in urinary BPA was associated with T2DM (OR = 1.08, 95% CI 1.02−1.16). However, when each NHANES cycle was examined individually, a statistically significant association was only found in the 2003/04 cycle, OR = 1.23.

Shankar and Teppala (2011) also examined the association between urinary BPA levels and diabetes mellitus (type 1) using the NHANES 2003−08. Results showed that positive association was observed, independent of confounding factors such as age, gender, race/ethnicity, body mass index (BMI), and serum cholesterol levels. Compared to quartile 1 (referent), the adjusted (age, gender, race/ethnicity, BMI, and serum cholesterol level) OR of diabetes associated with quartile 4 was 1.68 (1.22−2.30) (P-trend = .002). Prediabetes (5.7% −6.4% HbA1C or 100−125 mg/dL fasting blood glucose or 140−199 mg/dL 2-h blood glucose) was also associated (Sabanayagam et al., 2013). The adjusted odds ratio (AOR) was 1.34 (95% CI 1.03, 1.7) and was stronger among women and obese subjects.

Canadian Health Measures Survey

The Canadian Health Measures Survey (CHMS) is an ongoing national direct health measures survey (Health Canada, 2017). Statistics Canada, in partnership with Health Canada and the Public Health Agency of Canada, launched the CHMS in 2007 to collect health and wellness data and biological specimens from a nationally representative sample of Canadians. Biological specimens were analyzed for indicators of health status, chronic and infectious diseases, nutritional status, and environmental chemicals.

Four reports for four biennial cycles have been published on Human Biomonitoring of Environmental Chemicals in Canada in 2010, 2013, 2015, and 2017. Collection for cycle 5 began in January 2016 through the end of 2017. Data for Cycle 4 on 54 chemicals were collected from approximately 5700 Canadians aged 3−79 years at 16 sites in 10 provinces across Canada.

Selected findings on BPA concentrations expressed as the GMs of urine concentrations (μg/L) are shown as follows (adapted from Tables 9.1.1 and 9.1.2, Health Canada, 2017):

Total 3−79 years, N-2560/2559, 1.0 μg/L; 0.93 μg/L creatinine-adjusted
M 3−79 years, N-1273/1272, 1.2 μg/L; 0.92 μg/L creatinine-adjusted
F 3−37 years, N-1287, 0.92; 0.94 μg/L creatinine-adjusted
3−5 years, N-511, 1.2; 2.0 μg/L creatinine-adjusted
6−11 years, N-511/510, 1.1; 1.2 uμ/L creatinine-adjusted
12−19 years, N-505, 1.1; 0.83 μg/L creatinine-adjusted

20−39 years, N-362, 1.1; 0.91 μg/L creatinine-adjusted
46−59 years, N-311, 0.86; 0.78 μg/L creatinine-adjusted
60−79 years, N-360, 1.1; 1.0 μg/L creatinine-adjusted.

Generation R Study, The Netherlands

Various studies have reported on the Generation R study in Rotterdam, the Netherlands. The Generation R study biobank is a resource for epidemiological studies in children and their parents (Jaddoe et al., 2007). It is a population-based prospective cohort study in the Netherlands from fetal life until young adulthood. It focuses on four primary areas of research: (1) growth and physical development; (2) behavioral and cognitive development; (3) diseases in childhood; and (4) health and healthcare for pregnant women and children.

There are 9778 mothers enrolled (with a delivery date from April 2002 until January 2006) in the study. Prenatal and postnatal data collection has been conducted by physical examinations, questionnaires, interviews, ultrasound examinations, and biological samples. Major efforts have been conducted for collecting biological specimens including DNA, blood for phenotypes, and urine samples. Together with detailed phenotype measurements, these biological specimens form a unique resource for epidemiological studies focused on environmental exposures, genetic determinants, and their interactions in relation to growth, health, and development from fetal life onward.

Compared to other birth-cohort studies, the size of the Generation R study cohort is not larger, but the measurements are more detailed and the study group has a large ethnic variety.

An update on the Generation R study was provided by Kooijman et al. (2016). Response at baseline was 61%, and general follow-up rates until the age of 10 years were around 80%. Data collection in children and their parents include questionnaires, interviews, detailed physical and ultrasound examinations, behavioral observations, lung function, magnetic resonance imaging, and biological sampling. Genome and epigenome wide association screens are available.

Ye et al. (2008) reported on biological monitoring data from 100 pregnant women, a subset of participants in the Generation R study. The unadjusted and creatinine-adjusted concentrations were reported and compared to NHANES and other studies. The data showed similar exposure to BPA. Among the 100 pregnant women, BPA was detectable among 82% of samples. The creatinine-adjusted median concentration was 1.6 μg/g Cr, and the unadjusted median concentration was 1.2 μg/L. Urinary free BPA accounted for only a small percentage of total BPA.

Philips et al. (2018) examined first trimester bisphenol (BPX) and phthalate urine concentrations, including BPX and phthalate replacements, and found nutritional-, sociodemographic-, and lifestyle-related determinants. The authors measured first trimester BPX, phthalate, and creatinine urine concentrations in samples collected in 2004−05, with a median gestational age of 12.9 weeks in a population-based prospective cohort of 1396 mothers in the Netherlands. They examined associations of potential determinants with log-transformed BPX and phthalate concentrations. Outcomes were back-transformed. Nutritional analyses were performed in a subgroup of 642 Dutch participants only, as the Food Frequency Questionnaire was aimed at Dutch food patterns. Results showed that bisphenol A, bisphenol S (BPS), and bisphenol F (BPF) were detected in 79.2%, 67.8%, and 40.2% of the population, respectively. Bisphenol S and F are produced as alternatives to BPA, see Food Packaging and Bisphenol A Alternatives, below. The authors noted that bisphenol S and F exposure was highly prevalent in pregnant women in the Netherlands as early as 2004−05. Although associations of dietary and other key factors with BPX and phthalate concentrations were limited, adverse lifestyle factors including obesity and the lack of folic acid supplement use seem to be associated, likely as an indirect effect, with higher phthalate concentrations in pregnant women. The major limitation was the availability of only one urine sample per participant. The authors noted that previous studies among pregnant women generally reported higher levels of BPXs and phthalates to be associated with lower socioeconomic status, younger maternal age, and smoking (Arbuckle et al., 2014; 2015; Casas et al., 2013), likely due to food choices, but results are inconsistent (Arbuckle et al., 2014; Berman et al., 2014). Being overweight has also been suggested as a determinant of BPX and phthalate levels (Valvi et al., 2013). Likewise, this association is probably due to an indirect effect on food choices.

Jusko et al. (2014) determined the reproducibility of BPA using three urine specimens collected from 80 pregnant women selected as a random sample of the 1024 women with three urine specimens and complete data. Total maternal BPA concentrations were detectible in all specimens. On average (±SD), maternal urine specimens were collected at 13 (±1.7), 20 (±0.7), and 30 (±0.7) weeks of gestation, and median BPA concentrations were 1.1, 1.5, and 1.6 μg/L (3.0, 3.0, and 2.6 μg/g creatinine) across these three sampling periods. BPA concentrations in the present study were higher than those reported in a previous analysis of a subset of pregnant women in the Generation R study who had only one urine specimen collected after 20 weeks of pregnancy, likely owing to the greater proportion of older, Dutch, and better educated women participating in the present study, factors that have been also been associated with higher BPA concentrations in the Generation R study. In contrast, in the NHANES surveys BPA is higher in women of lower socioeconomic class (Calafat and Needham, 2008). To address the issue of potential contamination, uBPA concentrations in 26 samples having high total BPA were quantified, and all but one sample were found to have uBPA that comprised 1%−2% of the total BPA concentration.

Pair-wise measures of BPA concentrations were moderately correlated ($0.13 \leq$ rspearman$\leq$ 0.49), regardless of whether they were expressed on a volumetric or creatinine-adjusted basis. BPA measurements closer in time were more strongly correlated, although this was not true for the creatinine basis measures. The intraclass correlation coefficient (ICC, the percent of total variance explained by between-person variance) for the three sampling events were 0.32 (95% CI: 0.18, 0.46), and on a creatinine basis, 0.31 (95% CI: 0.16, 0.47), indicating low reproducibility.

Norwegian Mother and Child Cohort Study, Norway

The MoBa study was planned in the 1990s with the objective of testing specific etiological hypotheses by estimating the association between exposures (including genetic factors) and diseases, aiming at prevention and to collect data on as many relevant exposures and health outcomes as feasible (Magnus et al., 2006). It is a prospective birth cohort enrolling pregnant women throughout Norway from 1999 to 2008 (Rønningen et al., 2006). Biological material is to be collected from women in 100,000 pregnancies. In addition, cord blood from their newborn infants and samples from 80,000 fathers may result in more than 380,000 unique sample sets for long-term storage. In addition to biological materials, detailed questionnaire data are collected during pregnancy and as the child ages. Additional health outcome information is available through linkage to Norwegian national health registries. The overall aim is to study the effects of genetic and environmental factors on pregnancy outcomes and later health of the children as well as the parents. The study includes collection of questionnaires and registry information and aims at having DNA for all participants as well as biological samples from pregnant women to assess environmental exposures. The MoBa Biobank is charged with long-term storage of more than 380,000 biological samples from pregnant women, their partners, and their children for up to 100 years. Biological specimens include whole blood, plasma, DNA, and urine; samples are collected at 50 hospitals in Norway. The unique combination of biological specimens, DNA, and questionnaire data

makes the MoBa Study a resource for many future investigations of the effects of genetic and environmental factors on pregnancy outcome and on human morbidity.

Ye et al. (2008) measured BPA in 10 pooled urine samples representing 110 pregnant women who participated in the MoBa study in 2004. Daily intakes were estimated from urinary data and compared with RfDs and TDIs. The authors found that MoBa women had a higher mean BPA concentration (4.50 µg/L) than the pregnant women in the Generation R study in the Netherlands and the NHANES in the United States. The higher levels of may have been due to consumption of canned food, especially fish/seafood.

In the MoBa study whereby over 65,000 urine specimens were collected from pregnant women, Longnecker et al. (2013) encountered unexpectedly high concentrations of total and free BPA, with 24% containing more than 10 ng/mL of total BPA, suggesting external contamination. Subsequent investigation of the source of free BPA in the specimens showed that under typical conditions used to collect urine specimens in an epidemiologic study of outpatients, contamination with BPA occurred by two separate mechanisms, one due to the preservative, and the other possibly via dust in clinics.

Other General Population Exposure Studies in Various Countries

Calafat et al. (2005) also presented briefly the urinary BPA levels in various populations in Southeast Asia reported by various researchers: (1) In Japan for 1992, 1999, 2002, and 2003, BPA was measured in urine samples from two different groups of university students in 1992 ($n = 50$, 92% male) and 1999 ($n = 56$, 87.5% male) with most of the BPA found in the urine as the glucuronide conjugate, and the median urinary BPA levels were approximately 2.2-fold higher than in 1999. (2) BPA glucuronide was detected in all of the urine samples collected from 48 female Japanese college students at concentrations ranging from 0.2 to 19.1 ng/mL, with a median level of 1.2 µg/L (0.77 µg/g). (3) In 2004, a median daily urinary excretion of BPA of 1.2 µg/day and an estimated maximum daily intake of BPA to be 0.23 µg/kg/day were reported based on the measurement of BPA in 24-hr urine samples collected from 36 men. This estimated intake was lower than the temporary TDI (10 µg/kg) set by the European Commission's Scientific Committee in Food in 2002. (4) In Korea for nonoccupational exposure assessment, urinary levels of BPA in a group of 73 adults showed a GM concentration of BPA of 9.54 µg/L (8.91 µg/g).

Park et al. (2016) reported that BPA urinary concentrations in Korea may be higher than those in other Asian countries and North America, but lower than or

similar to those in European countries. The current study included a total of 2044 eligible adults of all ages and gender. The GM of preadjusted (adjusted) urinary BPA concentrations was 1.83 µg/L (2.01 µg/g) for subjects of all ages, and there was no statistically significant difference in BPA concentrations between males (1.90 µg/L, 1.87 µg/g) and females (1.76 µg/L, 2.16 µg/g).

In Sweden, phthalates and phenolic substances were investigated in urine samples from first-time mothers in Uppsala County, collected between 2009 and 2014 in the POPUP study (Persistent Organic Pollutants in Uppsala Primiparas) conducted by the Swedish National Food Agency (Gyllenhammar et al., 2017). The aim was to investigate if measures to decrease production and use of some of these nonpersistent chemicals have resulted in decreased human exposure, and to determine if exposure to replacement chemicals has increased. A total of 178 women were included in the data set; 30 women were sampled every year between 2009 and 2014 and the participating rate was 52%.

BPA showed a downward trend, with a half-life of 6.6 years, whereas BPF, identified as one of the substitutes for BPA, showed an increasing trend, with a doubling in mean concentrations every 3.8 years. The authors noted that declining temporal trends for BPA has also been seen in the US NHANES study between 2003 and 2012 (Lakind and Naiman, 2015) and also in young Swedish men between 2010 and 2013 (Jönsson et al., 2014). When compared with other studies, the authors indicated that median concentrations of BPA were in the same range as in young Swedish women and about 30% lower compared with Swedish mothers (Jönsson et al., 2014; Larsson et al., 2014). Concentrations of BPA found in the study were also lower compared to recent studies of 684 women in other European countries sampled in 2008 and 2011–12 (Covaci et al., 2015; Guidry et al., 2015).

