteins that changed with methyl parathion treatment are listed in Table 65.1.

The proteins PDIA3 (protein disulfide isomerase-associated 3), ALDH5A1 (aldehyde dehydrogenase 5A1), and MDH (malate dehydrogenase) were found to have significantly changed in with methyl parathion treatment in zebrafish brain tissue (Huang and Huang, 2011). The investigators suggested that these three proteins are suitable candidate biomarkers as they have been previously reported to be associated with methyl parathion toxicity in other studies (Huang and Huang, 2011). Interestingly, SDH (succinate dehydrogenase) was shown to decrease in sea slug, pleural-pedal ganglia and increase with methyl parathion treatment in zebrafish liver cells (Huang and Huang, 2012a; Chen et al., 2014). Organophosphates have been reported in early studies in aquatic species to decrease SDH activity in tissues, suggesting that these pesticides effect aerobic oxidation in the TCA cycle (Samuel and Sastry, 1989). SDH was also shown to decrease in the pleural-pedal ganglia of sea slug with methyl parathion treatment. However, in zebrafish liver cells, SDH was shown to increase with methyl parathion treatment. The investigators surmised that this increase in SDH might be

compensatory in light of aerobic oxidation being effected in the liver.

Diazinon

In addition to acetylcholinesterase inhibition, non-cholinergic targets of organophosphate pesticides are also of toxicological concern. Recent studies have suggested that diazinon, an organophosphate pesticide, may cause developmental defects in the absence of acetylcholinesterase inhibition (Harris et al., 2009). To investigate if sublethal doses of diazinon would affect cell development, a targeted proteomic study was conducted in mouse N2a cells to examine if diazinon would induce molecular changes in stress response and axonal cytoskeletal proteins (Harris et al., 2009). Using 2-DE

and MALDI-TOF MS, 12 proteins involved in cell survival, differentiation, and metabolism changed significantly with diazinon treatment. Notably, the protein cofilin increased approximately fivefold. Cofilin is an actin-binding protein that dissembles actin filaments, suggesting that diazinon disrupts microfilament organization. The researchers concluded that the cytoskeleton may be a target for the neurite inhibitory levels of diazinon, and that proteins important for microfilaments, microtubules, and neurofilaments are affected by diazinon.

Paraquat

Paraquat is a potent, restricted, nonselective herbicide that has been associated with high mortality in humans and animals exposed to the product. Ingestion of paraquat can cause multisystem organ failure through production of reactive oxygen species as a result of inhibiting reduction of NADH to NADPH (Gupta, 2018). Paraquat is also selectively taken up into the lungs, causing pulmonary edema, alveolar hemorrhage, and lung fibrosis (Gupta, 2018; Kim et al., 2013c). The use of proteomics in identifying diagnostic biomarkers for pulmonary toxicity in bronchoalveolar lavage fluid has been somewhat successful (Govender et al., 2009). However, isolating biomarkers in noninvasive samples as a result of pulmonary toxicity caused by paraquat intoxication have been challenging. Serum uric acid and acute phase response gene pentraxin-3 have been suggested as prognostic biomarkers for paraquat toxicity in serum (Kim et al., 2011; Yeo et al., 2011); however, these biomarkers may not be ideal for early diagnosis. In an attempt to discover early, diagnostic biomarkers of acute paraquat poisoning, 2-DE and MALDI-TOF MS/MS were used to isolate and identify proteins that change with paraquat poisoning (Kim et al., 2012). In this study, male CD(SD)IGS rats were dosed orally with paraquat dichloride and serum samples were collected from treatment and control groups. Out of approximately 500 protein spots observed, eight proteins were differentially expressed with paraquat treatment. Proteins related to the inflammatory process which included ApoE (apolipoprotein E), Hp (haptoglobin), and C3 (complement component 3) increased in the treatment group. Proteins that decreased with treatment were FGG (fibrinogen γ-chain) and Ac-158. Western blot and RT-PCR were used to further validate the usefulness of ApoE, Pphg, and FGG as diagnostic biomarkers of paraquat toxicity. These results concluded that ApoE, Hp, and FGG may be appropriate candidate biomarkers in serum samples for early diagnosis of acute paraquat toxicosis. The increased expression of the protein C3 is interesting in that C3 may play a role in acute inflammatory reactions caused by paraquat

(Sun et al., 2011). Therefore, the investigators concluded that C3 expression in serum may serve as a diagnostic biomarker for paraquat-induced, acute pulmonary inflammation.

Proteomic profiling of lung tissue has also been conducted to evaluate changes in proteins expressed in the lung subsequent to paraquat exposure. In this study, protein biomarkers of acute pulmonary toxicosis were investigated using 2-DE and MALDI-TOF MS/MS in rats dosed intraperitoneally with paraquat. It was discovered that CaBP1 (calcium-binding protein 1 regulates calcium-dependent activity in cell cytoskeleton), FKBP4 (important in immunoregulation and protein folding), osteonectin (glycoprotein that binds calcium), and S100A6 (calcium-binding protein that regulates cell cycle progression and differentiation) all increased in rat lung tissue with paraquat treatment.

Glyphosate

Glyphosate is widely used as a broad spectrum herbicide and is present in approximately 750 commercial herbicide products (Landrigan and Belpoggi, 2018). The herbicidal mechanism of action is through inhibition of plant enolpyruvylshikimate-3-phosphate synthase, an enzyme involved in the synthesis of tyrosine, tryptophan, and phenylalanine. Without these amino acids, the plant cannot synthesize proteins needed for growth. Due to its widespread use to control broadleaf weeds and grasses, trace amounts of glyphosate can be found in soil, foodstuffs, and water (Landrigan and Belpoggi, 2018). The impact of glyphosate on the environment, particularly in aquatic organisms, is an emerging concern. Glyphosate-based herbicides have been shown to cause a variety of toxic effect in nontarget aquatic organisms, such as hemorrhagic anemia, oxidative stress, and genotoxic effects (Arnett et al., 2014; Rocha et al., 2015). To assess the early toxicological response of glyphosate in fish, guppies (*Poecilia reticulata*) were housed in aquarium water fortified with 1.82 mg glyphosate/liter and the gill proteome evaluated using 2-DE and MALDI-Q-TOF MS/MS (Rocha et al., 2015). After a 24-h exposure time, 14 proteins involved in energy metabolism, regulation, cytoskeleton maintenance, and stress were identified. Glyphosate exposure inhibited expression of α-enolase, a protein that plays a role in hypoxia tolerance in cells. This inhibition was thought to be due to glyphosate-dependent hypoxia-induced stress in the gills. Proteins important for cytoskeleton regulation were also suppressed in gills from glyphosate-treated fish. Arp4, cortactin-binding protein, myosin-VI-like isoform 4, and actin isoforms decreased with glyphosate exposure, suggesting that glyphosate may interfere with stability of actin filaments in the gills of guppies. The investigators concluded that

glyphosate modifies expression of gill proteins and promotes changes in the cellular architecture of gill cells in response to hypoxia caused by glyphosate, and that the proteins identified could serve as potential biomarkers for biomonitoring water pollution by herbicides.

ORGANIC POLLUTANTS

Benzo(a)pyrene

Polycyclic aromatic hydrocarbons (PAHs) are known carcinogens, posing a significant health threat to humans and animals. Their ubiquitous presence in the environment is largely because they are produced by all types of combustion of organic materials such as the incomplete burning of fuels and other substances including tobacco (cigarette smoke) and other plant material (Kim et al., 2013b). One of the most studied PAHs is benzo(a)pyrene, which is metabolized by the cytochrome P450 monooxygenase system and epoxide hydrolase in mammals to form benzo(a)pyrene diol epoxide, a carcinogenic metabolite that forms an adduct with DNA (Di Giulio and Newman, 2013). The genotoxic effects of benzo(a)pyrene have been well studied; however, the effects of benzo(a)pyrene at the protein level are just beginning to be understood. Several researchers have taken advantage of proteomics techniques to begin to evaluate biomarker candidates of benzo(a)pyrene carcinogenicity in bladder cancer, prostate cancer, and lung cancer.

Tobacco smoking has been linked to bladder cancer cases in men (Castelao et al., 2001). One concern regarding tobacco is that cigarette smoke has been shown to contain 20–40 ng of benzo(a)pyrene per cigarette (Rodgman et al., 2000). Efforts to understand the possible role of benzo(a)pyrene in bladder cancer development have been attempted using proteomics. In one study, pig primary bladder epithelial cells were exposed to benzo(a)pyrene and the proteome isolated and analyzed using 2-DE and MALDI-TOF MS/MS (Verma et al., 2013). Twenty-five differentially expressed proteins were identified which are known to be important for either mitochondrial repair, DNA repair, or apoptosis. Proteins that were upregulated with benzo(a)pyrene exposure included RAD23, PMSD5, and PMSD4. These proteins play a crucial role in DNA repair and their upregulation suggests that benzo(a)pyrene caused DNA damage to the bladder epithelial cells (Verma et al., 2013). Many of the proteins identified that changed significantly were cathepsin D, VDAC 2 (voltage-dependent anion channel protein), HSP27, and HSP70 (heat shock proteins). These proteins are known to be involved in the mitochondrial death receptor pathway, ultimately inducing apoptosis. These proteins not only may serve as candidate biomarkers for benzo(a)pyrene-induced bladder cancer but also this study was able to show that at low concentrations and during short exposure time periods that benzo(a)pyrene can cause DNA damage in bladder epithelial cells leading to cell death due to apoptosis (Verma et al., 2013).

Benzo(a)pyrene in cigarette smoke has also been implicated in the development of lung cancer. Evidence has shown that benzo(a)pyrene diol epoxide-DNA adducts occur at the same codon positions that are known to be major, mutational hot spots in human lung cancers (Denissenko et al., 1996). The lack of biomarkers for early diagnosis of lung cancer has been a persistent, clinical challenge. Comparative proteomic analysis of the cellular response to (A549) human airway epithelial cells to benzo(a)pyrene was investigated in hopes of elucidating biomarkers and mechanisms of toxicity (Min et al., 2011). Using 2-DE and MALDI-TOF MS/MS, 23 proteins that play a role in signal transduction, antioxidation, energy and metabolism, and apoptosis were differentially expressed in cell lysates from the airway epithelial cells treated with benzo(a)pyrene. The proteins that increased were annexin A1, thioredoxin, cathepsin D, and heterogeneous nuclear ribonucleoprotein K. Peroxiredoxin I, vimentin, nucleoside diphosphate kinase A, poly(rC)-binding protein 1, and superoxide dismutase (Mn) all decreased in the benzo(a)pyrene-treated cells. Superoxide dismutase (Mn), which is a protein that is considered to be the cell's first line of defense against superoxides, was very significantly decreased with benzo(a)pyrene exposure in A549 cells (Min et al., 2011). The researchers suggested that accumulation of intracellular reactive oxygen species induced by benzo(a)pyrene exposure is why this protein likely decreased. This proteomic study helped clarify that benzo(a)pyrene can perturb the antioxidant status in airway epithelial cells and highlighted the proteins that change with benzo(a)pyrene toxicity in the lung.

In addition to being present in cigarette smoke, benzo(a)pyrene is also known to be present in grilled meat and that consumption of grilled meat has been linked to an increased risk of prostate cancer (Fatma and Kabadayi, 2005). Proteomic investigations conducted to assess benzo(a)pyrene-mediated prostate cancer have been conducted in vitro using PrEC normal prostate epithelial cells (Chaudhary et al., 2006). This investigation revealed 26 proteins that changed with benzo(a) pyrene exposure. Twenty-six proteins were differentially expressed in the prostate epithelial cells with benzo(a)pyrene, most having cellular function in metabolism, signal transduction, cytoskeleton protection, and oxidative stress. Peroxiredoxin I, which increased with benzo(a)pyrene, and peroxiredoxin II, which decreased with benzo(a)pyrene, were of particular interest to the researchers. These proteins are

Biomarkers for Testing Toxicity and Monitoring Exposure to Xenobiotics

Jorge Estévez, Eugenio Vilanova, Miguel A. Sogorb

Instituto de Bioingeniería, Universidad Miguel Hernández de Elche, Spain

INTRODUCTION

A biomarker (or a biological marker) is an indicator of a biological state that offers information about the exposure of an organism to a xenobiotic, the effect of this exposure on the organism, or the susceptibility of the organism to the xenobiotic. According to this definition, biomarkers can be classified into three different categories: (1) biomarkers of exposure, which determine whether an organism has been exposed to a certain xenobiotic; (2) biomarkers of effect (response), which determine the effect of the exposed organism to the xenobiotics; and (3) biomarkers of susceptibility, which predict the susceptibility (resistance) of the organism to the deleterious effect of a specific xenobiotic.

Fig. 66.1 summarizes the main uses of biomarkers in toxicology. Sometimes there are doubts about whether or not an organism has been exposed to xenobiotics, especially if that exposure was not strong enough to cause adverse clinical effects. Biomarkers of exposure reveal if such organisms have been exposed because the presence of xenobiotics or their metabolites in biological samples (both free or bound to endogenous molecules) from the monitored individual is proof of exposure. Thus, biomarkers of exposure are suitable for assessing exposure to xenobiotics, especially when the organism is not in direct contact with the source of xenobiotics in the moment of the sampling and also when an exposure assessment based on chemical determinations in environmental samples representative of the media to which the individual has been exposed is not possible. Another advantage is that biomarkers of exposure always refer to internal doses (that the xenobiotic has been absorbed). Therefore, biomonitoring is a better indicator of how many xenobiotics might reach endogenous targets, thus making

the expected intensity of the adverse effect more predictable. Aldridge (1996) divided toxic phenomena into five different stages, according to which, biomarkers of exposure might be used at any time after stage 1 (absorption) (Fig. 66.2).