PREGNANT WOMEN, MOTHER–INFANT/CHILD PAIRS, INFANTS, CHILDREN

Pregnant Women

Summary BPA levels for each study can also be found in Table 25.1.

Braun et al. (2011a) estimated the variability and predictors of serial urinary BPA concentrations taken during pregnancy (around 16 and 26 weeks of gestation) and at birth. Data were collected from pregnant women participating in the Health Outcomes and Measures of the Environment (HOME) Study, an ongoing prospective birth cohort in the Cincinnati, Ohio, metropolitan area designed to examine low-level environmental

toxicant exposure. Beginning in March 2003, through 2006, women were identified from seven prenatal clinics associated with three hospitals. Eligibility criteria for enrollment in the study included ≤19 weeks of gestation, age ≥18 years, living in a house built before 1978, negative HIV status, and not taking medications for seizure or thyroid disorders. Letters were mailed to 5184 women who were ≥18 years of age and living in a house built before 1978. Of the 1263 eligible responding women, 468 enrolled in the study (37%), but 67 dropped out before delivery, and 3 had stillbirths. This analysis was further restricted to 389 mothers who delivered singleton children between March 2003 and January 2006.

Women provided three spot urine samples collected at approximately 16 and 26 weeks of gestation at prenatal care appointments and at birth. Results showed that the GM creatinine-standardized concentrations (micrograms per gram, μg/g) were 1.7 (16 weeks), 2.0 (26 weeks), and 2.0 (birth).

Log10-transformed urinary BPA concentrations were weakly correlated at 16 and 26 weeks ($r = 0.28$), 26 weeks and birth ($r = 0.28$), and 16 weeks and birth ($r = 0.21$). Correlations between creatinine-standardized urinary BPA concentrations were even lower at 16 and 26 weeks ($r = 0.12$), 26 weeks and birth ($r = 0.12$), and 16 weeks and birth ($r = 0.06$).

The ICC for serial urinary BPA measurements indicated poor reproducibility in analyses using unstandardized (ICC = 0.25) and creatinine-standardized concentrations (ICC = 0.10). Creatinine-standardized BPA concentrations exhibited low reproducibility (ICC = 0.11). The ICC was used to assess BPA variability and estimated associations between log10-transformed urinary BPA concentrations and demographic, occupational, dietary, and environmental factors, using mixed models. Only maternal education and occupation was associated. By occupation, cashiers had the highest BPA concentrations (GM: 2.8 μg/g) and serum cotinine, a tobacco smoke metabolite, was associated with higher BPA concentrations. In children almost 99% of BPA exposure was estimated to come from dietary sources. Dietary findings are further discussed below, in the Food packaging and BPA alternatives section. The authors noted that future studies should standardize or adjust for the timing of urine collection or measure BPA at multiple times to minimize biases due to within-day and within-woman variability of urinary BPA and creatinine concentrations.

Braun et al. (2012) also characterized the variability of urinary phthalate and BPA concentrations before and during pregnancy. No prior study had examined the same woman before and during pregnancy. Women 18–45 years of age were recruited from clinical partners seeking evaluation and treatment for infertility at the Massachusetts General Hospital Fertility Center in Boston between November 2004 and December 2009 for a prospective open-cohort study, the Environment and Reproductive Health (EARTH) Study. For BPA analyses, 137 women provided two or more urine samples before and during pregnancy. They were predominately white, highly educated, and had a mean (±SD) of 35 ± 4.1 years of age at enrollment. Before pregnancy, women provided between 2 and 13 urine samples (median, 3 samples) during a period of <1–110 weeks after enrollment (median, 12 weeks). During pregnancy, a median of three samples was collected. Results showed that urinary BPA concentrations were variable before and during pregnancy, ICC = 0.12, which is similar to observations in studies with multiple samples during pregnancy.

In the EDEN mother–child cohort (Etude des Déterminants pré et post natals du développement et de la santé de l'Enfant) recruited in Nancy and Poitiers, France, a subgroup of 587 pregnant women were tested once for urinary BPA and phthalates between the 23rd and 29th weeks of gestation during 2003–06 (Philippat et al., 2014). Median BPA adjusted by statistical regression for creatinine, as well as day and time of sampling, gestational age, duration of storage at room temperature, and year of analysis, was 2.4 μg/L.

Occupational and nonoccupational contact with paper receipts was positively associated with BPA in conjugated (glucuronidated + sulfated) form after adjustment for demographic characteristics. The author noted that recent consumption of foods and beverages likely to be contaminated with BPA was infrequent among participants.

Arbuckle et al. (2014, 2015) reported on free and conjugated forms of BPA during pregnancy in about 1890 first-trimester urine samples from the Maternal-Infant Research on Environmental Chemicals (MIREC) Study, a large multicenter cohort study of Canadian pregnant women. Study participants tended to be well educated, > 30 years of age, born in Canada, had never smoked, had an underweight or normal BMI prior to pregnancy, and had a parity of 0 or 1. Results showed that the glucuronides of BPA were the predominant forms measured (detected in 95% of samples), whereas the free forms were detected in 43% of samples. The GM of SG-adjusted urinary BPA glucuronide was 0.91 μg/L. On average, only about 1% of the total BPA was present in the unconjugated form. However, at the 95th percentile level of total BPA the percentage of uBPA versus total BPA was 12%. Significant predictors of BPA included maternal age <25, current smoking, low household income, and low education level. The results from this study represent the largest nation-level data on urinary concentrations of free and conjugated forms of BPA in pregnant women.

Teeguarden et al. (2016) evaluated 30 healthy pregnant women for total BPA exposure over a 30-h period comprising one-half day in the field and 1 day in a clinical setting. BPA and its metabolites were measured in serum and total BPA was measured in matching urine samples, including sampling outside the clinical setting. It was also intended to identify potential explanations for previously reported and anomalously high serum BPA concentrations.

The 30 pregnant volunteers were recruited for the study from the Salt Lake City, UT metropolitan area in 2014. Eligibility included no tobacco—alcohol—drug use, 18—40 (mean 26.5) years of age, and being at 15—35 (mean 23.7) weeks of a normal, low-risk pregnancy, with normal GI tract, kidney, and liver function, as determined by clinical laboratory tests, medical history, and physical examination. Volunteers were not taking medications that alter hepatic glucuronidation/sulfonation or renal elimination, were HIV- and hepatitis-free, and had not undergone dental procedures in the 2 days preceding the study. Two cohorts were recruited from a pool of 116 candidates. A 20-member BPA cohort with the highest potential for exposure to BPA was selected based on the screening survey to assess exposure to BPA by ingestion of canned foods and handling of cash register receipts.

Serum BPA levels were assessed in samples with a high corresponding urinary BPA result. The mean total exposure was similar to that in NHANES. Women working as cashiers did not have higher total BPA exposure. BPA was detected in some serum samples (0.25—0.51 ng/mL) but showed no relationship to total BPA in corresponding urine samples, no relationship to total BPA exposure, and had uBPA fractions of 60%—80%, consistent with established criteria for sample contamination. The authors concluded that typical exposures of North American pregnant women produce internal exposures to BPA in the picomolar range. They also suggested that previously published human biomonitoring studies of BPA in pregnant women that reported serum uBPA/total BPA ratios much greater than 15% are probably the result of contamination during sampling, and the reported concentrations appear unrelated to typical exposures in the general population of pregnant women. However, the findings, below, of Veiga-Lopez et al. (2015), following the round robin methods discussed by Vandenberg et al. (2014a), partly contradict this conclusion.

Mother—Infant/Child Pairs

The study of mother—infant/child pairs enables the prospective type of epidemiological study design. Prospective studies are a superior design because the exposure metrics are established before the outcome is measured. This helps to avoid misclassification of exposure and some aspects of confounding. The studies mostly examined fetal growth, neurodevelopment, and thyroid and respiratory outcomes, summarized in Tables 25.2—25.5.

A large number of studies has been published from the prospective HOME birth cohort (see above, in the section on studies of Pregnant Women), which measured a large number of chemicals. Spanier et al. (2012) compared BPA concentrations in serial maternal urine samples of 398 mother—infant pairs and assessed parent-reported child wheeze every 6 months for 3 years. Results showed that for 365 children for which both BPA and respiratory data were available, BPA was detected in 99% of maternal urine samples during pregnancy (16 and 26 weeks of gestation), with a mean prenatal creatinine-adjusted GM = 2.4 μg/g.

In multivariate analysis, a 1-unit increase in log-transformed creatinine-standardized mean prenatal BPA concentration was not significantly associated with child wheeze from birth to 3 years of age. Potential confounder data included socioeconomic factors, race/ethnicity, season, familial and child history of allergy, pet ownership, insect exposure, urban/suburban/rural residence, and maternal cotinine, a surrogate for tobacco use. Mean prenatal BPA above versus below the median was positively associated with wheeze at age 6 months and AOR of 2.3 (95% CI: 1.3, 4.1), but not at later (12, 18, 24, 30, and 36 months) time points. In secondary analyses evaluating associations of early and late prenatal BPA concentration separately, urinary BPA measured at 16 weeks gestation were associated with wheeze (AOR 1.2, 95% CI 0.99, 1.5), but not BPA from 26 weeks of gestation or at birth. In this regard it is of interest that BPA levels in the two gestational samples were only weakly correlated ($r = 0.18$, $P = .03$). Discussion presented below (Donohue et al., 2013) suggests that urinary levels may not be as representative at later gestational time points of BPA because of increasing retention in the fetoplacental unit as gestation nears term.

A follow-up study (Spanier et al., 2014) tracked the children through age 5 years, adding spirometry data for forced-expiratory-volume-in-1-second (FEV1) from testing at ages 4 (N = 155) and 5 (N = 193). There was a combined total of 208. Mean maternal BPA was associated with FEV1 at age 4 (β = −14, 95% CI, −24, −4, $P = .007$), but not at age 5. Child BPA at 4 and 5 was not associated with FEV1. The degree of association was similar with the 16-week and the 26-week gestational samples.

Yolton et al. (2011) examined the association of prenatal exposure to BPA in the HOME study with data from a Neonatal Intensive Care Unit Network Neurobehavioral

[c]unconjugated BPA.

Scale, assessed during a postnatal visit at 5 weeks old. They did not find evidence of an association among the 350 mother/infant pairs. Braun et al. (2009) examined the association between prenatal BPA exposure and behavior in 2-year-old children and investigated whether gender modified the association. Study data were obtained from the HOME Study cohort. Child behavior was assessed using the second edition of the Behavioral Assessment System for Children-2 (BASC-2). The association between prenatal BPA concentrations and BASC-2 scores was analyzed using linear regression. Median BPA concentrations among the 249 mothers included in this first set of analyses were 1.8 (16 weeks), 1.7 (26 weeks), and 1.3 (birth) ng/mL. Mean (±SD) BASC-2 externalizing and internalizing scores (see next paragraph) were 47.6 ± 7.8 and 44.8 ± 7.0, respectively. After adjustment for confounders (maternal age, race, education, mental health, household income, marital status, and a care-giving score), log10-transformed mean prenatal BPA concentrations were associated with externalizing scores, but only among females ($\beta = 6.0$; 95% CI, 0.1—12.0). In contrast, the trend for boys was inverse. Notably, the statistically nonsignificant trends for internalizing behavior

[c]TSH.

exhibited a similar pattern—with higher maternal BPA girls had a higher score and boys had a lower score. Compared with 26-week and birth concentrations, BPA concentrations collected around 16 weeks were more strongly associated with externalizing scores among all children (β = 2.9; 95% CI, 0.2–5.7), and this association was stronger in females (β = 4.8; 95% CI, 1.3–8.3) than in males. Among all children, measurements collected at ≤ 16 weeks showed a stronger association (β = 5.1; 95% CI, 1.5–8.6) with externalizing scores than did measurements taken at 17–21 weeks (β = 0.6; 95% CI, −2.9–4.1).

Externalizing and internalizing behaviors are problem behaviors, summarized as composite scores. The former includes outwardly directed behaviors, such as fighting, disobedience, stealing, and vandalism. The latter behaviors are focused inward, such as fear and withdrawal. A positive score means more problems. Braun et al. (2011b) continued their follow-up of the HOME study by examining behavior and executive function of 3-year-old children of 244 enrolled mothers. In addition to the three maternal spot urine samples, children's spot urine samples were collected at 1, 2,

and 3 years of age during clinic or home visits, between 2004 and 2009. For statistical analysis, the authors characterized gestational and childhood BPA exposures by using the mean BPA concentrations of two urine samples from each mother and child. Behavior and executive function were measured by using the BASC-2 and the Behavior Rating Inventory of Executive Function-Preschool (BRIEF-P). BPA was detected in >97% of the gestational (median 2.0 μg/L) and childhood (median 4.1 μg/L) urine samples. Overall correlation of each individual's paired samples (i.e., early vs. later gestation, maternal vs. child, and the child's sequential samples) was weak: a Pearson R statistic < 0.25 or with creatinine-adjusted concentrations, a Pearson R < 0.18.

With adjustment for confounders, each 10-fold increase in gestational BPA concentrations was associated with more anxious and depressed behavior on the BASC-2 and poorer emotional control and inhibition on the BRIEF-P. The magnitude of the gestational BPA associations differed according to child gender; BASC-2 and BRIEF-P scores increased from 9 to 12 points among girls, but changes were null or negative among boys. Hyperactivity among girls was increased, β = 9.1

(95% CI: 3.1, 15), but was decreased among boys, $\beta = -6.3$ (95% CI: −12, −0.6). Anxiety and depression were also associated with BPA among girls. Associations between childhood BPA exposure and neurobehavior were largely null and not modified by child gender. Overall, gestational BPA exposure affected behavioral and emotional regulation domains (anxiety, hyperactivity, emotional control, and behavioral inhibition) at 3 years of age, especially among girls, in a manner consistent with their previous findings.

A follow-up study of 228 mother—child pairs from the HOME Study (Stacy et al., 2016) found that each

10-fold increase in prenatal BPA was associated with more externalizing behaviors (see below) in 8-year-old girls ($\beta = 6.2$, 95% CI: 0.8, 11.6) on testing with the BASC-2, but not among boys. In contrast, externalizing behaviors in boys was associated with urinary BPA level at age 8 ($\beta = 3.9$, 95% CI: 0.6, 7.2), but not in girls.

Stacy et al. (2017) examined the patterns, variability, and predictors of urinary BPA concentrations in 337 mothers and children from the HOME Study. From 2003 to 2014 six urine samples were collected from children between 1 and 5 and at 8 years of age. Urinary BPA concentrations had a low degree of reproducibility (ICC < 0.2). Estimated daily intakes (EDIs) decreased with age. BPA concentrations were linked to consuming food stored or heated in plastic, consuming canned food and beverages, and handling cash register receipts. EDIs decreased as child age increased, with median intakes of 190 and 39 ng/kg/day for 1- and 8-year-olds, respectively.

Romano et al. (2015) observed that BPA in the 26th gestational week was associated with a 43% decrease of thyroid stimulating hormone (TSH) in the cord blood of female, but not male, neonates. BPA in the 16th gestational week was not associated with neonatal TSH. There was no effect on thyroxine (T4), but there was a marginal statistically significant association with triiodothyronine (T3) in girls. Chemical covariates unique to this study's analysis included iodine intake, polychlorinated biphenyls, and hexachlorobenzene.

The INMA study (Infancia y Medio Ambiente; Childhood and Environment) is a population-based birth cohort study that recruited 657 pregnant women in the Spanish region of Sabadell between 2004 and 2006 (Guxens et al., 2012). Pregnant women were recruited at their first routine prenatal care visit. Maternal urine samples were collected at 12 ± 1.7 and 32 ± 1.4 weeks of gestation. Total BPA was determined in 470 mother–child pairs. Data available for multivariate analysis included maternal age, socioeconomics, weight and height, parity, marital status, dietary information, use of household cleaning products, tobacco use, and season of birth, as well as first trimester blood mercury, total polychlorobiphenyls, and the DDT metabolite, DDE.

For the 462 children included in Gascon et al. (2015), reported below, the median maternal BPA was 2.4–2.5 μg/g and the interquartile level was 1.7–3.7 μg/g. The ICC for the two maternal samples was 0.15 for unadjusted BPA and 0.14 for adjusted BPA (Casas et al., 2016), indicating low reproducibility. The GM for the 37 pregnant mothers <25 years of age was 3.3 μg/g, whereas for the 83 pregnant mothers ≥35 years of age the GM was 2.2 μg/g.

Respiratory parameters in the children of the INMA-Sabadell cohort were studied by Gascon et al. (2015). Children were tested at 6 months (N = 437–445), 14 months (N = 424), 4 years (N = 385), and 7 years (N = 361). For each doubling in concentration of mean maternal urinary BPA the adjusted relative risks (RRs) over all ages combined increased for wheeze (RR, 1.20; 95% CI, 1.03–1.40; P = .02), chest infections (RR, 1.15; 95% CI, 1.00–1.32; P = .05), and bronchitis (RR, 1.18; 95% CI, 1.01–1.37; P = .04). Asthma, tested only at age 7, showed an association but not with statistical significance (RR, 1.21 (0.94–1.57; P = 0.14). These were slightly lower in a model that adjusted for other pollutants. The associations with early and late gestation BPA have shown different degrees of effect.

Casas et al. (2016) estimated growth curves for femur length, head circumference, abdominal circumference, and biparietal diameter and estimated fetal weight during pregnancy (weeks 12—20 and 20—34), and for birth weight, birth length, head circumference at birth, and placental weight in 470 births. The median maternal BPA level was 2.3 µg/g. This study, one of the first to combine repeat exposure biomarker measurements and multiple growth measures during pregnancy, found little statistically significant evidence of an effect on fetal growth. However, the trend for BPA was for lower birth weight (−21.6 g per µg/g BPA for girls and −11.0 g per µg/g for boys). Notably, the high intraindividual variability of the measurements meant likely exposure misclassification, probably random, thereby reducing the degree of observable linkage.

At age 4 (Valvi et al., 2013), maternal BPA was associated with increased waist circumference (β per log 10 µg/g = 0.28, 95% CI, 0.01, 0.57) and, with marginal statistical significance, BMI (β = 0.28, 95% CI, −0.06, 0.63).

Neurobehavioral testing (Casas et al., 2015) revealed that (1) psychomotor scores at age 1 were reduced in the highest tertile of creatinine-adjusted prenatal urinary BPA, but not at age 4, and (2) for each log10 µg/g of prenatal exposure there was increased incidence of hyperactivity, as reported by teachers using the Diagnostic and Statistical Manual of Mental Disorders-IV tool for Attention-Deficit/Hyperactivity Disorder (ADHD), when the children were 4 years old. The adjusted incidence rate ratio (IRR) for hyperactivity was 1.72 (95% CI: 1.08, 2.73) and was stronger in boys, 1.9 (95% CI; 1.01, 3.7), than in girls, 1.6 (95% CI: 0.79, 3.2). The IRR for inattention was elevated in boys (IRR = 1.4) but was not statistically significant. However, the IRR for second tertile versus the first tertile showed a statistically significant elevation, 1.6 (95% CI: 1.01, 2.4). When the children were tested again at the age of 7, there was no association of prenatal BPA with hyperactivity, as measured by parents with the Conner's Parent Rating Scales, nor were there links with externalizing and internalizing problems (Strengths and Difficulties Questionnaire). There were no significant associations with cognitive scores or their subscales. However, it must be noted that, ADHD is a complex disease and still not well understood, so there may be other important environmental chemicals (and other confounders) that were not included in the analysis. The relationships between early and late pregnancy samples and neurobehavioral testing were not analyzed separately.

Perera et al. (2012) examined the association between prenatal BPA exposure and child behavior, adjusting for postnatal BPA exposure and hypothesizing gender-specific effects. Participants in this study were mothers and their children in the Columbia Center for Children's Environmental Health (CCCEH) low income cohort, predominantly African-American and Dominican women, in New York City. Enrollment in 1998 was limited to women who were in the age range of 18—35 years, nonusers of tobacco products or illicit drugs, free of diabetes, hypertension, or known HIV, and who initiated prenatal care by the 20th week of pregnancy. Urine samples were collected at the 34th week of gestation on average and from children between 3 and 4 years of age.

Out of 337 mother—child pairs with prenatal BPA measurements and maternal prenatal questionnaire data, BPA was detectable in the urine of >90% of both mothers and children. The ranges of total SG-adjusted BPA in maternal and child urine samples were 0.24—38.53 µg/L and 0.42—73.50 µg/L, respectively, indicating a wide variation in exposure. The GMs for maternal and child urinary concentrations of BPA were 1.96 and 3.94 µg/L, respectively. No significant differences were observed between boys and girls in median and mean prenatal or postnatal BPA concentrations, whether SG-adjusted or not.

The authors assessed behavior of children between 3 and 5 years of age using the Child Behavior Checklist (CBCL) in 198 of these mother—child pairs (87 boys, 111 girls). Among boys, high prenatal BPA exposure (highest quartile vs. the three lower quartiles) was associated with significantly higher CBCL scores (more problems) on Emotionally Reactive (1.62 times greater; 95% CI: 1.13, 2.32) and Aggressive Behavior scales (1.29 times greater; 95% CI: 1.09, 1.53). Among girls, higher exposure was associated with lower scores on all syndromes, reaching statistical significance for Anxious/Depressed (0.75 times as high; 95% CI: 0.57, 0.99) and Aggressive Behavior (0.82 times as high; 95% CI: 0.70, 0.97) scales. These results suggest that prenatal exposure to BPA may affect child behavior, and differently among boys and girls. Among boys they found significant positive associations between prenatal BPA and CBCL scores of Emotionally Reactive and Aggressive Behavior. In contrast, among girls prenatal BPA was associated with significantly lower scores for the Aggressive Behavior and Anxious/Depressed syndromes. The authors noted that these findings are inconsistent with reports by Braun et al. (2009, 2011b), discussed above, who reported evidence of adverse effects predominantly in girls. The different ethnicity and socioeconomic status levels of the two sets of subjects provide a somewhat different neurobehavioral developmental setting that might contribute to the inconsistency.

Among the first studies of the fetal effect of BPA on asthma published on maternal—infant/child pairs, Donohue et al. (2013) looked at asthma in the CCCEH cohort. Sampling for urinary BPA was conducted during

the third gestational trimester and in their children at ages 3, 5, and 7 years old. There was no correlation of BPA levels between gestational and child samples ($r \leq 0.02$) nor between samples taken at ages 3 and 5, but between ages 3 and 5 or 7 the r-statistic, 0.14–0.16, was significant. Wheeze was assessed with questionnaires at 5, 6, and 7 years of age, whereas an asthma assessment was conducted by a physician once between ages 5 and 12. The number of subjects with complete data for analysis ranged from 270 to 390. BPA levels at 3, 5, and 7 years were each associated with asthma, and the adjusted OR for mean child BPA was 1.6 (95% CI: 1.2, 2.1). The adjusted ORs were similar or lower for wheeze. Notably, third trimester maternal BPA was inversely associated with wheeze (AOR = 0.7, 95% CI: 0.5, 0.9).

The authors discussed a theory based on the pharmacokinetics of BPA in the pregnant mouse and measurements in human placenta in other studies. They noted that BPA was retained in the fetoplacental unit, which would limit the observable amount in the urine. If some pregnant women and fetuses displayed similar pharmacokinetics, it raises the possibility of significant misclassification of exposure, especially in the third trimester. This would be consistent with the finding above that 16th gestational week samples were more associated with childhood respiratory outcomes than 26th week samples (Spanier et al., 2012).

In the multicenter Study for Future Families II, initiated during 2002–05, maternal urinary samples were collected during a visit sometime in the 10–39 weeks (mean 27 weeks) of gestation timeframe (Evans et al., 2014). Maternal median BPA was 1.6 µg/g and mean BPA was 3.7 µg/g. Externalizing and internalizing behaviors measured with the CBCL in boys at aged 6–10 years was associated with maternal BPA among mother–child pairs in which the BPA was detectable (28 out of 153 pairs were excluded). The increases were small, but statistically significant, $\beta = 0.35$ ($P = .05$) and $\beta = 0.35$ ($P = .02$), respectively. Girls exhibited no associations with these measures.

Nested in the Generation R cohort, Snijder et al. (2013) analyzed a subset of 80 women for whom there was urinary BPA data from each trimester during pregnancy visits. The fetal growth rate was reduced in women with >4.2 µg/g BPA compared with women whose BPA was <1.54 µg/g. Weight at birth was reduced by 683 g and head circumference was reduced by 3.9 cm (See above for the analysis of BPA levels in this subset by Jusko et al. (2014)).

Maternal–child pairs in an agricultural area of California were the focus of the Center for the Health Assessment of Mothers and Children of Salinas study. Gestational urinary samples were taken at approximately 12 and 26 weeks during 1999–2000. The GM of creatinine-adjusted BPA was 1.1 µg/L and the two

samples were only weakly correlated ($r = 0.25$). Maternal BPA, particularly the 26-week sample, was associated with lower TSH in neonatal boys (−9.9% per log2 unit increase of BPA), but not in girls (Chevrier et al., 2013). BPA at 26 weeks but not 12 weeks was also associated with lower total maternal thyroxine ($\beta = -0.13$ µg/dL per log2 unit) measured at 26 weeks. Iodine level was not a confounder.