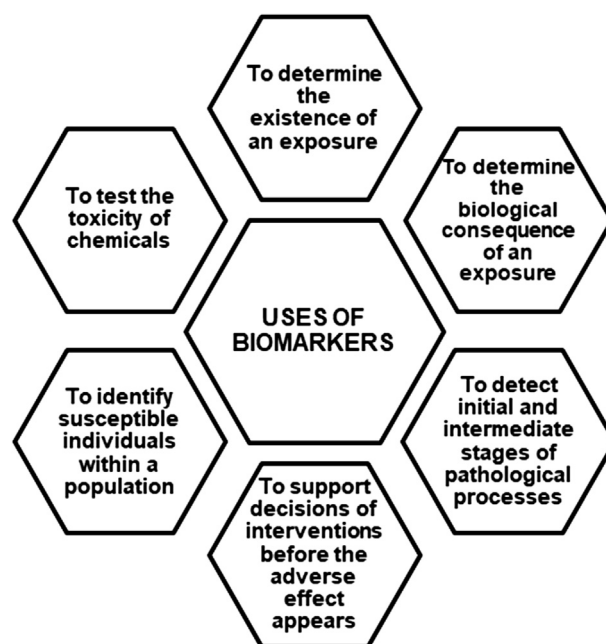
Exposure is a necessary cause, but it does not suffice to alter exposed organisms. In this way, biomarkers of effect can help to determine if the intensity of exposure is strong enough to cause an effect or a response in exposed organisms. According to Aldridge's scheme (Aldridge, 1996), immediately before clinical consequences appear in an organism,


FIGURE 66.1 Uses and applications of biomarkers in toxicology.
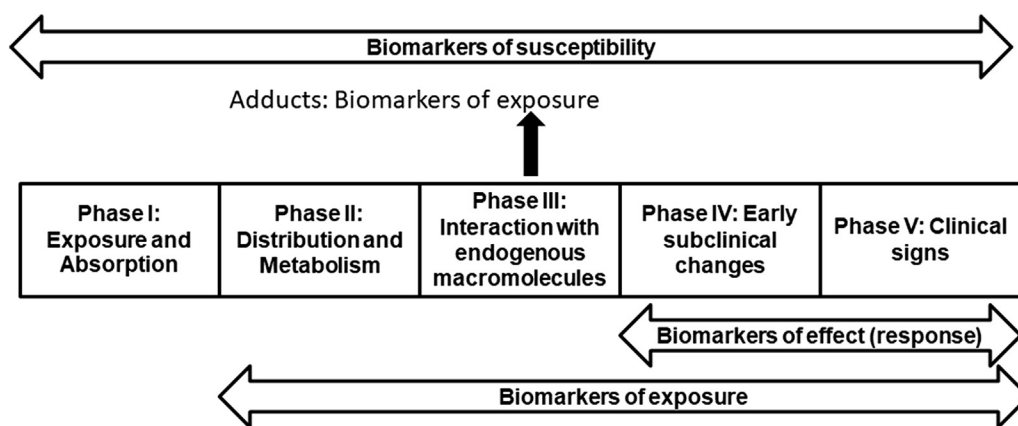

FIGURE 66.2   **Different stages of toxic phenomena in relation to different types of biomarkers.** The scheme is based on Aldridge's proposal (1996). Biomarkers of exposure can be determined at any time after stage 1 (exposure and absorption). Usually biomarkers of effect ideally address stage 4 (early subclinical effects) because they can help prevent clinical signs from appearing in stage 5 (clinical consequences of exposure). Biomarkers of susceptibility are related with bioavailability and/or endogenous targets; therefore, they can address the three first stages of the process, although measures in further stages also can yield relevant information.

there is an asymptomatic stage in which certain changes can be detected at the biochemical, cellular, tissue, or functional levels (Fig. 66.2). Biomarkers of effect are very useful for detecting these preclinical stages, which might lead to decision-making (basically decisions on acceptable levels of exposure and about whether allow the exposure or not) before adverse effects are declared in exposed organisms (Fig. 66.1). Biomarkers of effect are very important for in vivo and in vitro toxicology testing because in vivo assessments biomarkers are able to detect preclinical stages, whereas in vitro scenarios biomarkers offer molecular end points to measure the response of the exposed system to the assessed xenobiotics.

Finally, biomarkers of susceptibility allow us to identify, among all the people in a given population, those individuals who are particularly susceptible to xenobiotics. This would also allow us to provide greater protection to these individuals. Because biomarkers of susceptibility are related to bioavailability processes, these biomarkers can be determined for prevention purposes preferably at any point of the three first toxic phenomena stages (Fig. 66.2). Measures in the fourth and fifth stages can also be relevant for explaining the severity of the effects caused by the exposure. Biomarkers of susceptibility are also important for toxicology testing, despite the fact that they are not directly involved in exposure or response themselves. This can be highly relevant for explaining the intensity of the toxic responses.

The main limitations in employing biomarkers in toxicity toxicology testing and biomonitoring of xenobiotics exposure are related to the necessity of prior knowledge about the biomarker and the lack of utility for xenobiotics with either low absorption or immediate toxic effects. Previous knowledge is needed because information about toxicokinetics (i.e., route and rate of excretion, the tissue where the xenobiotic is potentially bioaccumulated, etc.) is very relevant to determine which biological sample is appropriate for biomonitoring and even which chemical has to be analyzed (the parental xenobiotics or some of its metabolites). Knowledge about mechanisms of action is also relevant because the closer its relationship with the basic toxicity mechanism, the more relevant the biomarker is.

Based on the information mentioned above, biomarkers are not usable if the xenobiotic offers a low absorption rate or if its toxic effects are immediate (i.e., irritation or corrosion) because, in these cases, there is no preclinical phase (stage 4 in Fig. 66.2). Therefore, it makes little sense because toxic effects become unavoidable after exposure.

REQUIREMENTS EXPECTED IN A BIOMARKER FOR TOXICOLOGY TESTING AND BIOMONITORING XENOBIOTICS EXPOSURE

The ideal biomarker should (1) be ethically acceptable, (2) imply simplicity for sampling, (3) be dependent on easy chemical analysis, (4) reflect a reversible change, (5) be relevant, and (6) be valid (Fig. 66.3).

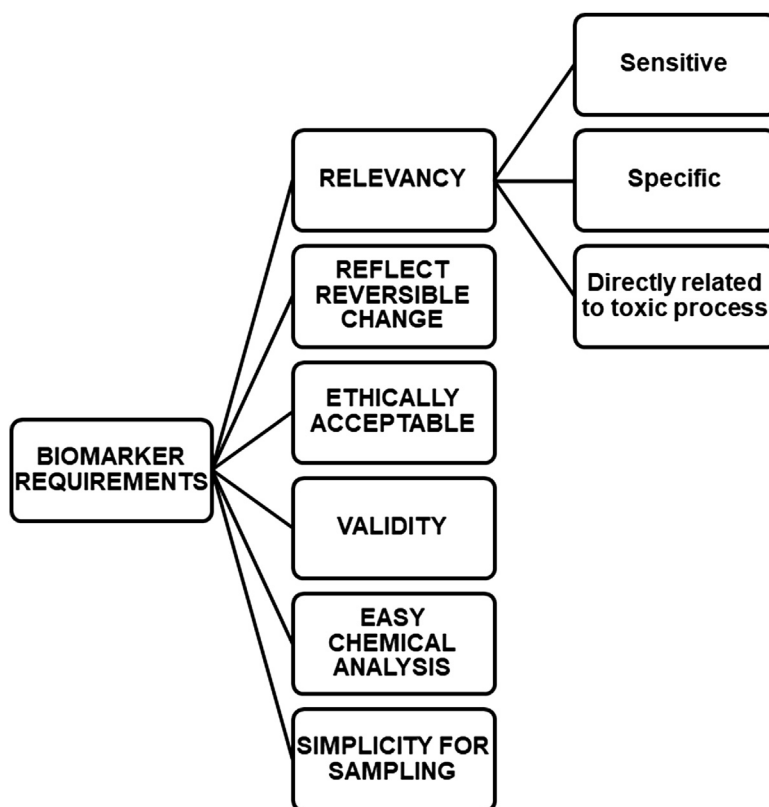
The relevancy of a biomarker is also an important point when having to make a choice. The relevance of a biomarker will only be as good as its sensitivity, specificity, and relationship with the toxic process. Sensitivity refers to the biomarker's capability to display major changes after mild exposures. Specificity is the biomarker's capability to react only after a single


FIGURE 66.3   Requirements expected in a good biomarker for toxicology testing and biomonitoring xenobiotics exposure.

xenobiotic challenge; i.e., the level of metallothioneins is considered a nonspecific biomarker of response to heavy metals because the level of these proteins increases after exposure to most heavy metals. This does not allow us to determine the heavy metals to which organisms have been exposed. Conversely, the level of a specific heavy metal in an organism is a specific biomarker of exposure to this given heavy metal.

A good biomarker also has to address the basic toxicity mechanisms as closely as possible. According to Aldridge (1996), with clinical signs of poisonings, the xenobiotic (or its metabolite) has to interact with an endogenous biomolecule (stage 3 in Fig. 66.2) to cause a primary alteration or response. This response may cause secondary alterations. Evidently, the biomarker reflects primary alterations or responses instead of secondary or tertiary ones.

The validity of a biomarker is regulated by several factors (Fig. 66.4). The capability to distinguish among different levels of exposure is important. This directly addresses the existence of reliable dose–response relationships to support decisions relating to interventions before adverse effects appear, which is one of the most relevant applications of biomarkers (Fig. 66.1).

Certain biomarkers, especially those of enzymatic activities, present an endogenous expression in the

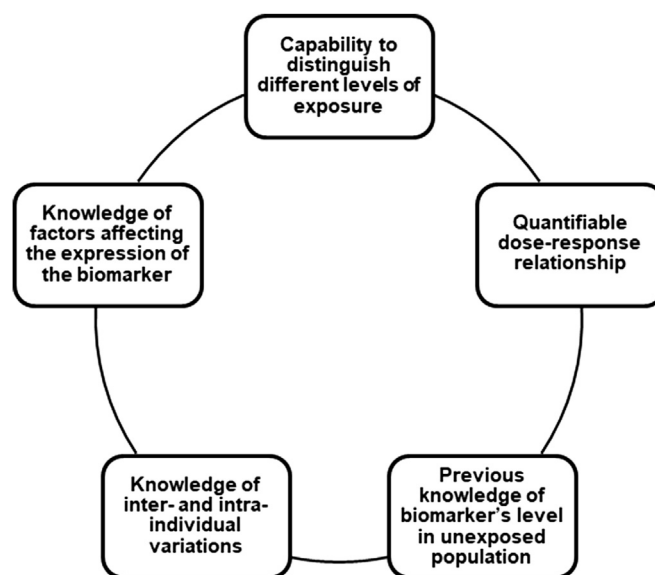
absence of exposure. The existence of previous knowledge on levels of expression in unexposed subjects becomes necessary to validate the biomarker (i.e., serum cholinesterases display a wide range of activity in people without detected exposure to their inhibitors),


FIGURE 66.4   Factors affecting the validity of a biomarker.

which may then act as controls for comparisons with subjects who have been exposed. Moreover, variations in the expression of the biomarker in the absence of exposure and the factors affecting the expression of the biomarker are also required because protein expression can be affected by several temporary situations, such as pregnancy, age, nutritional state, exposure to other environmental contaminants, etc.

Biomarkers are based on determinations of chemicals or processes in biological samples. This implies, especially in humans, that not all biological samples are acceptable for ethical reasons. Hence, the most used biological samples are hair, blood, and urine. Other biological samples from biopsies are acceptable, only if the patient risks are lower than the expected benefit. The necessity of the biomarker to be analyzed in easily accessible samples is also closely linked to ethical reasons. The process to determine the biomarker in a biological sample should, ideally, be as easy as possible. It is also advisable that biomarkers of exposure and effect address the reversible toxic effect because this would allow taking preventive measures to avoid irreversible adverse effects.

BIOLOGICAL SAMPLES USED FOR BIOMONITORING EXPOSURE THROUGH BIOMARKERS

The main requisites for a biological matrix to be used for biomonitoring exposure are that it is available in sufficient amounts and does not pose a risk to the donor (Esteban and Castaño, 2009). The biological samples typically used for biomonitoring biomarkers of exposure and response in humans are urine and blood. Both samples are ethically acceptable, but their main disadvantage is their temporary validity. Urine only reflects exposure that took place in the few hours before sampling, whereas blood can be valid in certain situations, but for longer periods (maximum 3 or 4 months). Conversely, hair might prove to be an ideal biomarker of exposure because it is bloodless and represents an individual's cumulative exposures, the time of the exposure to the time the sample is taken. Expired air may also prove suitable for volatile xenobiotics.

Other biological samples are also suitable but are less frequently used given either the small amount available (saliva, sweat), the temporary availability (breast milk, meconium) or because the sample is not always ethically acceptable (i.e., biopsies that require major surgery, risk for fetus involved, etc.).

BIOMARKERS OF EXPOSURE FOR MONITORING XENOBIOTICS EXPOSURE

A biomarker of exposure is the presence of a xenobiotic, its metabolites, or the product of its interactions with endogenous targets. Table 66.1 provides a general overview of the most widely used biomarkers of exposure, whereas Table 66.2 displays specific biomarkers for several xenobiotics, together with the biological sample used for biomonitoring. It is remarkable that the chemical to be analyzed may differ for the same xenobiotic depending on the biological sample used; i.e., benzene is exhaled and circulates in blood as such (in an untransformed form), whereas it is found in urine as a free phenol (biotransformation product) or glucuronized phenol.

TABLE 66.1   The Most Popular Biomarkers of Exposure

Exposure to:	Biomarker
Xenobiotics	Parental xenobiotic or its metabolites
Alkylating xenobiotics	Adducts among xenobiotic and DNA and proteins
Oxidizing xenobiotics	Damaged macromolecules (DNA, lipid, or proteins) Increases in oxidized glutathione Induction of superoxide dismutases

TABLE 66.2   Some Biomarkers of Exposure

Exposure to:	Biological Sample	Chemical
Benzene	Exhaled air and blood	Benzene
Benzene	Urine	Phenol
Styrene	Exhaled air and urine	Styrene
Styrene	Urine	Mandelic acid
Dioxins	Fat	Dioxins
Lead	Blood	Lead
Aluminum	Bone	Aluminum
Toluene	Exhaled air	Toluene
Methylmercury	Hair	Methylmercury
Aniline	Urine	p-aminophenol
Hexane	Urine	2,5-hexanodione
Ethyleneglycol	Urine	Oxalic acid
Acetone	Urine and blood	Acetone

The biomonitoring of xenobiotic exposure can be performed using biomarkers in biological samples where the target of toxicity is not found. For example, the inhibition of butyrylcholinesterase in plasma is considered a biomarker of exposure to organophosphorus or carbamate insecticides and can be performed without necessity of performing a biopsy in the nervous system. This overcomes obvious bioethical considerations in the case of humans or even protected wild fauna that would not have to be sacrificed for environmental biomonitoring purposes. Moreover, unlike biomarkers of effect, a xenobiotics' exposure assessment can be performed using biomarkers with still unknown physiological roles.