BASC-2 internalizing behaviors tended to be increased with higher maternal BPA in 7-year-old boys but not girls in both mothers' and teachers' reports, though the score differences were not statistically significant (Harley et al., 2013). Early and late pregnancy samples were not examined separately. BPA was also measured in 5-year-olds (GM = 2.5 µg/L) and was associated with outcomes, primarily among girls (Harley et al., 2013). Analysis of reports on girls completed by mothers linked child BPA to several externalizing behaviors (score difference of 1.2, 95% CI: 0.3, 2.1) and two of its scales, including conduct problems (score difference of 1.8, 95% CI: 0.8, 2.9) and inattention (score difference of 0.9, 95% CI: 0.2, 1.6). Using a different tool, the Conners' ADHD/Diagnostic and Statistical Manual for Mental Disorders-IV, data generated by the mothers uncovered associations with inattention (score difference of 1.3, 95% CI: 0.4, 2.2), hyperactivity (score difference of 1.1, 95% CI: 0.1, 2.0), and ADHD (score difference of 1.3, 95% CI: 0.3, 2.3). Analysis of data from teacher reports also provided evidence of statistically significant associations among both boys and girls of BASC-2 internalizing behaviors (boys score difference of 1.8, 95% CI: 0.14, 3.1; girls score difference of 1.8, 95% CI: 0.1, 3.6) and its scales, especially anxiety and depression, but not externalizing behaviors. CADS components scored by teachers tended to be associated with girls. Inattention, hyperactivity, and ADHD score differences were 1.7, 0.4, and 1.1, respectively for boys and 1.0, 1.7, and 1.7 for girls.

The EDEN (Etude des Déterminants pré et post natals du développement et de la santé de l'Enfant) cohort examined mother–infant/child pairs from Poitiers and Nancy, France. Maternal urinary BPA sampled between gestational weeks 22 and 29 (N = 520) had 2.4 µg/L creatinine-adjusted BPA (Philippat et al., 2014). There was no association of urinary BPA with birth weight, but there was increased head circumference (Philippat et al., 2012). Children tended to have heavier weight at 12, 24 and 36 months but not with statistical significance (Philippat et al., 2014). This was similar to findings by Valvi et al. (2013) in the INMA-Sabadell cohort.

Follow-up (Philippat et al., 2017) found only a small effect due to urinary BPA from gestational weeks 23–29 on the internalizing behavior score at 3 years of age (IRR = 1.06, 95% CI: 1.00, 1.12, per doubling in BPA concentration, N = 457), especially for peer

relationship problems, and on the externalizing behavior score, especially in the hyperactivity−inattention subscale at 5−6 years of age (IRR = 1.08, 95% CI: 1.01, 1.14, per doubling in BPA concentration). Dichotomizing the score data resulted in an OR for internalizing behavior of 1.2 with marginal statistical significance (95% CI: 0.96, 1.6) and an OR of 1.4 (95% CI: 1.08, 1.8) for hyperactivity−inattention. The data were provided by mothers (N = 464) who completed the Strength and Difficulties Questionnaire. Covariates included child age, maternal adiposity, parental education, breastfeeding duration, smoking, and maternal mental status. An IRR of 1.08 (95% CI: 1.01, 1.14) was reported. In addition, IQ was assessed in 5−6-year-old boys using the Wechsler Preschool and Primary Scale of Intelligence (Nakiwala et al., 2018). No association was observed.

Boys born to a subgroup of 587 women from the EDEN cohort in France were also examined at age 5 for respiratory health (Vernet et al., 2017). Comparison of FEV1 with log-transformed urinary BPA revealed a nonstatistically significant inverse relationship with FEV1 and a positive association with asthma (Hazard ratio = 1.2, 95% CI: 0.97, 1.55; third tertile HR = 1.4, 95% CI: 0.87, 2.2). There was no association with wheeze.

Preterm birth (<37 weeks) was studied by Canton-wine et al. (2015) in a study nested in a cohort enrolled during 2006−08 in Boston and Philadelphia. Urine samples were obtained over four visits (at 10th, 18th, 26th, and 35th weeks of gestation) from 1695 pregnant women. SG-corrected BPA indicated low stability across trimesters (ICC = 0.21; 95% CI: 0.16, 0.27), and ICCs were slightly higher in cases of preterm birth (0.25) compared with controls (0.19). Spearman correlations between study visits for BPA were low, 0.17−0.26 (all P-values < .01). The trend to preterm births with increasing gestational BPA was mostly not statistically significant, but notable, nonetheless, because the BPA from the fourth visit (33−38 weeks of gestation) was associated (P < .01) in all three statistical models with spontaneous preterm birth (N = 25; 298 controls). The AOR in the model with the most adjusting covariates, including total urinary phthalates, was 2.2 (95% CI: 1.3, 4.0).

Neonatal TSH was lower and thyroxine was increased with increased BPA, −8.2% and 4.8%, respectively, per natural log of the interquartile concentration (Aung et al., 2017). The association was primarily due to the gestational weeks of 26 and 35 samples, which are −13.5% and −17.3%. However, the conclusions are limited because this cohort was enriched with preterm births (116 preterm and 323 term neonates). The authors noted a general consistency between BPA and TSH in studies of men, nonpregnant women, and children.

Recently, Buckley et al. (2018) reported on the association of log-transformed urinary BPA in the third gestational trimester with previously diagnosed asthma in the respective 6−7-year-old boys (AOR = 3.0, 95% CI: 1.4, 6.6), but not girls, in the Mount Sinai Children's Environmental Health Study of 164 maternal−child pairs. The median unadjusted BPA concentration in the third trimester was 1.3 µg/L and the interquartile range was 0.6−2.3 µg/L.

A small blood sampling study of 80 maternal−infant pairs at the University of Michigan Hospital (Veiga-Lopez et al., 2015) found that birth weight of a female pregnancy was 183 g (P > .005) lower per twofold increase in plasma uBPA and 607 g (P = .0093) lower per 10-fold increase in uBPA, based on first trimester samples. The term uBPA had an opposite effect, a gain of 96 g (P < .05) per twofold increase of uBPA and 318 g (P = .034) per 10-fold increase, as well as an increased gestational age for female births, 1.1 days (P = .06) and 3.7 days (P = .06), respectively. There was no effect on male births. Notably, term uBPA was approximately twice as high as in the first trimester and was higher in 68% of term mothers. This may prove to be an example of a U-shaped dose−response curve. In addition, it is not clear from the literature whether the other studies analyzing birth weight and urinary BPA examined the different gestational weeks separately. If there was not a statistically significant difference, then, it may be that uBPA in blood is a more enlightening approach.

Children

The association between concurrently measured BPA and ADHD symptoms was examined in 460 8−15-year-old children, using data from the 2003−04 NHANES (Tewar et al., 2016). The prevalence of ADHD in the group was 7.1%. Among children with urinary BPA above the median, the prevalence was 11.2%, in contrast with 2.9% below the median. The AOR was 5.68 (95% CI: 1.6, 20), adjusted for child's age, family income, gender, race/ethnicity, urine creatinine, prenatal tobacco exposure, blood lead level (log-transformed), urine organophosphate metabolite level (log-transformed), and insurance status. For boys the AOR was 11 (95% CI: 1.4, 86), whereas in girls the AOR was 2.8 (95% CI: 0.4, 21).

Recently, the results of a case-control study of a group of 465 6−12-year-old children in Guangzhou, China showed that concurrently measured creatinine-adjusted urinary BPA was associated with ADHD in a concentration-dependent manner (Li et al., 2018). Study enrollment was composed of 215 children with ADHD and 250 controls. Comparing the second, third, and fourth quartiles to the first (referent) quartile of BPA, the AORs were, respectively, 1.8 (95% CI: 0.95, 3.4), 7.4 (95% CI: 3.9, 14), and 9.4 (95% CI: 4.9, 18). The effect

was stronger in boys than girls, AOR of 1.8, 9.1, and 10.1, versus 0.96, 3.35, and 4.6, respectively, but only 27 of the 215 cases were girls. For cases the GM of creatinine-adjusted BPA was 4.63 μg/g versus 1.71 μg/g for controls. Like other studies (see above) this difference was larger in 6–9-year-old children, among whom the creatinine-adjusted BPA GM was 5.15 μg/g in cases versus 1.74 μg/g in controls. Consistent with these findings was the greater use of plastic food and beverage containers by ADHD children, but one cannot easily say whether higher exposure to BPA preceded the ADHD diagnosis because of the study design.

In a respiratory disease study, Kim et al. (2014) tested 127 children every 2 years at an elementary school in Seoul, South Korea, starting with urinary BPA measurement at age 7–8 and wheeze and asthma testing every 2 years, ending at age 11–12. Children with diagnosed asthma were excluded. The GM of BPA was 1.0 μg/L. A one-unit increase in log-transformed creatinine-adjusted BPA was associated with wheeze (AOR = 2.5, 95% CI: 1.15, 5.3) and asthma (HR = 2.1, 95% CI: 1.5, 3.0), but the association with asthma was primarily in girls (HR = 2.4, 95% CI: 2.2, 2.8). Covariates for analysis included parental asthma history, parental education level, tobacco use, pet ownership, and cockroach sensitization.

FOOD PACKAGING AND BISPHENOL A ALTERNATIVES

Volkel et al. (2011) determined both free and total BPA in urine samples of 1–2-month-old infants collected via urine bags. The infants were not exposed to chemicals via medical devices. Data were collected on infants after use of BPA-containing BPA-bottles in contrast to infants without use of PC-bottles. Free BPA was observed above the limit of quantitation (LOQ) in only 3 of 91 (3%) samples from 47 infants. Total BPA was observed in only 38 (42%) urine samples, at concentrations up to 18 μg/L. The highest concentration was just under the current EFSA guidance. Infants who were fed using baby bottles showed approximately twofold higher median levels of total BPA. The data also indicate substantial conjugation of BPA in infants.

It is interesting to note that BPA (and phthalates) exposures were substantially reduced when individuals' diets were restricted to food with limited packaging. Rudel et al. (2011) evaluated the contribution of food packaging to exposure, and measured urinary BPA and phthalate metabolites before, during, and after a "fresh foods" dietary intervention. Twenty participants in five families were selected based on self-reported use of canned and packaged foods. Participants ate their usual diet, followed by 3 days of "fresh foods" that were not canned or packaged in plastic, and then returned to their usual diet. Evening urine samples were collected over 8 days in January 2010 and were composited into preintervention, during intervention, and postintervention samples. Results showed that urine levels of BPA metabolites decreased significantly during the fresh foods intervention (e.g., BPA GM, 3.7 ng/mL preintervention vs. 1.2 ng/mL during intervention). The intervention reduced GM concentrations of BPA by 66% with the maxima reduced by 76%.

Morgan et al. (2011) quantified urinary total BPA in 81 children 23–64 months of age in Ohio over 48-h periods to quantify the relationship with overall exposure. Estimated median intake doses of BPA for these 81 children were 109 ng/kg/day (dietary ingestion), 0.06 ng/kg/day (nondietary ingestion), and 0.27 ng/kg/day (inhalation). The estimated median excreted amount of urinary BPA was 114 ng/kg/day, which closely matched exposure.

Consuming canned vegetables at least once a day was associated in the HOME study (Braun et al., 2012) with higher BPA concentrations (GM = 2.3 μg/g) compared with those consuming no canned vegetables (GM = 1.6 μg/g). BPA concentrations did not vary by consumption of fresh fruits and vegetables, canned fruit, or fresh and frozen fish. In the Spanish INMA-Sabadell cohort investigators (Casas et al., 2013) estimated that 21%–25% of the urinary BPA in the pregnant women was associated with consumption of canned fish (Casas et al., 2013).

Findings of BPA alternatives that have gradually replaced BPA have also been reported in urine, some data of which were included in studies described above. The substitution of BPA includes alternative BPXs such as bisphenol S (BPS; 4,4-sulfonyldiphenol), bisphenol B (2,2-bis[4-hydroxyphenyl]butane), BPF (4,4-dihydroxydiphenylmethane), and bisphenol AF (4,4-[hexa-fluoroisopropylidene] diphenol) (Usman and Ahmad, 2016). BPA-related compounds or BPXs consist of two phenol groups attached through a bridging carbon or other chemical structure. The para-hydroxy groups are critical in binding to estrogen receptor. Because BPXs are structurally similar to BPA, it is expected that they may also have the same toxicological effects on the biological system.

BPF and BPS are selected here as examples to examine in brief some of the findings related to these alternatives. BPF is absorbed by oral route and distributed to the whole organism, including the reproductive tract and the fetus by crossing the placental barrier, is mainly excreted through the urine, and has been shown to be as hormonally active as BPA. BPF has a broad range of industrial applications including manufacture of epoxy resins and polycarbonates (Usman and Ahmad, 2016). BPF residues have been found in

foodstuffs packaged in containers with epoxy coatings, in the drinking water pumped out from the water pipes incidentally using bisphenol F diglycidyl ether—based epoxy resins for renovation; in vegetables, fish and seafood, meat and meat products, and beverages; and in indoor dust, and personal care products (PCPs). BPF was detected in 98% of the urine samples (LOQ of 0.03 µg/L) collected in the Swedish POPUP study during 2009—2014 with a median SG-adjusted concentration of 0.32 µg/L and with levels increasing between 2009 and 2014 (Gyllenhammar et al., 2017). As an environmental contaminant, BPF has been detected in environmental media such as surface water, sewage water, sediment samples, sewage sludge, liquid manure samples, compost water samples, and municipal landfill leachates.

BPS has hormonal potencies of the same magnitude as BPA. BPS use was increased in the production of epoxy resins, thermal papers, and infant feeding bottles after restrictions were put on BPA (Usman and Ahmad, 2016). It is more heat resistant and photoresistant than BPA. Studies showed that BPS has been detected in PCPs, foodstuffs (beverages, dairy products, fish and seafood, cereals, meat and meat products, and canned fruits and vegetables), indoor dust, river water, sewage, sediment, and sludge. The authors noted that moderate to high concentrations of BPS in the range of a few nanogram per gram to several milligrams per gram were detected in thermal receipts collected from various cities of United States, Korea, Vietnam, and Japan. The EDI through dermal absorption was 0.00418 mg/kg bw/day for the general population and 0.312 mg/kg bw/day for individuals who are occupationally exposed. BPS has a greater half-life and better dermal penetration than BPA and can lead to higher body burden in comparison to BPA. It is nondegradable in the aerobic conditions and likely to accumulate in the aquatic environment. Studies cited reported that (1) the detection rate of BPS in human matrices has been as high as 81% in urine and 3% in breast milk collected from United States and seven Asian countries; and (2) a mean EDI of 1.7 µg/day in Japan followed by China and the United States, 0.34 µg/day and 0.32 µg/day, respectively. Gyllenhammar et al. (2017) found BPS 68% of urine samples (Swedish POPUP study, see above) at an SG-adjusted median 0.048 µg/L.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

BPA has been measured in human urine samples in various biomonitoring programs and research studies worldwide. An integrated approach that uses all data types along the environmental disease continuum is required for a complete understanding of the findings. Biomarkers may be particularly useful when they provide linkage to important exposure but must be measured in the correct matrix for exposure route/source of interest, and the analytical technology must be available, reliable, and reproducible, among other considerations. Nondetection may mean that the technology is limited in measuring low concentrations of specific chemicals, or that the exposure occurred at an earlier point in time, allowing for the chemical to be eliminated from the person's body before measurement took place. Although biomonitoring provides reference ranges, for most environmental chemicals there are no "standard ranges" or "safe ranges" established for biomarkers.

In using data on human exposure to environmental chemicals for performing risk assessment of such exposure, the information needed include an understanding of the pattern of exposure, toxicology and epidemiology databases, estimates of intake, measurements of exposure, use of biomarker data, and interpretation of the data and parameters to evaluate the associated public health implications and environmental management and regulatory decision-making. Therefore, for biomarkers to be useful for environmental (and occupational) health risk assessments, they have to be relevant and valid (WHO, 2001).

A good biomarker of exposure should be useful to predict adverse effects, rather than exposure levels. In addition, biomarkers must be validated before application in the risk assessment process, i.e., the relationship between the biomarker, the exposure, and the health outcome must be established. The general criteria for validating biomarkers include understanding the natural history, biological and temporal relevance, pharmacokinetics, background variability, dose response, and confounding factors (WHO, 2001). The validation process includes the critical assessment of different relationships: exposure—dose, dose response (effect), and effect—disease. Validation can focus on the demonstration of a correspondence between a biomarker of exposure and external exposure, or the assessment of their relationship with the concentration in the critical organ (e.g., concentration in the kidney vs. in blood or urine) or with critical effects (e.g., lead neurotoxicity vs. blood lead concentration).

For BPA, health reference values have been established based on animal data, but in the meantime, the results of a number of laboratory animal studies has not been sufficiently consistent. There are still uncertainties particularly on two aspects—low dose effects and NMDRC.

BPA has been measured as uBPA, conjugated BPA, and total BPA. As the conjugated forms are currently viewed to be the inactivated forms without endocrine activities, knowing the forms of BPA and the associated

respective amounts present systemically in humans would be important for understanding the health implications of BPA in the body. Blood samples are a typical and valid approach to estimating systemic contaminant levels and uBPA is detectable in serum samples (Vandenberg et al., 2014a; vom Saal and Welshons, 2014), but it is not as practical as urine sampling.

A high degree of within-person variability has also been reported (Braun et al., 2011a; Jusko et al., 2014; Stacy et al., 2017). Lakind and Naiman (2015) noted the difficulties in interpreting urinary BPA data, despite efforts to account for urine dilution and translate spot sample data to daily exposure. In addition, the BPA levels measured in urine can vary by factors such as age, gender, and race/ethnicity.

A small but provocative study of blood plasma in mother—infant pairs (Veiga-Lopez et al., 2015) observed that gestational term uBPA was approximately twice as high as in the first trimester and was higher in 68% of term mothers. The results, if found to be accurate when repeated, may explain inconsistent findings within and between studies and suggest that the way forward in epidemiology of BPA should include blood sampling to better address different development time frames.

The implications of measurements of BPA concentrations in human tissues and their correlations to a dose—response relationship have yet to be clearly established. Likely, there are sensitive subsets of individuals and critical windows of effect during development, and the goal must be delineation of the mechanisms behind those subsets and time frames. Possibilities of mechanism include enzymatic and cellular receptor polymorphisms and epigenetic causes. Notably, behavior, cognitive ability, IQ, and ADHD are complex phenomena and still not well understood, so there may be other important environmental chemicals and other confounders that were not included. Other known critical pollutants also need to be included in the analysis, such as blood lead in the neurodevelopmental studies. However, the epidemiological studies point to a concern about neurodevelopmental and respiratory effects from fetal and childhood exposures.

INTRODUCTION

Insecticides have been used around the world for centuries to control insects. People are exposed to insecticides in their homes, offices, gardens, workplaces, aircrafts, on military uniforms, or through trace contaminants in food. Insecticides are used most extensively in agriculture, horticulture, and forestry. As a result, farmers, farmhands, and their families are maximally exposed to these chemicals. Insecticides are also used to control vectors, such as mosquitoes and ticks that are involved in spreading public health diseases, such as malaria, West Nile disease, Lyme disease, and others. In developing countries, insecticides are often involved in suicide attempts in humans and malicious or accidental poisonings in pets, birds, and wildlife (Gupta, 2006; Satoh and Gupta, 2010; Lamb et al., 2016).

Insecticides constitute a large number of chemicals of different classes, and they not only exert toxicity in insects but also in vertebrate mammals through different mechanisms of action. Because of distinct differences in chemical structures, insecticides interact with different target and nontarget sites, including receptors, enzymes, and many other known and unknown molecules. Most insecticides are neurotoxicants as they target the nervous system, but they can also target other organs and body systems. The binding sites and adducts can be used as biomarkers of exposure and/or effects of insecticides. The insecticides are metabolized through different metabolic pathways and either parent compounds or their metabolites are often used as

biomarkers of exposure. Insecticides can cause harmful health effects ranging from minor pain to death in nontarget mammalian (including humans), avian, and wildlife species.

Biomarkers of exposure from samples of human and animal tissues, fluids, and excreta offer qualitative and quantitative evidence of pesticide exposure (Barr and Buckley, 2011). These measurements are particularly useful in pesticides' toxicity because they can highlight population-based exposure trends and improve estimates of pesticide exposure and dose. Biomarkers of effects include measurements of biochemical, physiological, or behavioral alterations that are a consequence of pesticide exposure. Lastly, biomarkers of susceptibility are measurements of an individual's inherent ability to respond to insecticide exposures. These measurements include observations of molecular properties and functions, such as genetic polymorphisms and enzyme activities, which can affect the pharmacokinetics of insecticides, along with an individual's biochemical disposition toward disease progression and repair. Insecticide toxicity can be acute, subacute, or chronic, depending on the duration of exposure and the dose involved. Thus, selection of a sensitive, accurate, and validated biomarker of exposure, effects, and susceptibility appears to be a challenging task. In a very recent investigation, Appenzeller et al. (2017) highlighted that a specimen of hair can be as informative as plasma or urine for pesticide (organophosphates, carbamates [CMs], organochlorines, and pyrethroids) residue analysis for biomonitoring in epidemiological studies and

assessing adverse health effects. This chapter describes biomarkers of exposure, effects, and susceptibility of common insecticides in humans and animals.

ORGANOPHOSPHATES AND CARBAMATES

Organophosphate (OP) and CM insecticides are often discussed together as anticholinesterase (anti-ChE) agents because insecticides of both these classes inactivate the acetylcholinesterase (AChE) enzyme. AChE-inhibiting OPs are esters of phosphoric or phosphonic acid, while AChE-inhibiting CMs are esters of carbamic acid. Structurally, OPs are much more complex than CMs and are categorized into 13 different types, such as phosphates, phosphonates, phosphorothioates, and phosphoramidates. During the last half-century, anti-ChE insecticides have gained wide popularity around the world because of two major factors: (1) lack of residue persistence in the environment and in mammalian systems and (2) development of lesser resistance in insects compared with the organochlorine class of insecticides. Currently, hundreds of OPs and dozens of CMs are available on the market for their use as insecticides. Presently, OPs alone represent 50% of worldwide insecticide use. Due to their extreme toxicity and a lack of species selectivity, anti-ChE insecticides pose serious threats to the health of nontarget mammalian (including humans), wildlife, avian, and aquatic species. Depending on the dose and duration of exposure, these insecticides may adversely affect various body organs and systems (nervous system, skeletal muscles, digestive, cardiovascular, respiratory, ophthalmic, reproductive, endocrine, dermal, immune, and others) at cellular and molecular levels.

Mechanism of Toxicity

Mechanism of action differs substantially in acute, intermediate, and chronic toxicity of anti-ChE insecticides. Acute clinical signs of OPs and CMs are primarily attributed to AChE inactivation at synapses in the brain and at neuromuscular junctions in skeletal muscles (Pope, 1999; Gupta, 2006; Satoh and Gupta, 2010; Gupta and Milatovic, 2012; Heutelbeck et al., 2016). Physiologically, AChE is responsible for the hydrolysis of the neurotransmitter acetylcholine (ACh) and the termination of its biological activity within a microsecond. Both OPs and CMs react covalently with a serine residue in AChE in a similar manner to ACh. OPs and CMs inactivate AChE activity by phosphorylation and carbamylation, respectively, and differ quantitatively in rates of dephosphorylation and decarbamylation of inhibited AChE. It needs to be mentioned that the AChE enzyme can "age" with OPs and not with CMs. Following AChE inhibition, free ACh accumulates at the nerve endings of all cholinergic nerves and causes overstimulation of electrical activity. Inactivation of AChE activity >70% leads to a toxic level of ACh accumulation at central and peripheral sites. The molecular interactions between OPs and AChE have been studied in much more detail than those between CMs and AChE and have been described in previous publications (Timchalk, 2006; Gupta and Milatovic, 2012). Pavlovsky et al. (2003) demonstrated that pyridostigmine, by increasing free ACh, enhances glutamatergic transmission in hippocampal CA1 neurons. This mechanism offers an explanation as to how pyridostigmine and other AChE inhibitors, including OP nerve agents and pesticides, cause epileptic discharge and excitotoxic damage.

Evidence suggests that some of the AChE inhibitors directly interact with muscarinic ACh receptors (mAChRs) and nicotinic ACh receptors (nAChRs). The agonistic, antagonistic, potentiating, and inhibitory effects of AChE inhibitors on nAChRs were described by Smulders et al. (2003). These authors established that CM insecticides, which have a more potent interaction with nAChRs, are the less potent inhibitors of AChE; nAChRs are considered additional target sites, as they are involved in the toxicity of these insecticides.

In addition to AChE and ACh receptors, OPs and CMs bind to other serine-containing esterases (such as butyrylcholinesterase and carboxylesterases) and proteases in serum and tissues. In a series of experiments, Gupta et al. (1991a,b, 1993, 1994a,b) demonstrated significant changes in creatine kinase and lactic dehydrogenase, as well as changes in the isozymes of rats following an acute exposure to carbofuran and methyl parathion. Leakage of these enzymes into the serum from target tissues was due to carbofuran- or methyl parathion-induced depletion of ATP in tissues (Gupta et al., 2000, 2001a; b).

OP and CM insecticides also exert a myriad of toxic effects through multiple noncholinergic mechanisms soon after AChE inactivation (Gupta, 2004; Gupta et al., 2007, 2015; Zaja-Milatovic et al., 2009; Gupta and Milatovic, 2010, 2012; Terry, 2012). Among many noncholinergic mechanisms, activation of glutamatergic (NMDA receptors), adenosinergic, GABAergic, and monoaminergic systems appeared to be involved in the seizures and lethality associated with OP- or CM-induced poisonings (Solberg and Belkin, 1997; Choudhary et al., 2002; Dekundy and Kaminski, 2010; Slotkin and Seidler, 2012). In a very recent investigation, Umeda et al. (2018) suggested that carbofuran decreased glutamate receptor 2 (GluA2) protein expression and increased neuronal vulnerability to glutamate toxicity at concentrations that do not affect AChE activity.