A situation where both factors (the use of nontarget tissues and biomarkers with unknown roles) simultaneously appear is the use of the carboxylesterases found in the nervous system, which have to be discriminated from among the pool of esterases using inhibition kinetics with model organophosphorus compounds given the absence of a specific substrate. Three carboxylesterase enzymatic components were differentiated according to sensitivity to mipafox, paraoxon, and phenylmethanesulfonyl fluoride in chicken peripheral nerves (Estévez et al., 2004, 2011, 2012). Esterases with similar kinetic properties were found in serum, suggesting that they may be considered a "mirror" of the esterases of peripheral nerve for monitoring studies (García-Pérez et al., 2003; Estévez et al., 2011). Therefore, these esterases in the nervous system still cannot be biomarkers of effect because the physiological role is unknown and access to biopsies of the nervous systems is bioethically unacceptable in most cases. However, inhibition of their analogous esterases in plasma, a bioethically acceptable biomarker, warns about exposure to carboxylesterase inhibitors and may help prevent hazardous exposures because they are more sensitive to inhibition than classic biomarkers of exposure to carboxylesterase inhibitors with defined physiological roles as cholinesterases.

These same esterases have also been proposed for biomonitoring exposure to organophosphorus insecticides and carbamates in wild fauna, such as in birds (Sogorb et al., 2007), lizards (Basso et al., 2012; Sánchez-Hernández and Sánchez, 2002), earthworms (Sanchez-Hernandez et al., 2009, 2015), oysters (Ochoa et al., 2013), snails (Laguerre et al., 2009), crayfish (Vioque-Fernández et al., 2007), and other species like aquatic organisms such as fish and crustaceans (Solé and Sánchez-Hernández, 2015).

Adducts: A Relevant Case of Biomarkers of Exposure

Sometimes the xenobiotic or its metabolite binds to biological molecules (not necessarily a target of toxicity)

to yield stable new structures called adducts, which can be used as proof that the organism has been exposed to the xenobiotic. The main requisite of the adducts to be used as a biomarker of exposure is that adduct stability is sound enough to allow the detection of exposures that occurred in the past and to resist handling of the samples with the subsequent treatments needed for chemical analysis.

Adducts of xenobiotics can be formed either with DNA or proteins. The usual biological samples taken for monitoring adducts of DNA are lymphocytes because they do not arouse ethical concerns. Nevertheless, any other cellular sample can also be useful; i.e., from biopsies. DNA adducts are especially suitable for the detection of exposures to carcinogenic chemicals. Table 66.3 depicts some examples of DNA adducts that are detectable in people exposed to several genotoxic carcinogenic xenobiotics.

Adducts formed between xenobiotics and proteins are usually monitored with hemoglobin, which is an abundant easily accessible protein in blood. Albumin is also an another abundant easily accessible protein in blood that has been proposed as a biomarker of exposure. Indeed, it has been reported that this protein is able to form stable adducts with lots of organic compounds, such as: (1) chemoprotective agents such as isothiocyanates (Sabbioni and Turesky, 2017); (2) therapeutic drugs such as β-lactam antibiotics and nonsteroidal antiinflammatory drugs, acetaminophen, or nevirapine (Sabbioni and Turesky, 2017); (3) carcinogens such as benzene, naphthalene, styrene, aromatic amines, and aflatoxin B1 (Sabbioni and Turesky, 2017); (4) organophosphorus insecticides such as azamethiphos(oxon), chlorfenvinphos (oxon), chlorpyrifos-oxon, diazinon-oxon, malaoxon, dichlorvos, tricresyl phosphate, cresyl saligenin phosphate, parathion, chlorpyrifos, chlorpyrifos-oxon (Tarhoni et al., 2008; Li et al., 2010, 2013; Schopfer et al., 2010; Liyasova et al., 2012; Noort et al., 2009; Jiang et al., 2012); (5) nerve agents with an organophosphorus structure such as soman, sarin, cyclosarin, and tabun (Williams et al., 2007; Li et al., 2008; Read et al., 2010); (6) drugs such as diazepam and ketoprofen (Watanabe et al., 2000); (7) cyanide (Fasco et al., 2011); and

TABLE 66.3   Xenobiotics Capable of Forming DNA Adducts

Xenobiotics	DNA Adduct
Ethylene oxide	N-2-hydroxyethylvaline
Mycotoxins	Aflatoxin B1, ochratoxin A
Heterocyclic amines	2-amino-3,8-dimethylimidazoquinoxaline
Aromatic amines	2-acetylaminofluorene
Polycyclic aromatic hydrocarbons	Benzopyrenes, anthracenes

(8) p-nitrophenyl esters (Means and Bender., 1975; Sakurai et al., 2004). Adducts formation also involves the deactivation of a molecule of organophosphorus insecticide that will never be available for further phosphorylation of acetylcholinesterase. Therefore in the case of albumin, an extremely abundant protein, this binding also becomes a mechanism of defense against organophosphorus insecticides, which, depending on the capability of phosphotriesterases to hydrolyze insecticides, might even prove critical, as demonstrated with paraoxon (Sogorb et al., 2008; Sogorb and Vilanova, 2010a; b). The relevance of the adducts of albumin as a biomarker of exposure is such that a transgenic mouse model expressing human serum albumin as biomarker of exposure to carcinogenic chemicals has been developed (Sheng et al., 2016). It was considered necessary because in vitro studies have reported differences between human and rodent albumins in their reactivity with certain xenobiotics that might potentially allow the formation of different adducts with subsequent shortcomings in the interspecies extrapolations. According to the authors, the use of this transgenic animal will facilitate the development and validation of adducts of albumin as biomarkers of exposure to carcinogenic chemicals.

BIOMARKERS OF EFFECT FOR TOXICOLOGY TESTING

Biomarkers of effect exhibit a biological response (biochemical, physiological, behavioral, etc.) to the exposed organisms. Table 66.4 provides examples of biomarkers of effect for different xenobiotics, whereas Table 66.5 shows some biomarkers of effect in several target tissues (Gupta, 2014).

Sometimes biomarkers of effect are not easy to differentiate from biomarkers of exposure. In general, however, a requirement for biomarkers of effect is that the state

TABLE 66.4 Some Examples of Biomarkers of Effect

Exposure to	Biomarker
Organophosphorus and carbamate insecticides	Inhibition of acetylcholinesterase in red blood cells
Lead	Inhibition of δ-aminolevulinic dehydratase and subsequent increases of δ-aminolevulinic acid in blood
Oxidizing compounds	Induction of antioxidant enzymes such as superoxide dismutase and others
Heavy metals	Induction of metallothioneins

TABLE 66.5 Examples of Some Biomarkers of Effect Typically Used for Biomonitoring Challenges to Different Targets Systems by Different Xenobiotics

Target System	Matrix	Biomarker
Central nervous system	Platelets	Monoamine oxidase b
	Cerebrospinal fluid	Glial fibrillary acidic protein, ubiquitin C-terminal hydrolase-1, α-synuclein, neuron specific enolase
	Plasma	miRNA-124
Respiratory system	Bronchoalveolar lavaged fluid and sputum	Protein, albumin, lactate dehydrogenase, N-acetyl glucosaminidase, γ-glutamyl transferase, lysozyme, alkaline phosphatase, neutrophils, lymphocytes, eosinophils, macrophages, monocytes
Liver	Blood, serum, plasma	Alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, total bilirubin, cholesterol/triglycerides, ammonia, albumin
Kidney	Urine	Proteinuria, enzymuria, cystatin C,
	Blood and urine	Neutrophil gelatinase—associated lipocalin
	Serum	Kidney injury molecule-1
Gastrointestinal system	Blood	Citrulline, diamine oxidase, gastrin, C-reactive protein, pepsinogen I and II
	Feces	Calprotectin, lactoferrin, polymorphonuclear neutrophil elastase, bile acids, fecal S100A12
Pancreas	Serum/plasma	Amylase, isoamylase, and total amylase, lipase, carbohydrate-deficient transferrin, trypsinogen activation products amylase, isoamylase, phospholipase A2
	Urine	Amylase, isoamylase, phospholipase A2
	Feces	Elastase 1
	Pancreatic juice	Cathepsins B, L, and S
Skin	Biopsy of stratum corneum	Keratin 1, 10, 11, desmoglein-1, desmocollin-1, corneodesmosin, total protein, adherins junction protein gene expression
Blood	Urine	δ-Aminolevulinic acid levels

TABLE 66.5 Examples of Some Biomarkers of Effect Typically Used for Biomonitoring Challenges to Different Targets Systems by Different Xenobiotics—cont'd

Target System	Matrix	Biomarker
	Blood	δ-Aminolevulinic acid dehydratase activity
	Blood	Mean cell hemoglobin concentration
	Urine	Corproporphyrin
	Blood	Zinc protoporphyrin
	Blood	Hematocrit/packed cell volume blood, hematocrit, hematocrit oxidants, mean cell volume, reticulocyte count, carboxyhemoglobin, methemoglobin, bleeding time, platelet count, leukocyte count
	Bone marrow	Altered myeloid/erythroid ratio, Morphologic alterations
Immune system	Blood	Leukocyte count
	Spleen, thymus, lymph node	Organ weight
	Serum, secretions, exudates	IgA, IgD, IgG, IgE, IgM
	Serum, cell supernatant, saliva, sputum	Cytokine profiling
	Urine	Leukotriene E(4)
	Serum, inflammatory exudate	Autoantibodies

of the exposed organism has to change as a result of the xenobiotic challenge (i.e., increasing the level of expression of a protein).

As in biomarkers of exposure, the effect can sometimes be monitored in tissues where the main toxicity target is not found. This can be said of the biomarkers of effect of organophosphorus insecticides. The main target of organophosphorus insecticides is acetylcholinesterase (EC 3.1.1.7) (World Health Organization, 1986), which is considered the main biomarker of effect to organophosphorus insecticides. The biological sample usually taken for biomonitoring acetylcholinesterase inhibition is red blood cells. Erythrocytes express an acetylcholinesterase that is genetically identical to acetylcholinesterase expressed in the central nervous system. Therefore, it is considered that the level of inhibition of acetylcholinesterase in red blood cells will be a

reflection of the response of acetylcholinesterase in the nervous system. Organophosphorus insecticides also inhibit other esterases in the CNS that differ from acetylcholinesterase. This is the case with neuropathy target esterase (EC 3.1.1.5), an esterase target of a neurodegenerative syndrome caused by certain organophosphorus insecticides called organophosphorus inducing delayed polyneuropathy (Glynn, 2003). Neuropathy target esterase is also expressed in lymphocytes. Therefore the level of inhibition of the protein in these cells is considered a biomarker of response to the exposure to organophosphorus insecticides (Lotti et al., 1986; McConnell et al., 1999).

Molecular Biomarkers for In Vitro Testing Toxicity

Molecular biomarkers are a powerful tool for assessing the toxicity of chemicals, especially in vitro. In vitro and ex vivo systems offer an excellent opportunity for a fast and reliable assessment of the toxicity of chemicals through an appropriate selection of molecular biomarkers.

Omic methodologies have provided a great advance in toxicology during the 21st century (Choudhuri et al., 2018). Omic approaches allow designing sets of key molecular biomarkers that might play a notable role in toxicity testing. Within the omic methodologies, transcriptomics is probably the most promising tool for the discovery and validation of molecular biomarkers. Indeed, alterations in connectivity maps of the transcriptome after exposure to xenobiotics is able to play a double role in that it is able to help explain the mechanism of toxicity and build adverse outcome pathways (Leist et al., 2017). These alterations are also able to identify key genes in the development of the adverse outcome that will serve as biomarkers for testing toxicity.

Some examples of biomarker genes that have been proposed for toxicity testing (specifically developmental toxicity) are "van Dartel Heartdiff_24h" and "EST biomarker genes" that were able to correctly predict between 67% and 83% of embryotoxicants within a battery of model toxicants (van Dartel et al., 2011). The battery of 16 different genes proposed by Romero et al. (2015) that were able to predict the embryotoxicity potency of a set of five different embryotoxicants plus two negative controls with an in vivo–in vitro concordance of 100% is also very promising in this field of developmental toxicity.