OP- or CM-induced excitotoxicity for more than an hour can cause neurodegeneration and

neuroinflammation in the cortex, amygdala, hippocampus, and other brain regions involved in initiation and propagation of convulsions and seizures. The early morphological lesions include dendritic swelling of pyramidal neurons in the CA1 sector of the hippocampus. The AChE inhibitor—induced neuronal cell death is a consequence of a series of extra- and intracellular events leading to the intracellular accumulation of Ca^{+2} ions and the generation of free radicals (Gupta et al., 2001a; b; Milatovic et al., 2010; Kazi and Oommen, 2012). OP- or CM-induced excessive production of free radicals causes oxidative and nitrosative stress to which the brain is especially vulnerable (Gupta et al., 2007, Zaja-Milatovic et al., 2009; Gupta and Milatovic, 2010, 2012). Lipids are readily attacked by free radicals, resulting in the formation of a number of peroxidation products, such as F_2-isoprostanes and F_4-neuroprostanes, which are formed nonenzymatically. F_4-neuroprostanes are specific biomarkers of oxidative damage to the neurons. These events, in addition to many more described elsewhere, cause irreversible destruction of cellular components, including proteins, DNA, and, particularly, mitochondria (Milatovic et al., 2006). Oxidative/nitrosative stress has been demonstrated to cause depletion of high-energy phosphates (ATP and phosphocreatine) by multiple mechanisms in the brain of rats acutely intoxicated with OP and CM insecticides (Gupta et al., 2001a; b; Gupta et al., 2007; Zaja-Milatovic et al., 2009; Zepeda-Arce et al., 2017).

As mentioned earlier, in addition to the nervous system and skeletal muscles, OPs and CMs adversely affect many other body organs and systems, and therefore additional mechanisms of action are involved in toxicity (Gupta, 2006; Satoh and Gupta, 2010; Gupta et al., 2017).

Biomarkers

Acute Toxicity

For the monitoring of insecticides, biomarkers can typically be divided into three categories: biomarkers of exposure, effect, and susceptibility. Biomarkers of exposure to OPs and CMs may include determination of residue of parent compounds and/or their metabolites and modified cells or their molecules (e.g., DNA and protein adducts) in biological tissue/fluids. Highly sophisticated and sensitive chromatographic, spectrometric, and other assays allow the confirmation and quantitation of OP/CM insecticides and their metabolites in body fluids and tissues at the ppm or ppb level. Jain (2006) described detailed aspects of sample selection, extraction, concentration, and analytical methods for the detection of various OPs and CMs and their metabolites. Because these insecticides are unstable and metabolize in body systems very rapidly, it is highly

TABLE 26.1 List of Some Common Organophosphate Insecticides and Their Metabolites

Parent Compound	Specific Metabolite(s)
Azinphos-methyl/-ethyl	1,2,3-Benzotriazin-4-one
Chlorfenvinphos	2-Chloro-1-(2,4-dichlorophenyl) vinyl ethyl hydrogen phosphate, 1-(2,4-dichlorophenyl)ethyl-β-D-glucuronic acid, 2,4-dichloromandelic acid, and 2,4-dichlorophenylethanediol glucuronide
Chlorpyrifos-methyl/-ethyl	Chlorpyrifos oxon and 3,5,6-trichloro-2-pyridinol
Coumaphos	3-Chloro-4-methyl-7-hydroxypyrimidine
Diazinon	Diazoxon and 2-isopropyl-4-methyl-6-hydroxypyrimidine
Fenitrothion	3-Methyl-4-nitrophenol
Isazofos, methyl/ethyl	5-Chloro-1,2-dihydro-1-isopropyl-[3H]-1,2,4-triazol-3-one
Malathion	Malaoxon, 2-[(dimethoxyphosphorothioyl) sulfanyl] succinic acid, malathion monocarboxylic acid, and malathion dicarboxylic acid
Methamidophos/acephate	O,S-Dimethyl hydrogen phosphorothioate
Parathion-methyl/-ethyl	Paraoxon, 4-nitrophenol, also known as p-nitrophenol
Pirimiphos-methyl	2-Diethylamino-6-methylpyrimidin-4-ol

likely that most often metabolites will be detected and not the parent compounds. Some commonly used OPs and their major metabolites that are used as biomarkers of OP exposure are listed in Table 26.1.

Currently, a total of six dialkyl phosphate (DAP) metabolites are commonly identified as biomarkers of OP pesticide exposure and quantified in urine using gas chromatography—mass spectrometry (GC-MS) as biomarkers of OP pesticides exposure. Among these, there are three dimethyl phosphate metabolites (dimethylphosphate, dimethylthiophosphate, and dimethyldithiophosphate) and three diethyl phosphate metabolites (diethylphosphate, diethylthiophosphate, and diethyldithiophosphate). Maravgakis et al. (2012) demonstrated accumulation of diethylphosphates in rabbit hair as a biomarker of chronic exposure to diazinon and chlorpyrifos (CPF). Dimethyl phosphates are derived from pesticides such as dichlorvos, monocrotophos, and dicrotophos, and diethylphosphates are derived from pesticides such as chlorfenvinphos and paraoxon (Huen et al., 2012). These are the most

commonly assayed metabolites for the exposure, bio-monitoring, and risk assessment of OP pesticides (Duggan et al., 2003; Oulhote and Bouchard, 2013; Harley et al., 2016). Dulaurent et al. (2006) reported a liquid chromatography—mass spectrometry (LC-MS) method for simultaneous determination of six DAPs in urine. DAP concentrations provide nonspecific information about exposure to a class of OPs, rather than a specific OP compound. Currently, among OPs, the most common metabolite measured is 3,5,6-trichloropyridinol, a major metabolite of CPF (Smith et al., 2012; Morgan and Jones, 2013). Specific metabolites of malathion, such as malaoxon, malathion dicarboxylic acid, and α and β isomers of malathion monocarboxylic acid, are also measured. Martinez and Ballesteros (2012) determined chlorfenvinphos and its metabolites (2-chloro-1-(2,4-dichloro-phenyl)vinyl ethyl hydrogen phosphate; 1-(2,4-dichlorophenyl)ethyl-β-D-glucuronic acid; 2,4-dichloromandelic acid; and 2,4-dichlorophenylethanediol glucuronide) in various tissues and fluids using Gas Chromatograph-Flame Ionization Detector (GC-FID) and GC-MS. Other commonly determined metabolites of OPs include 2-isopropyl-4-methyl-6-hydroxypyrimidine, a metabolite of diazinon; 4-nitrophenol, a metabolite of parathion, methyl parathion, or o-ethyl o-4-nitrophenyl phenyl-phosphonothioate (EPN) (Barr and Buckley, 2011); and 3-methyl-4-nitrophenol, a metabolite of fenitrothion (Okamura et al., 2012). In a recent report, Appenzeller et al. (2017) suggested the use of hair analysis for residue determination of two commonly used OPs (diazinon and CPF) and metabolites (diethylphosphate, DEP; diethylthiophosphate, DETP; and trichloropyridinol, TCPy).

Residues of several CMs are measured in serum, plasma, or whole blood as biomarkers of exposure to CMs. Recently, Appenzeller et al. (2017) also used hair for the analysis of CMs. In general, CMs are unstable in blood, so their metabolites are often assayed. Metabolite(s) of carbaryl (1-naphthol), propoxur (2-isopropoxyphenol), and carbofuran (3-ketocarbofuran, 3-hydroxycarbofuran, and carbofuranphenol), methiocarb (methylthio-3,5-xylenol and methiocarb sulfoxide), and carbosulfan (carbofuran and 3-hydroxycarbofuran) are determined in serum or plasma for biomonitoring of CM insecticides (Gupta et al., 1994a,b; Tange et al., 2016; Zhang et al., 2018). Some commonly used CMs and their metabolites, which are used as biomarkers, are listed in Table 26.2.

Some CM insecticides commonly measured in urine include aldicarb, carbofuran, carbosulfan, and pirimicarb. Carbaryl exposure is usually estimated based on urinary measurements of 1-naphthol. However, 1-naphthol and 2-naphthol are also metabolites of naphthalene. Because the measurement of 1-naphthol does

TABLE 26.2 List of Common Carbamate Insecticides and Their Metabolites

Parent Compound	Specific Metabolite(s)
Aldicarb	Aldicarb oxime, aldicarb sulfone, aldicarb sulfoxide, and aldicarb nitrile
Carbaryl	1-Naphthol and 4-hydroxycarbaryl glucuronide
Carbofuran	3-Hydroxycarbofuran, 3-ketocarbofuran, carbofuranphenol, 3-hydroxycarbofuranphenol, and carbofuran protein adducts
Carbosulfan	Carbofuran and 3-hydroxycarbofuran
Methiocarb	Methylthio-3,5-xylenol and methiocarb sulfoxide
Methomyl	Methomyl oxime
Propoxur	2-Isopropoxyphenol

not distinguish these two pesticides, measurement of 4-hydroxycarbaryl glucuronide helps to circumvent this problem.

In some studies, OP and CM insecticides and their metabolites have also been measured in saliva. The data can be used as biomarkers of exposure and for pharmacokinetics and pharmacodynamics (Timchalk, 2006, 2010; Timchalk et al., 2007; Smith et al., 2012). In two acute carbofuran poisoning cases, residues of carbofuran and its major metabolite 3-hydroxycarbofuran were detected in human hair (Dulaurent et al., 2011). Recently, in a rat model, Appenzeller et al. (2017) used hair analysis for residue determination of 2-isoprpoxyphenol (2-IPP) and carbofuranphenol. Novel biomarkers of exposure to OP insecticides, nerve agents, and CM insecticides form their adducts with serine of butyrylcholinesterase and tyrosine of albumin, transferrin, tubulin, keratin, and other proteins (Grigoryan et al., 2009; Li et al., 2009, 2010; Stefanidou et al., 2009; Read et al., 2010; Schopfer et al., 2010; Tacal and Lockridge, 2010; Rehman et al., 2016). These measurements can be directly related to the dose of an insecticide and are a function of insecticide exposure.

Blood AChE inhibition is still considered one of the most sensitive and reliable biomarkers of exposure to OP and CM insecticides. Scientific and regulatory communities have identified and recognized red blood cell (RBC) AChE inhibition as a sensitive biomarker of exposure to OPs and CMs because it serves as a sensitive surrogate endpoint for the inhibition of brain AChE. In California, regulators specify monitoring blood ChE when using pesticides with toxicities <50 mg/kg (Class I pesticides) and ≥50 and ≤500 mg/kg (Class II pesticides). Examples are aldicarb, azinphos-methyl (Class I pesticides), and malathion (Class II pesticide). In a

recent experimental study, Reiss et al. (2012) stated that brain AChE inhibition is the most appropriate matrix for risk assessment of OP pesticides, such as CPF. Muttray et al. (2005) found that EEG is possibly more sensitive than ChE inhibition in farmers exposed to low doses of methyl parathion.

In recent years, egasyn-β-glucuronidase has also gained attention for being a sensitive biomarker of an acute OP exposure (Ueyama et al., 2010). In another study, liver prenylated methylated protein methyl esterase has been found as a sensitive enzyme in liver and brain to the exposure and effect of OPs. Perturbations in prenylated protein metabolism are involved in OP-induced noncholinergic toxicity, as prenylated proteins play a role in cell signaling, proliferation, differentiation, and apoptosis (Lamango, 2005). Yardan et al. (2013) suggested S100B protein as a potential biomarker in the assessment of clinical severity and prediction of mortality in acute OP poisoning. Alterations in these enzymes and proteins can be used as biomarkers of OP exposure or effects, but none of these can reveal the identity of a particular OP insecticide. Additionally, multiple noncholinergic mechanisms are involved in OP- and CM-induced developmental neurotoxicity that occurs at levels of OPs far below those that cause AChE inhibition (Slotkin, 2006; Bouchard et al., 2011; Slotkin and Seidler, 2012). Using an NMR-based metabonomic approach, Liang et al. (2012) reported alterations of urinary profiles of endogenous metabolites in rats subacutely exposed to propoxur. Interestingly, in many of the investigations cited here, noncholinergic alterations occurred at doses below those that induce AChE inhibition. These noncholinergic endpoints can also be used as biomarkers of OP- or CM-induced effects.

Intermediate Syndrome

Humans exposed to large doses of an OP (methamidophos, fenthion, dimethoate, monocrotophos, etc.) or a CM (carbofuran) insecticide can suffer from intermediate syndrome (IMS) after the acute cholinergic crisis. IMS usually occurs 24–96 h after exposure to the insecticide due to insufficient or lack of oxime therapy and severe and prolonged AChE inhibition. IMS is clearly a separate entity from acute toxicity and delayed neuropathy, and it is characterized by acute respiratory paresis and muscular weakness, primarily in the facial, neck, and proximal limb muscles. IMS is also accompanied by generalized weakness, cranial nerve palsies, depressed deep tendon reflexes, ptosis, and diplopia. These symptoms may last for several days or weeks, depending on the insecticide involved. It needs to be pointed out that despite severe AChE inhibition, muscle fasciculations and mAChRs-associated hypersecretory activities are absent. Multiple mechanisms appear to

be involved in IMS, such as AChE inhibition, oxidative stress, nAChR mRNA expression, and changes in repetitive nerve stimulation (RNS). In addition, electrophysiological abnormalities occur at the neuromuscular junctions in patients with IMS. All these parameters can be used as biomarkers of IMS induced by OPs or CMs (De Bleecker, 2006).