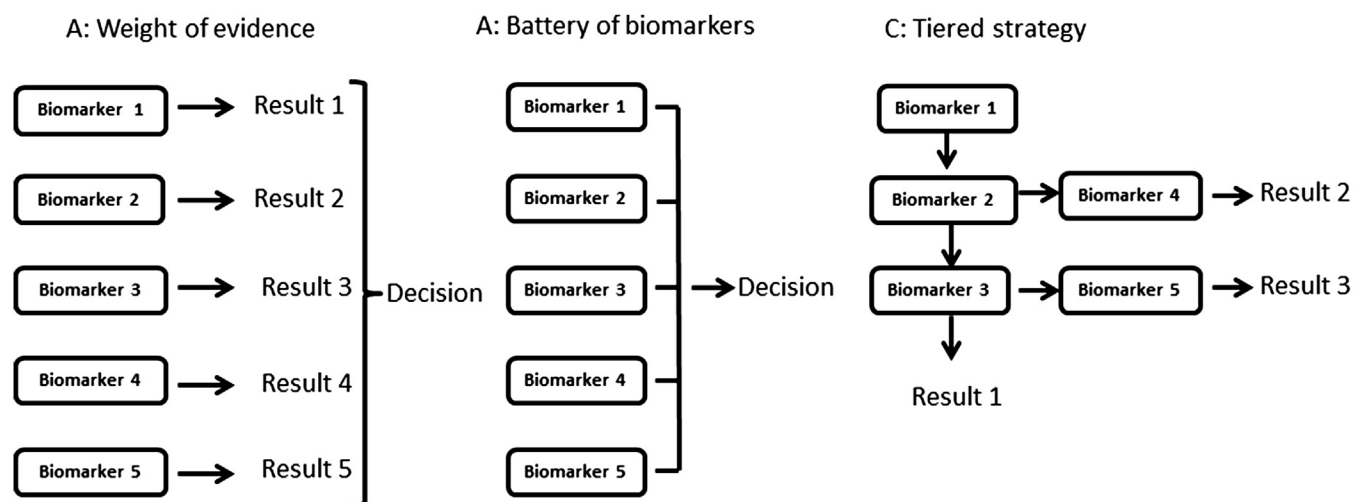
It is quite obvious that a single in vitro test based on a single biomarker will never be able to replace an in vivo test. However, it is theoretically possible to develop *Integrated Testing Strategies* that efficiently combine


FIGURE 66.5   **Schemes for the different approaches that are considered as form of Integrated Testing Strategy.** *Based on Rovida C., Alépée N., Api A.M., et al., 2015. Integrated testing strategies (ITS) for safety assessment. ALTEX 32(1), 25–40.*

different information coming from different biomarkers and which might introduce notable enhancements in the process of safety assessment of chemicals (in terms of reduction of cost, time, and consumption of animals). This would theoretically allow (1) the preliminary assessment of the potential toxicity of the tested chemical, which might be especially relevant in screening processes; (2) the understanding of the mechanism of toxicity, which might allow for safer assessment of the hazards/risks associated with exposure because the adverse effect to be tested will be preliminarily well identified; (3) when negative results are obtained, the design of more focused in vivo experiments (e.g., using a single limit dose) will also be potentially possible; and (4) when results are positive, this will still allow a more rational approach for proposing which cellular, physiological, and biological end points will deserve further research in more complex in vitro or in vivo assays.

Three different approaches are currently being considered for developing *Integrated Testing Strategies* (Rovida et al., 2015): (1) the weight of evidence; (2) the battery of tests; and (3) the tiered strategy (Fig. 66.5). In the weight of evidence approach, independent assays providing the same number of independent results have to be analyzed to make a decision, as none of the available results are suitable for such a decision alone (Fig. 66.5A). In the battery of tests, the final decision is defined by the sum of the results from many analyses, all of which must be performed (Fig. 66.5B). However, the tiered strategy is an open system that allows one to decide the next test to perform based on the results of the first step (Fig. 66.5C). Each of the three strategies will be

considered for defining a set of specific biomarkers that allow performing hazard identification and risk characterization of developmental toxicity in the fastest, safest, and more reliable way.

The development of biomarker signatures also allows the grouping of chemicals with common mechanisms of toxicity, which would notably cut the number of animals used in toxicity testing because only the most representative chemicals of a specific group can be assayed, and the further extrapolation of the results to the remaining members of the group is possible without animal experimentation.

The sets of in vitro biomarkers might also be part of *Integrated Approach for Testing and Assessment* strategies with future consequences at the regulatory level, which would allow the assessment of chemicals exclusively on the basis of in vitro assays, as suggested specifically for neurodevelopmental toxicity testing by Fritsche et al. (2017).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Biomarkers are a powerful tool for risk assessments of aspects of exposure assessment and risk characterization. Biomarkers of exposure are indicated for exposure assessment, especially when the chemical species being analyzed is the adduct resulting from the interaction between the xenobiotic and an endogenous molecule (not necessarily the toxicity target). These adducts are usually eliminated from organisms more slowly than the free xenobiotic (or its free metabolites), which allows

the detection of exposures, even when they have been totally eliminated from the exposed organism. Biomarkers of effect are useful for recording the responses of exposed organisms to the toxic insult and are used to detect exposures before clinical consequences appear. The development of integrated testing strategies based on molecular biomarkers is a promising and powerful approach for assessing the safety of chemicals on the basis of in vitro or ex vivo toxicity tests. Ideally, a risk assessment should be performed on the basis of the analysis of a complete battery of good biomarkers of exposure, effect, and susceptibility because a single biomarker does not usually yield enough information to allow a good risk assessment process.

Biomarkers in Epidemiology, Risk Assessment and Regulatory Toxicology

A.M. Fan[1], P. Cohn[2], S.H. You[3], P. Lin[4]

[1]California Environmental Protection Agency (retired), Oakland/Sacramento, CA, United States; [2]New Jersey Department of Health (retired), Trenton, NJ, United States; [3]Institute of Food Safety and Risk Management, National Taiwan Ocean University, Keelung, Taiwan; [4]National Institute of Environmental Health Sciences, National Health Research Institutes, Taiwan

INTRODUCTION

Biomarkers have been used in clinical medicine and molecular epidemiology, mainly as biologic indicators of exposure or risk of disease, and their use in toxicology, risk assessment, and environmental chemical regulations has been discussed by Fan (2014). The earlier discussion focused on the three types of biomarkers (namely biomarkers of exposure, effects, and susceptibility) related to the study of environmental chemicals and the associated human exposures and health effects, how biomarkers fit into the toxicological evaluation and risk assessment considerations, and how risk assessment with the potential use of biomarkers is integrated into the development of chemical guidance and regulations. It highlights some successes in advancing the understanding of some of the most critical elements of the risk assessment process, and in using biomarkers to address environmental and public health issues. Several examples were given for polycyclic aromatic hydrocarbons (PAHs), pesticides that are cholinesterase (ChE) inhibitors, triazines, lead, selenium (Se), cotinine, methylmercury (MeHg), and nitrate. It is encouraged that it should be read as a compendium to this chapter.

This chapter updates the discussion with additional relevant information on the definition and uses of biomarkers, and on MeHg from fish consumption, ChE-inhibiting pesticides (e.g., chlorpyrifos), Se, and formaldehyde. It focuses on environmental chemicals and the associated biomarkers (excluding clinical and diagnostic tools, surrogate endpoints in clinical research, and therapeutic intervention), and it includes recent reports from the National Research Council (NRC) that substantially advance the conceptual and experimental approaches in the fields of exposure science, biomonitoring, -omics technologies, and toxicology/toxicity testing and risk assessment, with the recognition that biomarkers are anticipated to play a role in these related advances.

A focus of this chapter is exposure science and its use in health risk assessments, in particular, risk from oral exposure. In brief, the usual risk assessment procedure involves developing health reference values such as an oral reference dose (RfD). The RfD is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime (approximated as 70 years). It is expressed as mass per kilogram of body weight per day, e.g., microgram (μg)/kg-day. The first step is the selection of the best study or studies, followed by the determination of a point of departure (POD) such as a no-adverse-effect level (NOAEL), a lowest-observable-adverse-effect level (LOAEL), or a benchmark dose (BMD). The BMD is usually expressed as the dose at which there is a 10% or 5% benchmark response rate for the effect of interest, BMD_{10} or BMD_{05}. This process typically involves applied statistical software that also generates an upper and, in particular, lower 95th percentile limit, the $BMDL_{10}$ or $BMDL_{05}$. Application of part or all of a set of uncertainty factors (UFs) to the $BMDL_{10}$ or $BMDL_{05}$ establishes the RfD. The margin of exposure is the degree to which the actual exposure exceeds or is less than the RfD. This process is discussed below in examples that help to illustrate how exposure science informs risk assessment.

BIOMARKERS

Biomarkers are measures reflecting interactions between biological systems, as in the human body, and environmental chemicals to which the individual is exposed. A major factor is the need to identify critical toxicological endpoints with cause—effect and dose—response relationships for quantitative risk assessment. This can then provide a scientific health basis for regulatory and risk management decision-making, often achieved by setting guidance levels or regulatory standards.

Traditionally, biomarkers have been classified by various researchers and scientific bodies as markers of exposure, effect, or susceptibility, with some variations (Fan, 2014). These biomarkers, sometimes referred to as biologic indicators, generally include biochemical, molecular, genetic, immunologic, or physiologic signals of events in biologic systems. The events are presented as a continuum between an external exposure to a chemical and resulting biological effect in the body, which may or may not lead to clinical manifestations or diseases.

For environmental chemicals, biomarkers of exposure, effect, and susceptibility are defined as follows (WHO, 2001; NRC, 2006):

Biomarker of exposure. The chemical or its metabolite or the product of an interaction between a chemical and some target molecule or cell that is measured in a compartment in an organism.

Biomarker of effect. A measurable biochemical, physiologic, behavioral, or other alteration in an organism that, depending on the magnitude, can be recognized as associated with an established or possible health impairment or disease.

Biomarker of susceptibility. An indicator of an inherent or acquired ability of an organism to respond to the challenge of exposure to a specific chemical substance.

Various elements are involved before exposure biomonitoring can be used for risk assessment and management decisions (NRC, 2006). These include scoping, screening, exploratory investigations, source investigations, societal-hazard identifications, status and trends, exposure surveillance, population research, pathway research, decision validation and health surveillance, exposure and health research, epidemiologic research (ecologic and analytic), toxicologic research, pharmacokinetic and pharmacodynamic research, and community and occupational investigations. With the related relevant and adequate information, risk assessment, population risk characterization, individual risk characterization, and clinical applications can be considered. The interpretation and use of biomonitoring data will depend on the entire body of knowledge on these elements.

NRC (2006) described the properties for biomarkers of exposure for which all the relationships needed are clearly delineated and thus would probably be useful for risk assessment purposes. A framework to characterize biomarkers links the potential uses of biomarkers to their properties and is based on the simplified relationships between external dose, internal dose, and biological effects. In this framework, the seven qualitative properties (based on a weight-of-evidence approach) are described as follows:

1. reproducible sampling and analytical method;
2. known relationship of external dose to biomarker in animals;
3. known relationship of external dose to biomarker in humans;
4. known relationship of biomarker to biological effects in animals;
5. known relationship of biomarker to biological effects in humans;
6. known relationship of external dose to response in animals; and
7. known relationship of external dose to response in humans.

The advantages and limitations of biomarkers are presented by Shea (WHO, 2011). The advantages include the following:

1. confirming absorption into human body;
2. measuring integrated exposure from all routes and all sources—not dependent on models or assumptions;
3. detecting very low-level exposures because analytical techniques have become exquisitely sensitive over the past several decades;
4. helping to test and validate exposure models when the results of modeling predictions are compared to internal doses actually measured in exposed persons;
5. helping to follow exposure trends when individuals or representative samples of groups are followed with serial biomarker testing over time; and
6. helping to evaluate public health interventions.

The limitations of biomarkers include the following:

1. does not define sources or pathways of exposure;
2. cannot define toxic dose—unless toxicology and epidemiology studies have defined toxicity and the dose response curve;
3. susceptible to inferior or unscrupulous analytical laboratories;
4. lack of meaningful reference levels for most chemicals; and

5. lack of toxicological and epidemiological information about the vast majority of environmental contaminants.

The US Food and Drug Administration (FDA)-NIH Biomarker Working Group (USFDA, 2016a,b) recently developed the BEST (Biomarkers, EndpointS, and other Tools) resource with the first phase comprising a glossary that clarifies important definitions and describes some of the hierarchical relationships, connections, and dependencies among the terms it contains. It was created with the goal of harmonization of terms used in translational science and medical product development, with a focus on terms related to study endpoints and biomarkers. The BEST glossary aims to capture distinctions between biomarkers and clinical assessments and to describe their distinct roles in biomedical research, clinical practice, and medical product development fields. The glossary showed biomarkers to be a defined characteristic that is measured as an indicator of normal biological processes, pathogenic processes, or responses to an exposure or intervention, including therapeutic interventions. Thus molecular, histological, radiographic, or physiological characteristics are approaches to measuring biomarkers, and a biomarker is not an assessment of how an individual feels, functions, or survives.

New Advances in Biomonitoring, Exposure Science, Toxicology, Risk Assessment, and Decision-Making

NRC has released several reports that substantially advance the conceptual and experimental approaches in the fields of exposure science and biomonitoring, and the companion fields of toxicology and risk assessment (NRC, 2012). Biomarkers are anticipated to play a role in these related advances.

In the 2012 report Exposure Science in the 21st century (NRC, 2012), exposure science addressed the intensity and duration of contact of humans or other organisms with certain agents (defined as chemical, physical, or biological stressors) and their fate in living systems. Exposure assessment was described as being instrumental in helping to forecast, prevent, and mitigate exposures that led to adverse human health or ecological outcomes; to identify populations that had high exposures; to assess and manage human health and ecosystem risks; and to protect vulnerable and susceptible populations. For example, the ability to detect chemical contaminants in drinking water at low but biologically relevant concentrations can help to identify emerging health threats, and it is valuable for assessing the value of proposed public health actions in policy and regulatory decisions (or success following implementation).

Exposure science has evolved from other disciplines as industrial hygiene, radiation protection, and environmental toxicology into a theoretical and practical science that includes development of mathematical models and other tools for examining how individuals and populations come into contact with environmental stressors. It has played a fundamental role in the development and application of many fields related to environmental health, including toxicology, epidemiology, and risk assessment. In this regard, exposure information is critical in the design and interpretation of toxicology studies and is important in epidemiology studies to compare outcomes in populations that have different exposure levels. Increasing collection and evaluation of biomarker data through the Centers for Disease Control and Prevention National Health and Nutrition Examination Survey and other government efforts offers the potential for improving evaluation of source–exposure and exposure–disease relationships.

The concept of the exposome has been defined as the totality of exposures individuals experience over the course of their lives (including such factors as diet, stress, drug use, and infection) and how those exposures affect health (DeBord et al., 2016). The three domains of the exposome are internal, specific external, and general external. Internal factors are those that are unique to the individual, and specific external factors include occupational exposures and lifestyle factors. The general external domain includes sociodemographic factors such as education level and financial status. A variety of tools have been identified to measure the exposome. Biomarker measurements will be one of the major tools in exposomic studies. Biomonitoring and biomarker data from -omics or other techniques would be used in the internal domain. The exposomic data in epidemiologic studies can provide greater understanding of the relationships among a broad range of chemical and other risk factors and health conditions and ultimately lead to more effective and efficient disease prevention and control. Many of the techniques for assessing exposure and the exposome involve molecular epidemiologic studies which use biological markers (exposure, effect, susceptibility) in epidemiologic research.