Delayed Toxicity

Exposure to some OPs can cause another type of toxicity known as OP-induced delayed polyneuropathy (OPIDP). Symptoms of OPIDP appear after symptoms of acute cholinergic crisis and IMS subside, i.e., 2–3 weeks after a single-dose exposure. Symptoms of this syndrome include tingling of the hands and feet, followed by sensory loss, progressive muscle weakness, and flaccidity of the distal skeletal muscle of the lower and upper extremities, and ataxia. Pathogenesis of OPIDP involves phosphorylation (inhibition) of neuropathy target esterase (NTE) enzyme and its "aging" in peripheral nerves (Gupta and Milatovic, 2012). NTE is a large polypeptide of 1327 amino acids, a membrane-bound esterase with a molecular weight of 155 kDa. Its physiological role has not yet been established. Large epidemics of OPIDP occurred in the United States, Morocco, Fiji, and India from ingestion of triorthocresyl phosphate affecting tens of thousands of people. OPIDP has also been caused by certain OP pesticides, such as leptophos, dichlorvos, fenthion, trichloronat, trichlorfon, methamidophos, and CPF (Lotti and Moretto, 2005; Jokanović et al., 2011). Although the severity of OPIDP does not appear to correlate with the degree of aged NTE, NTE inhibition and its aging are still considered as the best understood mechanisms and biomarkers (Mangas et al., 2012; Heutelbeck et al., 2016).

Chronic Toxicity

Following chronic exposure to low levels of OPs, pesticide application workers, greenhouse workers, agricultural workers, and farm residents reveal a relatively consistent pattern of neurobehavioral deficits (Rohlman et al., 2011; Lein et al., 2012). Patients can suffer from chronic OP–induced neuropsychiatric disorder with symptoms of anxiety, depression, difficulty in concentrating, memory impairment, and others (Jamal et al., 2002; Pancetti et al., 2007; Ross et al., 2010; Chen, 2012; Payan-Renteria et al., 2012). Pancetti et al. (2007) described the role of an enzyme, acylpeptide hydrolase, in cognitive processes, which are usually compromised following chronic OP exposure. Mixers, loaders, applicators, and flaggers, but not field workers themselves, are tested for blood ChE activity, if they work with pesticides for 7 days or more within a 30-day period (Wilson et al., 2005). Some studies demonstrated a link between neurobehavioral performance and current

biomarkers of OP exposure including blood ChE activity and urinary metabolites of OPs. Arguably, other studies suggested that these biomarkers are neither predictive nor diagnostic of the neurobehavioral effects of chronic pesticide exposure, and biomarkers of neuroinflammation and oxidative stress need to be included, in addition to blood ChE and urinary metabolites (Banks and Lein, 2012). Pancetti et al. (2007) described acylpeptide hydrolase as a more sensitive enzyme than AChE and therefore proposed it as a biomarker of OP exposure and associated cognitive deficits.

In addition, dystonic reactions, schizophrenia, cogwheel rigidity, choreoathetosis, and EEG changes have been reported with high-dose exposure. These extrapyramidal symptoms are thought to be due to the inhibition of the AChE in the human extrapyramidal area. Psychosis, delirium, aggression, hallucination, and depression may also be seen during recovery from the cholinergic syndrome. Schizophrenic and depressive reactions with severe memory impairment and difficulties in concentration are observed in workers exposed to these pesticides, and RBC AChE is used as a biomarker of these effects.

In an experimental study, Middlemore-Risher et al. (2010) observed that repeated exposures to low-level CPF caused impairments in sustained attention and increased impulsivity in rats. Speed et al. (2012) examined hippocampal synaptic transmission and pyramidal neuron synaptic spine density in mice treated with a non—signs-producing dose of CPF (5 mg/kg/day for 5 consecutive days) early (2—7 days) and late (3 months) after the last injection. Increased synaptic transmission was found in the CA3—CA1 region of the hippocampus of CPF-treated mice 2—7 days after the last injection. In contrast, 3 months after CPF treatment, a 50% reduction in synaptic transmission occurred due to a 50% decrease in CA1 pyramidal neuron synaptic spine density. Findings suggested that progressive synaptic abnormalities occurred leading to persistent brain damage, despite the absence of cholinergic toxicity. Rats acutely intoxicated with a signs-producing dose of carbofuran (1.5 mg/kg, sc) or DFP (1.5 mg/kg, sc) showed marked decreases in dendritic length and spine density in the CA1 region of hippocampal pyramidal neurons because of oxidative/nitrosative stress and depletion of high-energy phosphates (Gupta et al., 2007; Zaja-Milatovic et al., 2009). Both AChE inhibitors also caused significant increases in PGE2, a marker of neuroinflammation. Of course, cytokines and C-reactive protein can also be used as biomarkers of inflammation (Lein et al., 2012).

OPs and CMs produce a variety of reproductive and developmental toxicity in humans and animals. Following in utero exposure to OP/CM insecticides, brain damage can occur in children in an absence of cholinergic toxicity. Biomarkers for reproductive and developmental effects of these insecticides are described in detail by Gupta et al. (2017).

In an electrophysiological study, Nio and Breton (1994) investigated the effects of paraoxon and physostigmine on rabbit pyramidal cells firing pattern and hippocampal theta rhythm. The results revealed that paraoxon and physostigmine have a rather similar influence on the septohippocampal pathway and also suggested that paraoxon could act within local hippocampal circuitry through other systems than the cholinergic system exclusively. In similar studies, Desi and Nagymajtenyi (1999), Papp et al. (2004), and Narahashi (2006) investigated electrophysiological effects of various OPs and CMs, suggesting the involvement of noncholinergic mechanisms. In a preliminary study, De Luca et al. (2006) showed the electromyographic signal as a presymptomatic indicator of OPs in the body, using diisopropyl fluorophosphate (DFP) as a test substance. These parameters can be used as biomarkers of morphological and electrophysiological changes in central nervous system (CNS) and peripheral nervous system (PNS) and early indicators of behavioral alterations.

A human genetic polymorphism of paraoxonase-1 (PON-1) in detoxification of several OP insecticides, including the active metabolite of CPF, CPF oxon, is well established, resulting in the expression of PON-1 activity within a segment of the population. PON-1 and cytochrome P450 can be used as biomarkers of genetic polymorphism in regard to OP toxicity (Costa et al., 2006; Furlong et al., 2006; Huen et al., 2012; Lein et al., 2012). Huen et al. (2012) found that, compared with their mothers, newborns have much lower quantities of the detoxifying PON-1 enzyme, suggesting that infants may be especially vulnerable to OP pesticide exposure.

CHLORINATED HYDROCARBONS

Chlorinated hydrocarbon or organochlorine insecticides are classified into three groups: (1) dichlorodiphenylethanes (dichlorodiphenyltrichloroethane [DDT], dicofol, methoxychlor, and perthane); (2) hexachlorocyclohexanes (benzene hexachloride, chlordane, lindane, mirex, and toxaphene); and (3) chlorinated cyclodienes (aldrin, dieldrin, endrin, endosulfan, and heptachlor). The first use of the chlorinated hydrocarbons or organochlorines was for dielectrics and as fire retardants. The first use of these compounds as insecticides occurred when benzene was added to liquid chlorine in the field and it was noted that the product killed insects. Cyclodienes, such as aldrin and dieldrin, used as insecticides, became available for use in the 1940s.

DDT became available during World War II and was used extensively as an insecticide worldwide. Because of their persistence in the environment and in biological systems, most insecticides of this group have been eliminated from use today. Endosulfan and lindane are the most biodegradable organochlorines and are still used today.

Mechanism of Toxicity

There are at least two different mechanisms of action for organochlorine insecticides (Narahashi, 1987; Ensley, 2018a). DDT type insecticides affect the peripheral nerves and brain by slowing down Na^+ influx and inhibiting K^+ efflux, resulting in excess intracellular K^+ in the neuron, which partially depolarizes the cell. The threshold for another action potential is decreased leading to premature depolarization of the neuron. The aryl hydrocarbons and cyclodienes, in addition to decreasing action potentials, may inhibit the postsynaptic binding of GABA (Bloomquist and Soderlund, 1985). The cyclodiene-induced hyperactivity of the CNS and convulsions can be explained based on their structural resemblance to the GABA receptor antagonist picrotoxin. The cyclodienes act by competitive inhibition of the binding of GABA, an inhibitory neurotransmitter at its receptor, causing stimulation of the neurons. Both $GABA_A$ and $GABA_B$ receptors play a vital role in mammalian toxicity. $GABA_A$ receptors present in the mammalian synapse are ligand-gated chloride ion channels. In the human brain, the $GABA_A$ receptor consists of four or five hydrophobic domains, namely M_1, M_2, M_3, M_4, and M_5. The five M_2 domains are arranged to form a 5.6 Å diameter ion channel. $GABA_B$ receptors present in mammals are coupled to calcium and potassium channels and the action of this neurotransmitter is mediated by G proteins. Following its release in the synapse, GABA diffuses to the presynaptic terminal of another nerve, where GABA binds to its $GABA_A$ receptors. The binding of GABA to its receptor causes chloride ions to enter the synapse, leading to hyperpolarization of the terminal, which inhibits the release of other neurotransmitters. Due to such inhibition, postsynaptic stimulation of other nerves by other neurotransmitters, such as ACh, is reduced. As a consequence of inhibition of GABA, there is no synaptic downregulation and there can be excessive release of other neurotransmitters. CNS symptoms in animals poisoned by chlorinated cyclodienes include tremors, convulsions, ataxia, and changes in EEG patterns. The CNS symptoms could be due either to (1) inhibition of the Na^+/K^+-ATPase or the Ca^{2+}/Mg^{2+}-ATPase activity, which can then interfere with nerve action or release of neurotransmitters, or (2) inhibition of the GABA receptor function.

Mladenovic et al. (2010) reported that lipid peroxidation may contribute to the neurotoxic effects of lindane in early acute intoxication and that behavioral manifestations correlate with lipid peroxidation in the rat brain hippocampus, which is one of the sites for initiation and propagation of seizures.

The nervous system of the developing organism appears to be more vulnerable to the toxicity of organochlorine insecticides, and multiple mechanisms are involved. DDT and related compounds produce a direct effect on the motor fibers and on the motor area of the cerebral cortex or they act as endocrine disruptors in the hypothalamic—hypophysis—thyroid axis. Neonatal exposure to DDT causes a significant reduction in the density of muscarinic receptors in the cerebral cortex of mice. These cholinergic receptors have a direct involvement in the process of neuronal excitement and inhibition. Following chronic exposure, DDT causes disruption of the thyroid system. DDT or its metabolites alter the production of thyroidal hormone and its availability to target tissues, given that the insecticide blocks glucuronidation. Thyroid hormone is known to play a pivotal role in the development of the cerebral cortex. This hormone serves as a signal for neuronal differentiation and maturation and participates in neuronal migration and proliferation, synaptogenesis, and myelinization.

Developmental exposure to dieldrin has been shown to alter the dopamine system and increase neurotoxicity in an animal model of Parkinson's disease. The dopamine transporter (DAT) and the vesicular monoamine transporter 2 (VMAT2) play an integral role in maintaining dopamine homeostasis, and the alteration of their levels during development could result in increased vulnerability of dopamine neurons later in life. Prenatal exposure of mice during gestation and lactation to low levels of dieldrin (0.3, 1, or 3 mg/kg every 3 days) caused a dose-dependent increase in protein and mRNA levels of DAT and VMAT2 in their offspring at 12 weeks of age (Richardson et al., 2006). In a recent investigation, Kamel et al. (2012) suggested that amyotrophic lateral sclerosis risk may be associated with use of organochlorine pesticides.

Biomarkers

Residues of organochlorine insecticides and their metabolites can be detected at ppb levels in human and animal tissues and fluids (blood, urine, and milk). Recently, Appenzeller et al. (2017) also suggested hair analysis for determination of organochlorines (γ-hexachlorocyclohexane (HCH), β-HCH, β-endosulfan, p,p′-DDT, p,p′-DDE, p,p′-DDD, dieldrin, and pentachlorophenol). GC and GC-MS are most commonly

used to confirm and quantitate the residues of organochlorines and their metabolites. Biomonitoring studies have revealed that these insecticides are widely distributed throughout the body and deposit in fat and fatty tissue. Residues have been found in various human reproductive tissues, including amniotic fluid, blood stream, maternal blood, umbilical cord blood, breast milk, colostrum, placenta, semen, and urine (Malik et al., 2017). Studies suggest that the organochlorine endosulfan causes AChE inhibition, neurotoxicity, and brain function impairment in rats, rabbits, and zebrafish (Mor and Ozmen, 2010; Silva de Assis et al., 2011; Pereira et al., 2012).

In general, residues of organochlorine insecticides and/or their metabolites in blood/serum/plasma, fat, and urine are used as biomarkers of exposure. In the case of endosulfan, AChE inhibition can also be used as a biomarker of toxicity.