The Toxicity Testing in the 21st century report (NRC, 2007) laid the foundation for a paradigm shift toward the use of new scientific tools to expand in vitro pathway-based toxicity testing (NRC, 2012). A key component of that report is the generation and use of population-based and individual human-exposure data for interpreting test results and using toxicity biomarker data with exposure data for biomonitoring, surveillance, and epidemiologic studies. The focus of the report on systems approaches to understanding human biology, coupled with information about systems-level perturbations resulting from human–environment

interactions, is critical for understanding biologically relevant exposures. By emphasizing early perturbations of biological pathways that can lead to disease, the report moves the focus of risk assessment along the exposure–disease spectrum toward exposure, especially the role of prior and current exposures in altering vulnerability of individuals and communities to additional environmental exposures. The resulting toxicology focus is on early biomarkers of effects in the population. At the same time, such concepts as the exposome have moved the focus of exposure science along the exposure–disease spectrum toward the health-effects side, especially biologic perturbations that correlate with exposure and are predictive of disease. The interconnections between fields of exposure science and toxicology allows for better linkages between exposure and disease.

In the report Using 21st century Science to Improve Risk-Related Evaluations (NASEM, 2017), a committee discussion on the best ways to incorporate the emerging science into risk-based evaluations was presented. Several large-scale US and international programs have been initiated to incorporate advances in molecular and cellular biology, -omics technologies, analytical methods, bioinformatics, and computational tools and methods into the field of toxicology. In addition, the causal understanding for human health risk-based decision-making was discussed at a recent NAS panel meeting (NASEM, 2018.).

BIOMARKERS OF EXPOSURE

Measuring a biomarker of exposure starts with the choice of the biological media to study and whether the original chemical or its metabolite (or ionic state, species in the case of metals and metalloids) is more available and/or quantifiable. The choice of biological media for measuring biomarkers is linked to the pharmacokinetics of the contaminant of interest, though there are other factors, such as ease of collection and willingness to participate. Each chemical must be evaluated separately for validity of the media choice. However, there are some general approaches. While biomonitoring programs typically choose one biological media, many research studies look at more than one to better characterize exposure among what is typically a smaller group of participants. Blood and urine are the most common media, but in the case of metals (e.g., mercury) and metalloids (e.g., arsenic) that bind to sulfhydryl moieties in amino acids, exposure can also be measured in hair and nails, which is useful for estimating longer-term exposures and the overall body burden of the metal. Lipophilic chemicals, including persistent organic pollutants, are best measured in a lipid-rich environment, such as breast milk.

The choice of what to measure must also be well considered. For example, many volatile organic chemicals are quickly exhaled, so exhaled air could be the most appropriate method of exposure estimation if done shortly after exposure, such as at the end of a shift at a work site, whereas measurement of nonvolatile metabolites (e.g., after glycosylation) in blood or urine might be more appropriate at a later point.

Interpretation of biomonitoring data for use in exposure and risk assessment can be greatly assisted by application of pharmacokinetic models (Ruiz et al., 2011).

METHYLMERCURY

In this discussion, emphasis is placed on concentrations in blood and hair in fish-eating populations based on best available data, and how these internal exposures relate to external intakes from fish consumption, toxicology and dose–response assessment, health risk assessment, derivation of health-protective reference values (e.g., USEPA RfD), and implications in regulatory decision-making and public health risk management guidance. The update includes a recent study by the authors on estimates of MeHg intake through internal and external exposures, using measurement of total mercury (THg) in blood as a biomarker of exposure in young children and adolescents in Taiwan, plus intake estimates from food consumption data, based on two national biomonitoring databases (You et al., 2018). The current issues of interest relate to widespread MeHg contamination and exposure from fish consumption, the regulatory implications, and the need to provide awareness and guidance to the general public, especially the sensitive populations (women of childbearing age, infants, and children), along with risk–benefit considerations, and the increasing knowledge of dose–effect (response) relating to internal and external biomarkers. Emphasis is placed on quantitative data of biomarker concentrations and health concern levels.

In most epidemiologic and exposure studies, mercury exposure is assessed by analysis of hair, blood, or urine, most commonly in occupational contexts, and nail analysis has been used to assess body burdens of metals, often in relation to nutritional epidemiology (WHO, 2010a). The physiological and kinetic relationships between body burden and toenail levels are less understood, as compared to hair. Toenail mercury has not been used in studies of children, but it has been applied as a biomarker of exposure in studies of mercury exposures related to cardiovascular endpoints in adults. There have been relatively few direct comparisons of the informational value of results by compartment.

The major source of MeHg exposure is through the consumption of contaminated fish and seafood (WHO,

2010a,b,c). Human MeHg exposures are often assessed through the use of biomarkers, which serve as a surrogate for the biologically relevant internal dose of MeHg (NRC, 2000). The commonly used biomarkers are concentrations in blood, red blood cells (RBCs), hair, and urine (WHO, 1990; Groth, 2010; EFSA, 2012). Typically, blood and urine Hg levels are reported as THg, which comprises both inorganic and organic Hg. THg or organic Hg (total minus inorganic Hg) have been used to estimate MeHg in whole blood (WB) based on studies showing that 70%−95% of THg in blood is in the form of MeHg and is bound to hemoglobin (Mortensen et al., 2014), and the relationship of THg to MeHg has been assumed to be linear and constant across population demographics. MeHg is the toxic form responsible for adverse neurodevelopmental effects seen in fish-consuming human populations in contrast to effects due to inorganic mercury poisoning.

There is a direct relationship between Hg concentrations in human blood and consumption of fish contaminated with MeHg (WHO, 2008; Mahaffey et al., 2004; Grandjean et al., 1997; Karagas et al., 2012). In the general population, the total blood Hg concentration is due mostly to the dietary intake of organic forms, particularly MeHg (CDC, 2018), and it reflects short-term exposure, giving an estimate of exposure over the most recent 2−5 months, with an average half-life of MeHg in blood of 50 days (NRC, 2000). When measured at a specific point in time, it reflects contributions from both recent exposures, which may be increasing if intake is ongoing, and older exposures whose relative contribution decreases over time. Urinary Hg consists mostly of inorganic Hg.

Hg concentration in hair is often used to estimate MeHg exposure as the predominant form of Hg in hair is MeHg among persons exposed to MeHg (WHO, 2010a). The incorporation of Hg into the growing hair follicle is assumed to be directly proportional to the blood concentration, with a delay of 1−2 months between MeHg intake and measurement in the visible proximal hair shaft (Budtz-Jørgensen et al., 2004; WHO, 2010a; NRC, 2000). The relationship between location along the hair strand and timing of exposure can be ascertained by assuming a constant rate of hair growth, and 1.1 cm per month is commonly assumed.

Sheehan et al. (2014) reviewed and synthesized the evidence from published studies reporting total hair Hg and total blood Hg biomarkers to systematically compare global MeHg exposure among women and their infants from seafood-consuming populations. The authors compared the findings with the WHO provisional tolerable weekly intake (PTWI) reference level for fish (1.6 µg/kg bw/wk) and compared that intake to the approximate equivalent level in hair (2.2 µg/g). They found that pooled central THg biomarker distribution for various studied populations exceeded the WHO reference level based on the upper bound median (2.9−23.1 µg/g) or high-end biomarkers for women and infants in rural riverine communities, near tropical gold mining sites, Arctic traditional food consumers, industry and fishing categories, Pacific coastal subcategory, and Mediterranean and inland categories.

To relate the levels of MeHg biomarkers to the corresponding daily intakes of MeHg, an empirical one-compartment kinetic model describing the fate of MeHg in the human body has been used (WHO, 1990, 2007, 2010b; US EPA, 2001; You et al., 2018). The steady-state conditions (i.e., the intake equals the excretion) are assumed in establishing the relationship, resulting in a constant ratio between the MeHg daily intake and the total Hg measured in the biological matrices. In practice, the consumption pattern varies among individuals.

Various adverse health effects of MeHg have been shown in humans and in animal studies. The nervous system is the most sensitive target organ, particularly in developing organisms. More recent human health effects data were obtained from three studies that have been used for quantitative risk assessment. These are the three longitudinal developmental epidemiologic studies in Faroe Islands, New Zealand, and the Seychelles Islands that were conducted to study in utero MeHg exposure in the fish-eating populations (NRC, 2000; US EPA, 2001). The biomarkers of exposure are THg in maternal hair collected at delivery and Hg in infant cord blood and maternal blood, as internal dosimeters of MeHg exposure during pregnancy. The NRC conducted a comprehensive review of these studies on MeHg-related health effects and concluded that neurodevelopmental impacts from prenatal MeHg exposures are the most sensitive and best-documented endpoints (NRC, 2000).

For the purposes of risk assessment, biomarker concentrations of MeHg serve two functions (NRC, 2000). First, the concentration of a biomarker is used as a surrogate for the unknown biologically relevant dose of MeHg in the developing fetal brain, representing the dose in the development of a dose−response relationship. Second, in this dose−response relationship, the biomarker concentration identified as the critical (e.g., benchmark) concentration must be translated into an estimate of the ingested dose. The estimated ingested dose is used to guide public health interventions and regulatory measures. The latter step involves the use of toxicokinetic modeling to recapitulate the steps that precede the biomarker presence as measured.

In 1995, the USEPA derived an RfD for MeHg based on data from a poisoning episode in Iraq that reported clinical neurologic signs in 81 mother-and-child pairs. In its 2001 assessment, the US EPA used cord blood as

the biomarker for a risk assessment of the Faroe Islands data (US EPA, 2001) and developed an RfD because a comparison of the analyses based on hair and cord blood in the study suggested that the cord-blood measure explained more of the variability in more of the outcomes than hair Hg. Maternal daily dietary intake levels were used as the dose surrogate for the observed developmental effects in the children exposed in utero. The daily dietary intake levels were calculated from blood concentrations measured in the mothers with supporting additional values based on their hair concentrations. The US EPA used the *K* power model for BMD analysis, with the constraint that $K \geq 1$. This model response was set at the lowest 5% (fifth percentile) of children. The BMDL values were converted into ingested daily amounts that would result in exposure to the developing fetus at the BMDL levels in terms of ppb Hg in blood. The one-compartment model for dose conversion is used. The concentration in blood (c) corresponds to the $BMDL_{05}$.

$BMDL_{05s}$ were developed from a number of endpoints, all indications of neuropsychological processes involved in a child's ability to learn and process information, in terms of cord-blood Hg. The BMDLs for these scores were all within a relatively close range. Hair mercury was converted into blood mercury using a 250:1 ratio and an assumption of equivalent maternal and cord levels. $BMDL_{05}$ values were developed in the range of 46–79 ppb in maternal blood for different neuropsychological effects in the offspring at 7 years of age, corresponding to a range of maternal daily intakes of 0.857–1.472 µg/kg-day. The RfDs were developed from $BMDL_{05s}$ with application of a UF of 10 and a modifying factor of 1 to account for pharmacokinetic variability and uncertainty in estimating an ingested mercury dose from cord-blood mercury concentration, and a factor of 3 for pharmacodynamic variability and uncertainty. The calculated RfD values of all three studies converge at the same point: 0.1 µg/kg/day. The PODs were the BMDL for a number of endpoints from the Faroe Islands study, with supporting analyses from the New Zealand study, and an integrative analysis of all three recent large epidemiological studies. This convergence provides reassurance that additional UFs, other than for intraspecies variability, are not needed.

WHO (2007) evaluated MeHg using data from studies included in the NRC (2000) evaluation plus studies published between 2004 and 2006, investigating correlations among a number of biomarkers. The summarized correlations included additional data on MeHg in maternal hair, hair at 7 and 14 yrs, blood at 7 and 14 yrs, maternal and cord blood, and placental tissues. The original PTWI for MeHg (3.3 µg/kg bw) was revised at the 61st meeting of the Joint FAO/WHO Expert Committee on Food Additives (JECFA) to 1.6 µg/kg bw, based on an assessment of results from various epidemiological studies involving fish-eating populations and developmental neurotoxicity (WHO, 2004) and confirmed in 2007 and 2010. Specifically children 5.5- to 7-years old were assessed for neurodevelopmental endpoints, and maternal hair Hg levels were measured. WHO (2007) stated: "An average BMDL/NOEL of 14 mg/kg (14 µg/g) was derived for concentrations of mercury in maternal hair in the studies of neurodevelopmental effects, which was calculated to arise from a daily Hg intake of 1.5 µg/kg bw. The PTWI was derived by dividing this intake by a total UF of 6.4 to give a value of 1.6 µg/kg bw. For adults, the Committee considered that intakes of up to two times higher than the existing PTWI would not pose any risk of neurotoxicity, although in the case of women of childbearing age, intake should not exceed the PTWI to protect the embryo and fetus. Concerning infants and children up to 17 years, no firm conclusions may be drawn regarding their sensitivity compared with that of adults. While they are clearly not more sensitive than the embryo or fetus, they may be more sensitive than adults due to continuing neurodevelopment in infancy and childhood. Therefore, the Committee could not identify a level of intake higher than the existing PTWI that would not pose a risk of developmental neurotoxicity."

In its scientific opinion on the risk for public health related to the presence of Hg and MeHg in food, the European Food Safety Authority (EFSA, 2012) Panel on Contaminants in the Food Chain reevaluated the WHO PTWI for MeHg of 1.6 µg/kg and set a tolerable weekly intake (TWI) of 1.3 µg/kg bw/week after considering the counteracting effects of omega-3 fatty acids in fish. The panel analyzed THg converted into MeHg inorganic Hg by applying conversion factors based on the MeHg/THg proportion derived from literature data, using a conservative approach. For fish meat, fish products, fish offal, and unspecified fish and seafood a conversion factor of 1.0 was used for MeHg and 0.2 for inorganic Hg. For crustaceans, molluscs, and amphibians the conversion factor was 0.8 for MeHg and 0.5 for inorganic Hg. For all other food categories apart from "fish and other seafood," THg was regarded as inorganic Hg.

More recent data from the Seychelles Child Development Study showed no consistent pattern of adverse associations present between prenatal MeHg exposure and detailed domain-specific neurocognitive and behavioral testing at 17 years of age (Davidson et al., 2011) and no impaired autonomic heart rate control in young Seychellois adults 19 years of age (Périard et al., 2015). Two prospective cohort studies provided quantitative data that showed neurodevelopment benefits of the omega-3 fatty acid, docosahexaenoic acid, in children following maternal fish consumption during gestation (WHO, 2010c). There is the Avon Longitudinal Study of Parents

and Children (ALSPAC) (Hibbeln et al., 2007) which included 7223 mother–child pairs in England, and the Project Viva (Oken et al., 2008) which included 341 mother–child pairs in the United States, both of which showed dose–response relationships between maternal fish consumption and child verbal IQ gains.

Few data are available on estimates of internal (blood) versus external exposure (dietary) for MeHg from fish consumption, especially in children. You et al. (2018) evaluated the potential health risk of MeHg in Taiwanese children from fish and seafood consumption using estimations of internal exposures and dietary intakes. Seafood is a major part of the Taiwanese diet among all ages of the general population, and its consumption was estimated at approximately twice that of meat and twice that of eggs in 2014 (Taiwan CoA, 2017). Recent studies were reported in adults relating to measurements of MeHg in blood and hair and their possible association with fish and seafood consumption (Hsi et al., 2016; Lee et al., 2012); however, data on MeHg exposure assessment in children and adolescents are limited.

In the study of You et al. (2018), Hg was measured in WB and RBCs of children obtained from two biomonitoring programs. Internal exposures from blood measurements were assessed for preschool children aged 4–6 years, school children aged 7–12 years, and adolescents aged 13–18 years using data from the Nutrition and Health Survey in Taiwan (NAHSIT) 2005–08 (7- to 18-year-olds), and the Taiwan Maternal and Infant Cohort Study (TMICS) 2003 (4- to 6-year-olds). A total of 189 children were included in the study from the overall 815 subjects aged 3 to over 63 in the database. Consumption of fish and seafood was assessed using data from the Taiwan National Food Consumption Database (TNFCD). To assess external exposure from fish and seafood consumption, the daily intake rates of fish and seafood in children were reanalyzed individually for subjects 0–3, 4–6, 7–12, and 13–18 years old. Data on THg concentrations in edible fish and seafood species were collected from published studies in Taiwan on regional species. Three categories of fish and seafood were included as freshwater fish, saltwater fish, and shellfish, and cephalopods and crustaceans (SCC). The THg concentrations in each fish and seafood product were compiled and converted into MeHg concentrations by applying a conversion factor of 1.0 for freshwater and saltwater fish, and 0.8 for SCC (EFSA, 2012). A toxicokinetic model (WHO, 1990) was used to estimate the MeHg body burden in the study subjects. The potential risk for children from exposure to MeHg from fish and seafood consumption was estimated using the hazard index (HI) approach. The results indicated that the highest median daily MeHg intake was estimated in children consuming saltwater fish. A median HI of greater than one, based on WB-THg, was found in 28% of 4- to 6-

year-old children. The internal exposure estimates based on WB-THg, though slightly higher, were comparable to intake estimates based on consumption data. The results support the use of dietary exposure estimates as surrogates for internal dose estimates using blood measurement of MeHg in children in Taiwan.

The fish consumption guidelines for women of childbearing age is particularly important as risks during pregnancy may exist from a single-meal exposure if the fish tissue concentration is high enough (Ginsberg and Toal, 2000). The Hg hair concentration associated with the US EPA RfD is 1.1 ppm. Ginsberg and Toal (2000) used model simulations of the single-meal scenario at different fish MeHg concentrations and found that concentrations of 2.0 ppm or higher can be associated with maternal hair concentrations elevated above the RfD level for days to weeks during gestation. A single meal of 2 ppm is projected to elevate hair concentrations to 1.1 ppm for a brief period (several days), whereas consumptions above 2 ppm are projected to cause elevated hair concentration for 1–2 weeks. This would be in addition to the body burden from intake of other fish sources.

The exposure–effect data on MeHg from human fish-eating populations are used in health risk assessments, and regulatory, risk management, and public health outreach and policy decisions. The US EPA RfD has been used to guide related activities providing development of fish advisories which are fish consumption guidelines that present restrictive and safe consumption advice to prevent excessive exposure to MeHg (US EPA, 2018b). US EPA (2018b) and US FDA (2018) have issued joint advice regarding eating fish. This advice is geared toward helping women who are pregnant or may become pregnant, as well as breastfeeding mothers and parents of young children, to make informed choices when it comes to fish that is healthy and safe to eat. Health advisories present recommendations on how much of the affected fish in the affected areas can be safely eaten. Women of childbearing age and children are encouraged to be especially careful about following this advice because of the greater sensitivity of fetuses and children to MeHg.

Currently, most states in the United States have issued advisories concerning consumption of certain fish in various water bodies due to findings of MeHg and its toxicity (US EPA, 2018c). On the other hand, it is well recognized that fish is a key source of dietary protein in much of the world, and important polyunsaturated fatty acids. MeHg contamination of fish has the potential to impact the health of geographically diverse populations, the market for fish and seafood and the dietary choices of Americans. The US FDA and American Heart association have developed dietary guidelines on safety of eating fish, relating to the type of fish with low

or high mercury levels, frequency of consumption, and meal portions, with special precautionary guides to women of childbearing age and infants and children.

BIOMARKERS OF EFFECT

Biomarkers of effect are indicators of a change in biologic function in response to a chemical exposure and can more directly relate to insight into the potential for adverse health effects compared with biomarkers of exposure. These have been less universally used than exposure markers. One example of a biomarker of effect is blood ChE activity, which can become depressed following exposure to ChE-inhibiting pesticides such as organophosphate (OPs) and N-methyl carbamate pesticides.

Acetylcholinesterase (AChE) activity measured in RBCs is an example of a bioindicator with the adverse outcome/biological process being toxicity due to AChE inhibition (AChEI) (US EPA, 2018a). The effect may be reversible if the specific exposure is discontinued. As the biomarker events are in a continuum, in many cases, a clear distinction among some effective dose markers, early effect markers, and markers of adverse effects cannot be readily made. Various levels of RBC ChE activity inhibition represent different levels of severity of effects, which can eventually lead to death at very high effect levels.

CHOLINESTERASE INHIBITION

This discussion focuses on the recent status of cholinesterase inhibition (ChEI) as a critical endpoint for toxicology evaluation, risk assessment, and regulation. It relates to ChE-inhibiting pesticides as a group, and specifically recent developments on chlorpyrifos which has been getting intensive attention. The current issues of interest are as follows: (1) adequacy of using ChEI as an endpoint for risk assessment and health protection; (2) finding of neurodevelopmental effects at exposure levels lower than those producing ChEI for chlorpyrifos; (3) estimated risks following use of cord blood time-weighted average (TWA) as an internal biomarker with a first-time use of a physiologically based pharmacokinetic–pharmacodynamic (PBPK-PD) model; and (4) US EPA's regulatory actions on chlorpyrifos which have been viewed by some as not consistent with the scientific findings.

OPs, including chlorpyrifos, are known for their mode of action (MOA) being ChEI with toxicity manifested as central and peripheral cholinergic effects producing a steady-state AChEI (US EPA, 2018d; Fan,

2014). After repeated dosing at the same level, the degree of inhibition comes into equilibrium with the production of new, uninhibited enzyme. At this point, the amount of AChEI at a given dose remains relatively consistent across duration. In general, OPs reach steady state within 2–3 weeks. Therefore, for OPs it is appropriate to assess steady-state exposure durations (up to 21 days) instead of longer-term exposures. The steady-state POD is protective of longer exposure durations, including chronic exposures. In addition, blood ChEI by ChE-inhibiting pesticides can be also considered a biomarker of exposure in identifying the occurrence of exposure to these pesticides, stratifying individuals according to intensity of exposure, and identifying actions to prevent further exposure.

As discussed in Fan (2014), the US EPA derived an acute population oral adjusted dose of 0.0036 mg/kg using a $BMDL_{10}$ of 0.36 mg/kg as the POD associated with RBC ChEI in male and female rat pups exposed to chlorpyrifos. This includes the consideration of new epidemiological studies in mothers and children regarding the relation between gestational exposure to chlorpyrifos and adverse neurodevelopmental effects in infants and children, pending more evaluation. A chronic population oral adjusted dose of 0.0003 mg/kg was derived using a $BMDL_{10}$ of 0.03 mg/kg/d as the POD based on developmental neurotoxicity data and RBC ChEI in pregnant rats.

The question and concern has been raised for a long time as to whether human-exposure limits for ChE-inhibiting pesticides, based on the detection of ChEI, are sufficient to provide heath protection, especially in children. Recent findings on the effect of chlorpyrifos on brain development have intensified this concern and associated discussions (Rauh, 2018). Chlorpyrifos is one of the chemicals evaluated under US EPA's Cumulative Risk Assessment (US EPA, 2006). It is a broad spectrum, chlorinated OP insecticide, acaricide, and miticide with registered uses including a large variety of food crops, and nonfood use settings. General public and occupational exposures are two major areas of concern for potential adverse effects. A study of its MOA has identified brain ChEI as the most appropriate dose metric for risk assessments. The current issue is the new finding of neurodevelopmental effects in children below the exposure level that caused ChEI (USEPA, 2016, 2018d).

Since its first registration in 1965, chlorpyrifos has been reviewed by US EPA for tolerance reassessment, reregistration, and most recently, as part of its ongoing registration review (US EPA, 2018b). Some major regulatory and manufacturer volunteered activities were undertaken in 1996, 2000, 2001, 2002, and 2012 to address environmental, public, and worker exposure and the associated health risks. In 2014, as part of the registration

review process, the US EPA completed a revised human health risk assessment for all chlorpyrifos uses, which updated the June 2011 preliminary human health risk assessment, and was further updated in 2016.

In March 2017, the USEPA denied a petition to revoke all pesticide tolerances (maximum residue levels in food) for chlorpyrifos and cancel all chlorpyrifos registrations (US EPA, 2018b). The agency concluded that despite several years of study, the science addressing neurodevelopmental effects remains unresolved and further evaluation of the science during the remaining time for completion of registration review is warranted. As a part of the ongoing registration review, the agency will continue to review the science addressing neurodevelopmental effects of chlorpyrifos and intends to complete the assessment by the statutory deadline of October 1, 2022, in the program that reevaluates all pesticides on a 15-year cycle.

For OPs, US EPA has used the guidelines for detecting AChEI to set safe exposure limits, including for chlorpyrifos. The recent concern focuses on data from studies in animals and more recent studies in humans show that OPs are developmental neurotoxicants even at exposure levels below the threshold for systemic toxicity due to AChEI (Rauh, 2018; US EPA, 2016). The results of these studies implicate other pathogenic mechanisms involving widespread disruption of neural cell replication and differentiation, axonogenesis and synaptogenesis, and synaptic function (Slotkin and Seidler, 2007). In light of such mechanisms, all related to processes required for later cognitive and behavioral tasks, there is good reason to be concerned about possible longer-term, potentially irreversible effects (Rauh, 2018). Rauh (2018) noted that among the most worrisome findings are the corroborative results from several prospective cohort studies of children, which show an inverse dose—response effect of prenatal exposure to chlorpyrifos on cognition at 7 years of age (Rauh et al., 2011). In a subgroup of inner-city children 5.9—11.2 years of age from one of the cohorts, investigators found structural anomalies in the brains of the most highly exposed children in the superior temporal, posterior middle temporal, and inferior postcentral gyri bilaterally, and in the superior frontal gyrus, gyrus rectus, cuneus, and precuneus along the mesial wall of the right hemisphere (Rauh et al., 2012). Cognitive and behavioral processes subserved by these cortical regions include attention, receptive language, social cognition, reward, emotion, and inhibitory control; complementary functional deficits were also observed in a number of auditory attention skills. Deformations were detected in the dorsal and mesial surfaces of the left superior frontal gyrus, which supports executive function—a critical set of mental skills that permit people to plan, organize, and complete tasks throughout life (Rauh et al., 2012, 2018).

In addition, persistent motor deficits among children have been linked to high early exposure to chlorpyrifos (Silver et al., 2017).

The 2014 US EPA revised human health risk assessment used dose—response data on AChEI in laboratory animals and recent data in humans to derive a POD using a new approach. This assessment incorporated the following: (1) a PBPK-PD model for deriving toxicological PODs based on 10% RBC AChEI and (2) evidence on neurodevelopmental effects in fetuses and children resulting from chlorpyrifos exposure as reported in epidemiological studies, particularly the results from the Columbia Center for Children's Environmental Health (CCCEH) study on pregnant women which reported an association between fetal cord blood levels of chlorpyrifos and neurodevelopmental outcomes. The assessment retained the 10X Food Quality Protection Act (FQPA) Safety Factor (SF) for children because of the uncertainties that neurodevelopmental effects may be occurring at doses lower than those that cause 10% RBC AChEI and used for the POD.

For the 2016 assessment, the the use of US EPA vs. USEPA cord blood data quantitatively for deriving PODs (US EPA, 2016, 2018d). Following consultation with the FIFRA panel which concluded that epidemiology and toxicology studies suggest there is evidence for adverse health outcomes associated with chlorpyrifos exposures below levels that result in 10% RBC AChEI, which was used as the POD in the USEPA's 2014 assessment and for the 2015 proposed revocation rule, USEPA used the TWA blood level as the internal dose for determining separate PODs for infants, children, and adults exposed to chlorpyrifos. These separate PODs were calculated by PBPK modeling for dietary (food, drinking water), residential, and occupational exposures. The TWA blood concentration of chlorpyrifos for the CCCEH study cohort as the POD for risk assessment was recommended because the window(s) of susceptibility are currently not known for the observed neurodevelopmental effects, and the uncertainties associated with quantitatively interpreting the CCCEH cord blood data. With the exception of the acute (single day) exposure for non-occupational bystander post-application inhalation exposures, only steady state (repeat) exposure durations are considered in this assessment as assessing the steady-state exposure duration most closely matches the TWAs calculated for the PODs. The PODs derived from the TWA blood level are protective of any additional acute exposures to chlorpyrifos.

The TWA blood level resulting from chlorpyrifos exposure from the crack and crevice scenario is considered a LOAEL rather than a NOAEL, because this is the exposure level likely to be associated with neurodevelopmental effects reported in the CCCEH study (US EPA, 2016, 2018d). As a NOAEL has not been identified,

the 10X factor for extra fetal/infant/young child protection (the FQPA factor) has been retained to account for the uncertainty in using a LOAEL in this assessment. The revised risk assessment also applies a 10X UF for intraspecies variability. With the use of the PBPK-PD model which accounts for the pharmacokinetic and pharmacodynamic differences between animals and humans to derive PODs, the interspecies factor is reduced to 1X from the typical 10X when animal data are used. Therefore, the total UF is 100X.

For dietary assessment, PODs are divided by the total UF (100) to derive a population adjusted dose (PAD). The chlorpyrifos exposure values resulting from dietary modeling are compared to the PAD. The steady-state PADs (ssPAD, µg/kg-d) are 0.002 for infants <1, 0.0017 for children 1−2 yrs, 0.0012 for children 6−12, and 0.0012 for females 13−49 yrs. Estimated exposures were found to be 6200 to 14,000% of the ssPAD.

The CCCEH study, with supporting results from two other US cohort studies and the seven additional epidemiological studies reviewed in 2015, provides sufficient evidence that there are neurodevelopmental effects occurring at chlorpyrifos exposure levels below that required for AChEI. The CCCEH study is primarily tested for the presence of chlorpyrifos in cord blood and is most relevant for the purposes of chlorpyrifos risk assessment. When comparing high to low exposure groups at 3 years of age in the CCCEH study, there were increased odds of mental delay, psychomotor delay, attention disorders, attention deficit hyperactivity disorder, and pervasive developmental disorders. In a follow-up study at age 11, CCCEH study authors observed increased odds of mild to moderate tremor when comparing high to low exposure groups. Evaluation of the relationship between prenatal chlorpyrifos exposure and neurodevelopment in 265 of the CCCEH cohort participants at age 7 years revealed that the log of Working Memory Index of children was linearly associated with concentration of chlorpyrifos in cord blood. For each standard deviation increase in exposure (4.61 pg/g), the authors observed a 1.4% reduction in Full-Scale IQ and a 2.8% reduction in Working Memory.

Presently, the US EPA will continue to review the science addressing neurodevelopmental effects of chlorpyrifos and plans to complete the assessment by October 1, 2022.

SELENIUM

For toxicity, the biomarker of effect for Se is selenosis (Fan, 2014). The present discussion updates recent toxicological findings and discusses the relationship of toxicity to the nutritional values of Se and biomarkers of Se status.

Selenium (Se) occurs naturally and is found ubiquitously in the environment, being released from both natural and anthropogenic sources (Fan and Vinceti, 2013; ATSDR, 2015; Combs, 2015). Se exists in various chemical forms and oxidation states that can affect its occurrence, properties, uses, and toxicity. Soils contain inorganic selenites and selenates that plants accumulate and convert to organic forms, mostly selenocysteine (SeCcys) and selenomethionine (SeMet) and their methylated derivatives. Ingestion of the organic form from food, including dietary supplements, is the main source of exposure for the general population. Dietary intake is mainly as the amino acid SeMet in grains, cereals, and forage crops; as SeCys in meats and dairy products to a lesser extent; and as the inorganic selenate and selenite, which are the main soluble forms in aqueous media. Se is an essential nutrient, and evaluation of human exposure and health effects or toxicity has to consider both essentiality and toxicity.

Selenosis, presented primarily as hair loss and nail changes, is the biomarker of Se toxicity which is used as the basis for risk assessment and regulation of the chemical in drinking water (Fan, 2014; US EPA, 2018f). Major findings on selenosis were documented in local populations in studies carried out in the endemic seleniferous areas of Enshi County, Hubei province in central China in the 1980s. Residents who consumed food grown in areas with unusually high environmental concentrations of Se in soil contaminated by stony coal showed a wide spectrum of hair, nail, and skin abnormalities related to Se exposure, plus other clinical signs and gastrointestinal symptoms (Yang et al., 1983, 1989a). Persistent clinical signs of selenosis were observed only in 5/349 adults, a potentially sensitive subpopulation. The dermatological abnormalities were ascribed to daily Se intake ranging from 1500 to 5000 µg/day, though nail brittleness was detected in a subsequent study following supplementation with 600 µg/day of Se.

The biomarker of effect was used for risk assessment to derive reference levels for regulations (e.g., 50 ppb in drinking water, 50 ppb in bottled water) and public health policies (e.g., health guidance on dietary intake and fish consumption advisories). Based on data obtained from the Se poisoning episode in China, the US FDA (Poirier, 1994) set a NOAEL for Se at a WB Se concentration of 1000 ng/mL, corresponding to a dietary intake of 853 µg/day in an adult male. The US EPA (1991, 2018f) established an RfD of 5 µg/kg/day based on clinical selenosis observed in China as described in the studies of Yang et al. (1983, 1989a, 1989b), with a NOEL of 15 µg/kg/day and an UF of 3. The US Institute of Medicine (IOM, 2000) set the LOAEL of Se intake at 900 µg/day, and NOAEL at 800 µg/day. A UF of 2 is used based on determination that the adverse health effects observed at the LOAEL as not severe, but likely not

readily reversible, thus establishing a tolerable upper intake level (UL) of Se from food and supplements at 400 μg/day for adults 14 and older. The ULs for other age groups are 1–3 yrs, 90 μg/day; 4–8, 150 μg/day; 9–13, 280 μg/day.

The Norwegian Scientific Committee for Food Safety (Vitenskapskomiteen for mattrygghet, VKM, 2017) evaluated the intake of Se in the Norwegian population and reviewed four risk assessments undertaken by the Institute of Medicine (IOM, USA), Scientific Committee on Food (SCF, European Union), Expert Committee on Vitamins and Minerals (EVM, United Kingdom), and the Nordic Nutrition Recommendations (NNR, Nordic Project Group). It decided to use the tolerable Upper intake Levels (ULs) of 300 μg/day for adults set by the SCF, including pregnant and lactating women, later adopted by NNR. The UL was extrapolated to children and adolescents that range from 60 (1–3 years) to 250 μg Se/day (15–17 years).

Se was originally known mainly for its high toxicity, then recognized as an essential trace element and studied for its protective role in human health and diseases. More recently, interest has increased regarding its protective role and possible link to human diseases, including studies of the potential role of Se compounds in the prevention of specific cancers and antitumorigenic effects and its link to human diseases. Se supplementation in animal nutrition led to the consideration of possible inadequate dietary Se in human health.

The essential functions of Se for human and animal health are mediated through selenoproteins (NIH, 2018). Se is a constituent of more than two dozen selenoproteins that play critical roles in reproduction, thyroid hormone metabolism, DNA synthesis, and protection from oxidative damage and infection. Most Se is in the form of SeMet in animal and human tissues, where it can be incorporated nonspecifically with the amino acid methionine in body proteins. The most commonly used measures of Se status are plasma and serum Se concentrations. Concentrations in blood and urine reflect recent Se intake. Analyses of hair or nail Se content can be used to monitor longer-term intakes over months or years. Quantification of one or more selenoproteins (such as glutathione peroxidase and selenoprotein P) is also used as a functional measure of Se status. Plasma or serum Se concentrations of 8 μg/dL or higher in healthy people typically meet the needs for selenoprotein synthesis.

Biomarkers for Se status have recently been discussed by Combs (2015). In animal studies and accidental exposures of humans, clinical indicators were reported, but few biomarkers were available with predictive value. The default approach has been to use as risk indicators the highest Se tissue levels observed with no associated adverse effects. Most studies show no adverse effects in human subjects with plasma Se levels <1000 ng/mL. Some cases showed garlic odor of the breath due to the excretion of volatile Se metabolites across the lung, but measurement of such metabolites has not been used in cases of selenosis and diagnostic criteria have not been established.

Combs (2015) also noted that the multiple biological activities of Se call for biomarkers that can provide information about Se status relative to nutritional (functional) needs, antitumorigenic potential, and risk of adverse effects. He described two types of Se biomarkers. Se biomarkers such as GPX3, GPX1, and SEPP1 provide information about function directly. GPX3 is the extracellular glutathione peroxidase, and it reduces hydroperoxides using reducing equivalents from reduced glutathione. SEPP1 is the Se-transporter selenoprotein P produced and excreted by the liver, functioning as the primary transporter of Se to peripheral tissues, and comprising 40%–60% of total plasma Se. These biomarkers are useful under conditions of Se intake within the range of regulated selenoprotein expression, which for humans is less than about 55 μg/day (e.g., in parts of China, New Zealand, and Europe), and for animals is less than about 0.1 mg/kg diet. These biomarkers are also useful in identifying nutritional Se deficiency and tracking responses of deficient individuals to Se treatment. Selenocysteine occurs in only two plasma selenoproteins, SEPP1 and GPX3, which contain 10 and 4 SeCys residues, respectively. Other Se biomarkers provide information indirectly through inferences based on Se levels in foods, tissues, urine, or feces. They can indicate the likelihood of deficiency or adverse effects, but they do not provide direct evidence of either condition. For example, SeMet in plasma and tissues can indicate the amount of Se potentially available for functional use, the likelihood of Se deficiency, or the likelihood of adverse effects of Se, but it provides no direct evidence of either of these states. These biomarkers are useful in providing information about Se status over a wide range of Se intake, particularly from food forms, over which tissue retention of SeMet is unregulated.

Relatively low Se intakes determine the expression of selenoenzymes in which Se serves as an essential constituent, whereas higher intakes have been shown to have antitumorigenic potential; and very high Se intakes can produce adverse effects. Se status, as in nutrition, refers to the amount of biologically active or potentially active Se as a nutrient in the body. Nutritional status is a product of a nutrient's intake, retention, and metabolism. It includes the nutrient pool that is metabolically functional and, thus, the most nutritionally relevant, as well at that pool that can be readily mobilized to functional forms. Combs (2015) described Se status as having four components: Se intake, tissue Se, Se excretion, and Se function, and there are biomarkers associated with

each status. Se status is assessed for several purposes such as to determine the risk of nutritional Se deficiency; to estimate the potential for reducing cancer risk; and to monitor the risk of adverse effects associated with excess Se. Such assessments are made in research and clinical care, and they may also provide useful information for public health programs. All these purposes can rely on different sets or interpretations of biomarkers.

In examining toxicity and beneficial effects and indicators of Se status, Vinceti et al. (2017) reviewed environmental studies conducted in populations characterized by abnormally high or low Se, and from high-quality and large randomized controlled trials (RCTs) with Se carried out in the United States and in other countries after the poisoning reports in China in the 1980s. The authors noted that these studies indicate that the minimal amount of environmental Se which is a source of risk to human health is much lower than anticipated on the basis of older studies, with toxic effects shown at levels of intake as low as around 260 μg/day for organic Se and around 16 μg/day for inorganic Se. On the other hand, populations with average Se intake of less than 13–19 μg/day appear to be at risk of Keshan disease, a severe cardiomyopathy. Regarding selenoproteins, the authors noted that the relations between Se exposure and selenoprotein activity are complex, and a clear relation between selenoprotein activity and health outcomes has not been established in epidemiologic studies. Although the amount and activity of antioxidant selenoproteins, particularly glutathione peroxidases and plasma selenoprotein P, have been used as indirect indicators of Se intake, and detection of low levels has been interpreted as a consequence and a biomarker of Se deficiency, a proteomic approach based on maximal upregulation of selenoprotein levels by ingested Se has not been adopted for regulatory purposes or used for setting the dietary reference values for this element.

A subject of intense interest is the potential antitumorigenic effect of Se. Vinceti et al. (2017) reported that recent trials have consistently shown that Se does not modify risk of overall cancer, prostate cancer, and other specific cancers, whereas it may even increase risk of cancers such as advanced or overall prostate cancer, nonmelanoma skin cancer, and possibly breast cancer in high-risk women. The authors showed that at Se exposure (baseline dietary intake plus supplementation) of around 250–300 μg/day, there is an increased risk of type-2 diabetes. Such excess diabetes risk linked to Se overexposure was first discovered in trial carried out in a population with a "low" baseline Se status and later confirmed in large trials. Finally, the largest of the Se RCTs, the Selenium and Vitamin E Cancer Prevention Trial (SELECT), whose overall Se intake in the supplemented group averaged 300 μg/day, has shown that

such an amount of exposure induces "minor" adverse effects such as dermatitis and alopecia, a long-recognized sign of Se toxicity.

National drinking water regulations establish a Maximum Contaminant Level, MCL, of 50 ppb for Se in drinking water based on risk assessment of exposure to Se and findings on hair or fingernail loss, numbness in fingers or toes, and circulatory problems as observed in cases of selenosis (US EPA, 2018e). The public health goal in California, which is used as the health basis for California regulation, is established at 30 ppb based on the same toxicology data, but using drinking water consumption rate for infants (OEHHA, 2010). No special sensitivity to Se is found in infants or children (ATSDR, 2015).

BIOMARKERS OF SUSCEPTIBILITY

Kelly and Vineis (2014) defined biomarkers of susceptibility as indicators of an elevated sensitivity to the effects of an environmental agent that can be objectively measured in a biological system or a sample. These markers are used to identify "at-risk" individuals, where risk is either acquired (e.g., they indicate a disorder that renders people more susceptible to an environmental exposure) or, more usually, inherited (as indicated by genetic markers). Genetic markers in particular play a vital role in understanding disease risk. Most complex disorders, including cancers, arise not from single gene variants or single exposures, but rather from the interplay between an individual's genetic susceptibilities and their personal exposure histories. Underlying genetic differences may influence the uptake, metabolism, retention, and excretion of chemical carcinogens and therefore susceptibility to their effects. Variants of critical cell function proteins, including those underlying differentiation, cell division, and cell death, are also important and can represent important susceptibilities. Another susceptibility mechanism is the presence of higher or lower levels of antioxidants, such as glutathione, that reduce the level of oxidizing radicals in the tissue where damage occurs or in the liver, where a wide variety of metabolism of xenobiotics can be impacted. Cellular repair mechanisms, including DNA-adduct repair, also play a role in susceptibility. Consequently, variants in the genes of all of these processes are candidates for susceptibility biomarkers and gene–environment interactions.

Kelly and Vineis (2014) explored the issues involved in the study of gene–environment interactions which complicate the design and the interpretation of findings and consider how the results emerging from these studies can be utilized to identify novel biomarkers of susceptibility in cancer epidemiology, using non-

Hodgkin's lymphoma (NHL) as an example. The results suggest a modifying role for genetic susceptibility to a number of occupational and environmental exposures including organochlorines, chlorinated solvents, chlordanes, and benzene in the etiology of NHL. They noted that the potential importance of these gene—environment interactions in NHL may help to explain the lack of definitive carcinogens identified to date for this malignancy. Although a large number of genetic variants and gene—environment interactions have been explored for NHL, to date replication is lacking, and therefore the findings remain to be validated. The ability to select a subset of individuals at risk to development of disease caused by a specific chemical would improve the epidemiological ability to observe effects by reducing the "noise" from individuals not at risk or at much lower risk.

The -omics technologies that have been applied in epidemiological research have expanded beyond genomics to include epigenomics, proteomics, transcriptomics, and metabolomics (NASEM, 2017). -Omics technologies have advanced the paradigm of molecular epidemiology, which focuses on underlying biology (pathogenesis) rather than on empirical observations alone. Many studies have utilized -omics technologies in epidemiological research as exemplified by the incorporation of genomics. For example, the genetic basis of disease has been explored in genome-wide association studies in which the genomic markers in people who have and do not have a disease or condition of interest are compared. New studies are being designed with the intent of prospectively storing samples that can be used for existing and future -omics technologies. From this, obtaining data from human population studies that are parallel to data obtained from in vitro and in vivo assays or studies is already possible and potentially can help in harmonizing comparisons of exposure and dose. It was also noted that -omics technologies have the potential for providing a suite of new biomarkers for hazard identification and risk assessment.

The advantages and limitations of -omics technologies have been described by Vineis et al. (2009) and adapted by NAS (NASEM, 2017) as follows. The advantages include use in large, hypothesis-free investigations of the whole complement of relevant biological molecules; better understanding of phenotype—genotype relations; and potential for insights into the effects of interactions between environmental conditions and genotypes, and mechanistic insights into disease etiology. The limitations include cost of assays, quality of biological material available (such as instability of RNAs), and the amount of labor needed.

Many techniques are still in their discovery phase and need to be carefully investigated and compared with existing biological information from in vivo and in vitro tests. Moving from promising techniques to successful application of biomarkers in occupational and environmental epidemiology and medicine requires not only standardizing and validating techniques but also appropriate study designs and sophisticated statistical analyses for interpreting study results.

CANCER-RELATED BIOMARKERS

There are two general groups of cancer-related biomarkers. The focus in this chapter is on those used to predict and measure the impact of environmental chemicals. Readers are probably also familiar with clinical cancer biomarkers, used increasingly for cancer screening, monitoring the effect of treatment, and prognosis. Some of these may also become important in the study of gene—environment and susceptibility studies.

DNA adducts represent key events in mutagenesis and carcinogenesis (Poirer, 2012; Basu, 2018). They can serve as biomarkers of exposure that are by and large repairable, whereas mutations are biomarkers of unrepaired effect that are passed on to daughter cells. Chemicals forming adducts with DNA are chemically electrophilic, reacting with DNA purine or pyrimidine bases (which are nucleophilic) in a process called alkylation (Gates, 2009). Many of them are first enzymatically transformed to a reactive chemical before the adduct can be formed. There are similar reactions with nucleophilic targets in certain amino acids in proteins and with certain lipids. Bifunctional agents (with two or more reactive sites, such as dialdehydes) can crosslink DNA bases or crosslink DNA bases to amino acids in proteins. "Bulky" adducts, such as PAHs and the liver carcinogen, aflatoxin (produced by a fungus growing particularly in peanuts), were among the first to be studied (Poirer, 2012). Reactions with oxidizing radicals (reactive oxygen species) also occur and can result in adduct formation (Gates, 2009; Kasai, 2016).

There are also endogenously produced reactive chemicals that can cause adducts with DNA or proteins. Those endogenous adducts can result in mutations that are considered to be associated with the background level cancer in conjunction with other predisposing genetic and epigenetic factors. One such chemical is formaldehyde, discussed below. However, a critical issue is whether adduct formation alone adequately captures the risk from exogenous exposure. Systemic response at the portal of entry may provide other mechanisms that contribute to carcinogenesis.

FORMALDEHYDE

Formaldehyde is a very reactive compound, an electrophile, directly targeting nucleophilic chemicals like

DNA and protein. It can induce DNA adducts including N2-hydroxymethyl-deoxyguanosine (dG), N6-hydroxymethyldeoxyadenosine (dA), and N4-hydroxymethyl-deoxycytosine (dC) in vitro. These DNA adducts are considered to be promutagenic, and formaldehyde exposure has been shown to induce mutations in bacterial test systems and laboratory animals (NRC, 2014). DNA—protein crosslinks are also formed. Both have been used as biomarkers. Formaldehyde has been linked to sinonasal cancer in laboratory animal studies and nasopharyngeal cancer, Hodgkin's lymphoma and certain leukemias in occupational settings with activities like production/use of formaldehyde—melamine resin and embalming. Laboratory animal studies also found hematotoxicity, which would be consistent with leukemogenic effects.

Formaldehyde is also produced by endogenous metabolism. Adducts formed from exogenous exposure are chemically identical to endogenous DNA adducts created from reactive chemicals produced by the body during normal metabolism. Thus, exogenous and endogenous DNA adducts with formaldehyde have the same structure and likely the same mutational efficiency.

Starr and Swenberg (2013, 2016) and their coworkers (Lu et al., 2010; Yu et al., 2015) separately quantified endogenous and exogenous adducts induced by formaldehyde (by use of exogenous carbon-13 labeled formaldehyde) and derived the relationship between the number of exogenous DNA adducts derived from the inhaled formaldehyde exposure and the number of endogenous adducts present in bone marrow. Based on 28-day exposures of rats (up to 9 ppm) and 2-day exposures (up to 6 ppm) of macaques, they found that in bone marrow there was less than one exogenous DNA adduct present for approximately 14,000 endogenous formaldehyde adducts. This is evidence that formaldehyde is not transported systemically, due to its reactivity and its metabolism. They concluded that one additional identical DNA adduct would not likely drive the biology that leads to carcinogenesis, assuming that both endogenous and exogenous dG adducts give rise to proportional tissue-specific risks of cancer development (up to the point that local formaldehyde tissue concentrations become so high as to cause cytotoxicity, saturate DNA repair, or deplete detoxification). However, the authors noted that the validity of short-term formaldehyde exposures for this analysis is not yet proven.

In their model, the statistical 95% confidence limit upper bound dose—response of exogenous formaldehyde declined linearly toward the background endogenous level and the associated background cancer level. The nasopharyngeal cancer and leukemia/lymphoma risk estimates they developed were considerably smaller than the corresponding US EPA estimates, developed

from epidemiologic data for exposed workers. (Linearity also assumes that exposures are below those that cause cytotoxicity and regenerative cell proliferation, deplete detoxification processes, e.g., glutathione depletion, or saturate DNA repair pathways.) In both epidemiology and risk assessment, enhanced understanding of endogenous and exogenous DNA adduct formation, especially at low doses, can potentially be used as a molecular dosimeter to place bounds on the plausibility and potency of exogenous exposures to induce disease.

Whether all of the attributable risk is dependent on the concentration of adducts as measured following short-term exposures is not clear. An NRC expert committee reviewing formaldehyde for the National Toxicology Program 12th Report on Carcinogens (NRC, 2014) found that

1. There is sufficient evidence of carcinogenicity from studies of humans based on consistent epidemiologic findings on nasopharyngeal cancer, sinonasal cancer, and myeloid leukemia for which chance, bias, and confounding factors can be ruled out with reasonable confidence.
2. There is sufficient evidence of carcinogenicity in animals based on malignant and benign tumors in multiple species, at multiple sites, by multiple routes of exposure, and to an unusual degree with regard to type of tumor, and.
3. There is convincing relevant information that formaldehyde induces mechanistic events associated with the development of cancer in humans, specifically genotoxicity and mutagenicity, hematologic effects, and effects on gene expression.

In addition, the NRC reviewers stated that, "while it would be desirable to have an accepted mechanism that fully explains the association between formaldehyde exposure and distal cancers, the lack of such mechanism should not detract from the strength of the epidemiological evidence that formaldehyde causes myeloid leukemia", given the uncertainties in the scientific understanding of the potential mechanisms of the systemic effects of formaldehyde.

Based on the NRC review (2014), areas that need further investigation include (1) whether inhalation exposure results in release of cytokines that might impact homeostasis in lymphohematopoiesis; (2) the extent of systemic oxidative stress due to formaldehyde exposure, (3) the nature and degree of immune responses to formaldehyde exposure; (4) the nature and degree of local effects on leukocytes at the portal of entry (also in relation to immune responses) that could lead to leukemia or lymphoma; and, (5) changes in adduct formation, gene expression, epigenetic effects during long-term versus short-term exposure. Variation of alcohol dehydrogenase (also known as formaldehyde

dehydrogenase) enzyme activity in the population may also play a role in susceptibility by allowing more formaldehyde to move from the portal of entry to systemic circulation. An epidemiological study design incorporating this susceptibility marker would be useful to more accurately measure risk. Likewise, there may be different DNA repair enzyme differences that could be examined because there is a paucity of data on that topic (NRC, 2014).

Since that review, the validity and consistency of the epidemiology, including new studies, has come under criticism that has yet to be fully resolved. Overall, existing data indicate that for formaldehyde, the MOA and ultimately the biomarkers need more research for a better understanding of the related issues. The state of science in this area is an example of the difficulties that can occur in trying to apply data from biomarkers to risk assessment when the MOA is not yet clear.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Biomarkers for environmental chemicals are being used increasingly for assessing human exposure to toxic substances. It involves sampling and measuring environmental chemicals in human fluids and tissues, such as blood and urine, as humans are exposed to chemicals through air, water, food, soil, dust, and consumer products. Correlation of dose—effect relationship provides the basis for health risk assessments which, in turn, provide the basis for regulatory and risk management decision-making for health protection.

Examples are given for biomarkers of exposure such as MeHg in blood, and biomarkers of effect such as ChEI by ChE-inhibiting pesticides, and selenosis from selenium exposure. MeHg exposure from fish consumption is widespread and few data are available specifically for infants and children. Fish consumption guidance relating to MeHg has been developed with special attention to children and women of childbearing age. A concern for evaluating ChEI-inhibiting pesticides is whether neurodevelopmental effects occur at levels below those that cause ChEI, as in the case of chlorpyrifos. Consideration of selenium toxicity needs to include consideration of its nutritional status and new data on possible adverse health effects of low-dose overexposure. Study of biomarkers of susceptibility has involved the study of gene—environment interactions and more recently the -omics technologies that have been applied in epidemiological research have expanded beyond genomics to include epigenomics, proteomics, transcriptomics, and metabolomics, to name a few. The -omics technologies have the potential for providing a suite of new biomarkers for hazard identification and risk assessment. The case of formaldehyde is an example of the difficulties that can occur in trying to apply data from biomarkers to risk assessment when the MOA is not yet clear. More research for a better understanding of the related issues is needed.

New advancements in biomonitoring, exposure science, -omics technologies, toxicology, risk assessment, and decision-making have been made and are anticipated to be made, with the further development and use of biomarkers, increased biomonitoring efforts and research, improvement of methods and techniques, and development and implementation of the visions and strategies described in several recent NRC reports that advance the conceptual and experimental approaches in these fields. Biomarkers are anticipated to play an increasing role in these fields advancing the understanding of human health and diseases, and improving human health and welfare, partly through providing data to support regulatory and risk management actions.

SECOND EDITION

BIOMARKERS IN TOXICOLOGY

EDITED BY

Ramesh C. Gupta

DVM, MVSc, PhD, DABT, FACT, FACN, FATS, Professor and Head, Toxicology Department, Breathitt Veterinary Center, Murray State University, Hopkinsville, KY, USA

Biomarkers in Toxicology, Second Edition is a timely and comprehensive reference dedicated to all aspects of biomarkers that relate to chemical exposure and their effects on biological systems. This revised and completely updated edition includes both vertebrate and nonvertebrate species models for toxicological testing and development of biomarkers. Divided into several key sections, this reference volume contains new chapters devoted to topics in adverse outcome pathways, reproductive toxicity, ototoxicity, neuroimmunotoxicity, blood–brain barrier dysfunction, and osteoarthritis, as well as a look at the latest cutting-edge technologies (proteomics, metabolomics, and microarrays) used to detect biomarkers of exposure and effects. Each chapter is enriched with references to the current literature and important resources for further reading. Given this comprehensive treatment, *Biomarkers in Toxicology, Second Edition* is an essential reference for all those interested in biomarkers across the scientific and biomedical fields.

KEY FEATURES

- Evaluates the expansive literature currently available on this topic providing one resource covering all aspects of toxicology biomarkers

- Includes completely revised chapters and additional chapters on the newest developments in the field

- Identifies and discusses the most sensitive, accurate, unique, and validated biomarkers used as indicators of exposure and effect of chemicals of different classes

- Covers special topics and applications of biomarkers, including chapters on molecular toxicology biomarkers, biomarker analysis for nanotoxicology, and the development of biomarkers for drug efficacy and safety evaluation

Dr. Gupta has also published these Elsevier titles

Veterinary Toxicology, Third Edition, March 2018, 9780128114100
Reproductive and Developmental Toxicology, Second Edition, April 2017, 9780128042397