PYRETHRINS AND PYRETHROIDS

Pyrethrins and pyrethroids (synthetic pyrethrins) have a wide variety of applications in agriculture, public and animal health, and residential settings throughout the world. Pyrethroid insecticides are also used to disinfect commercial aircraft and military uniforms (Wei et al., 2012; Proctor et al., 2014). Pyrethrins were first developed as insecticides from extracts of the flower heads of *Chrysanthemum cinerariaefolium*. There are six naturally occurring pyrethrins (pyrethrins I and II, cinerins I and II, and jasmolins I and II). Because of their rapid decomposition by light and air, synthetic derivatives were developed and are commonly referred to as pyrethroids (Anadon et al., 2009). The first-generation pyrethroids were developed in the 1960s, including bioallethrin, tetramethrin, resmethrin, and bioresmethrin. By 1974, a second generation of more persistent compounds was developed, including permethrin, cypermethrin, and deltamethrin. These insecticides have significantly greater mammalian toxicity compared with first-generation pyrethroids. Later, some other pyrethroids, such as fenvalerate, lambda-cyhalothrin, and β-cyfluthrin, were discovered. Because of their high insecticidal potency, broad-spectrum activity, relatively low mammalian toxicity, lack of environmental persistence, and less insect resistance, pyrethroids have gained much success in the recent past and now account for more than 25% of the global insecticide market.

Using a recent nomenclature, pyrethroids are of two types and produce two syndromes through multiple mechanisms of action. Type I pyrethroids are those that lack α-cyano-3-phenoxybenzyl moiety and give rise to the tremor syndrome (T syndrome). A few examples of type I are pyrethrin I, allethrin, bioallethrin, tetramethrin, resmethrin, cismethrin, phenothrin, and permethrin. These insecticides cause severe fine tremors, marked reflex hyperexcitability, sympathetic activation, and paresthesia (with dermal exposure). Type II pyrethroids are those that contain α-cyano-3-phenoxybenzyl moiety and cause the choreoathetosis/salivation (CS) syndrome. A few examples of type II pyrethroids include cyphenothrin, cypermethrin, deltamethrin, fenvalerate, cyfluthrin, cyhalothrin, flucynthrate, and esfenvalerate. These insecticides produce profuse watery salivation, coarse tremors, increased extensor tone, moderate reflex hyperexcitability, sympathetic activation, choreoathetosis, seizures, and paresthesia (dermal exposure).

The clinical signs of type I and type II pyrethroids appear to be largely independent of the route of administration. *Trans-* and *cis*-isomers of fluorocyphenothrin confusingly produce type I and type II effects, respectively. Some pyrethroids, such as fenpropathrin, have been classified as hybrids and appear to show a mixture of type I and II effects (T and CS). All pyrethroids cause a reduction in motor activity. Reduced locomotor activity in the rat after oral gavage dosing has been used to quantify pyrethroid neurotoxicity. Unfortunately, the effect is nonspecific and does not readily allow conclusions to be made about mechanism of action (Gammon et al., 2012). Overall, type I pyrethroids with a *trans*-substituted acid moiety have a much lower mammalian toxicity than the corresponding *cis* isomers. This is partly due to the more rapid ester hydrolysis of *trans* rather than *cis* isomers. For type II pyrethroids, there is much less difference in toxicity between *trans* and *cis* isomers, suggesting a similar target site for type II pyrethroids.

Both pyrethroid classes have a similar range of mammalian toxicity, but for commercial pesticides, type II pyrethroids such as deltamethrin and cypermethrin are generally more toxic than type I pyrethroids such as permethrin (Ray and Forshaw, 2000). A survey of the general US population has revealed that exposure to pyrethroid insecticides is widespread and that children may have higher exposures than adolescents and adults (Barr et al., 2010). In general, young animals and children are more susceptible than adults to pyrethroid toxicity, and the focus of ongoing research is to explore to which degree children are more susceptible than adults. Flight attendants of commercial aircrafts disinfected with pyrethroids have complained of irritation of the skin and mucosa, sore throat, vomiting, abdominal pain, headache, dizziness, and nausea (Murawski, 2005; Sutton et al., 2007; Wei et al., 2012). It is important to mention that pyrethrins and pyrethroids also exert reproductive and developmental toxicity in animals and humans (Malik et al., 2017; Martin-Reina et al., 2017; Saito et al., 2017).

Mechanism of Toxicity

The primary effects of pyrethroids in mammalian species include neurotoxicity and neurobehavioral toxicity, which result primarily from hyperexcitation of the nervous system. Type I syndrome involves action in the CNS and PNS, whereas type II syndrome (CS) involves primarily the CNS. Hyperexcitation of the nervous system is caused by repetitive firing and depolarization of the nervous system. The primary site of action of pyrethroids is the sodium channels of cells, but they also affect chloride and calcium channels. These insecticides slow down the opening and closing of the sodium channels, ultimately leading to the excitation of the cell. An increase of sodium in the sodium channels results in a cell which is in a stable and hyperexcitable state. The duration of the sodium action potential is much shorter for type I pyrethroids than for type II. While type I pyrethroids result in primarily repetitive charges, cell membrane depolarization is the main mechanism of toxic action exerted by type II pyrethroids. The effect of type I pyrethroids on sodium channels in nerve membranes is similar to those produced by DDT-type insecticides. The direct action of pyrethroids on sensory nerve endings leads to paresthesia, as they cause repetitive firing (Ensley, 2018b).

If not all, most of the neurotoxic effects of pyrethroids are due to their interaction at voltage-gated sodium channels. The degree of hyperexcitability is dose-related, but the nature of this excitability is pyrethroid structure—dependent. Insect sodium channels are hundred times more sensitive than rat brain sodium channels. The lower sensitivity of mammalian sodium channel isoforms compared with insect channels to pyrethroids offers a mechanistic explanation for its species selective toxicity. Of course, it has become clear that besides insensitive mammalian sodium channels (e.g., Na_v 1.2 and Na_v 1.7), more sensitive isoforms also exist (e.g., Na_v 1.3, Na_v 1.6, or Na_v 1.8). McCavera and Soderlund (2012) provided direct evidence for the preferential binding of deltamethrin and tefluthrin (but not S-bioallethrin) to Na_v 1.6Q3 channels in the open state and implied that the pyrethroid receptor of resting and open channels occupies different conformations that exhibit distinct structure—activity relationships. Interestingly, the Na_v 1.6 isoform is not only a target for developmental neurotoxic effects but also a likely target for the central neurotoxic effects of pyrethroids in adult animals.

Voltage-gated chloride and calcium channels have been implicated as additional sites of action (Soderlund, 2012). Voltage-sensitive chloride channels are found in nerves, muscles, and salivary glands and are modulated by protein kinase C. The function of chloride channels is to control cell excitability. The decrease in the chloride-open channel state produced by type II pyrethroids serves to increase excitability and therefore to synergize pyrethroid actions on the sodium channel. While calcium channels may contribute in some way to the action of at least some pyrethroids, there is no basis at present to identify effects on calcium channels as an essential mechanism of pyrethroid intoxication (Shafer and Meyer, 2004). Gammon et al. (2012) suggested that different clinical signs associated with type I and type II syndromes result from effects on different channel isoforms or a combination of them. Interestingly, Ali (2012) demonstrated involvement of oxidative stress in pathogenesis of neurotoxicity by type II pyrethroid lambda-cyhalothrin in rats. For further details on molecular mechanisms in neurotoxicity and neurobehavioral toxicity of pyrethrins and pyrethroids, readers are referred to Wolansky and Harrill (2007), Soderlund (2012), and Van Thriel et al. (2012).

Recently, Lei et al. (2017) investigated the inhibitory effects of six commonly used pyrethroids (fenpropathrin, cyhalothrin, deltamethrin, fenvalerate, *tau*-fluvalinate, and permethrin) on two major human carboxylesterases (CES1 and CES2). Deltamethrin was found to be a strong inhibitor of CES1. Although its toxicological significance is yet to be determined, it could be used as a surrogate marker of deltamethrin exposure.

Biomarkers

Pyrethrins and pyrethroids are structurally diverse, and understanding their chemistry and toxicology plays a vital role in the development of biomarkers. Significant advancements in analytical chemistry and toxicology have led to the development of biomarkers to assess biomonitoring in the environment and exposure in the general population (Sudakin, 2006; Barr et al., 2010; Gammon et al., 2012; Furlong et al., 2017; Yoshida, 2017). Future challenges in the application of these biomarkers in epidemiological studies are being explored, as there is a need for improved understanding of the toxicokinetics and pharmacodynamics of pyrethroids in mammalian species, including humans.

Pyrethroids are of low to moderate toxicity because of their moderate absorption (40%—60%) and rapid metabolism following oral administration (Anand et al., 2006; Barr et al., 2010; Gammon et al., 2012; Furlong et al., 2017; Saito et al., 2017). Oxidases and esterases, primarily in the liver, metabolize pyrethroids at varying rates. The most rapidly metabolized pyrethroids have the lowest toxicity. Based on experimental data, Gammon et al. (2012) described that brain or blood plasma concentrations of parent pyrethroids correlate with acute toxicity and that metabolites (especially hydrolytic products) generally have little or no effect on neurotoxicity. In the context of biomarkers, most studies

have investigated urine as the analytical matrix (Barr et al., 2010; Weilgomas, 2013; Weilgomas et al., 2013; Furlong et al., 2017; Oulhote and Bouchard, 2013; Yoshida, 2017). Leng et al. (1996) and Leng and Gries (2005) detected metabolites of some pyrethrins and pyrethroids (permethrin, cypermethrin, cyfluthrin, and deltamethrin), using GC-MS, in the urine of pesticide applicators. Using the same methodology, Wei et al. (2012) assayed metabolites of these pyrethroids in the urine of commercial flight attendants. Elflein et al. (2003) also used GC-MS to detect metabolites of some other commonly used pyrethroids, including allethrin, resmethrin, phenothrin, and tetramethrin in human urine. Recently, Yoshida (2017) developed an analytical method to detect 11 pyrethroid metabolites in urine using GC-MS. High-performance liquid chromatography (HPLC)— and LC-MS—based methods have also been employed to determine the residues of pyrethroids and their metabolites in body tissues and fluids (Baker et al., 2004; Anand et al., 2006; Kim et al., 2006; Barr et al., 2010). Ishibashi et al. (2012) developed a high-throughput assay for cypermethrin and tralomethrin using supercritical fluid chromatography—tandem mass spectrometry.

Metabolites of some of the commonly used pyrethrins/pyrethroids determined in urine as biomarkers are summarized in Table 26.3.

Barr et al. (2010) reported that 3-phenoxybenzoic acid (3-PBA), a metabolite common with many pyrethroid insecticides, was detected in >70% of urine samples tested in the United States. Non-Hispanic blacks had significantly higher 3-PBA concentrations than non-Hispanic whites and Mexican Americans, and children had significantly higher concentrations of 3-PBA than adolescents and adults. *Cis-* and *trans*-(2,2-dichlorovinyl)-2,2-dimethylcyclopropane-1-carboxylic acid (*cis-* and *trans*-Cl2CA) were highly correlated with each other and with 3-PBA, suggesting that 3-PBA was primarily derived from exposure to permethrin, cypermethrin, or their degradates. Wei et al. (2012) found that the flight attendants working on pyrethroid-disinsected commercial aircraft had significantly higher concentrations of 3-PBA and *cis-* and *trans*-Cl2CA in the postflight urine samples than those working on nondisinsected aircrafts and the general US population. Increase of pyrethroid metabolites in the preflight urine samples suggested an elevated body burden from a long-term exposure for those flight attendants routinely working on pyrethroid-treated aircraft. Interestingly, flight attendants working on international flights connected to Australia had higher urinary levels of 3-PBA and *cis-* and *trans*-Cl2CA than those on either domestic or other international flights flying between Asia, Europe, and North America. At veterinary diagnostic labs, residues of pyrethrins/pyrethroids have also been detected in

TABLE 26.3 Metabolites of Pyrethroids in Urine Used as Biomarkers for an Exposure to Pyrethroid Insecticides

Parent Compound	Specific Metabolite(s)
Allethrin	*Trans*-chrysanthemumdicarboxylic acid
Cyfluthrin	4-Fluoro-3-phenoxybenzoic acid, 3-phenoxybenzoic acid (3-PBA), *cis-* and *trans*-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropane carboxylic acid
Lambda-cyhalothrin	*Cis*-3-(2-chloro-3,3,3-trifluoroprop-1-en-1-yl)-2,2-dimethylcyclopropane carboxylic acid and 3-PBA
Cypermethrin	*Trans*-chrysanthemumdicarboxylic acid, *cis-* and *trans*-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropane carboxylic acid; 3-PBA
Deltamethrin	*Cis-* and *trans*-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropane carboxylic acid; *cis*-3-(2,2-dibromovinyl)-2,2-dimethylcyclopropane carboxylic acid; 3-PBA
Permethrin	*Cis-* and *trans*-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropane carboxylic acid; 3-PBA
Phenothrin	*Trans*-chrysanthemumdicarboxylic acid
Pyrethrum	*Trans*-chrysanthemumdicarboxylic acid
Resmethrin	*Trans*-chrysanthemumdicarboxylic acid
Tetramethrin	*Trans*-chrysanthemumdicarboxylic acid

(Ed.), Reproductive and Developmental Toxicology. second ed. Academic Press/Elsevier, Amsterdam, pp. 633—655; Khemiri, R., Côte J., Fetoui, H., et al., 2017. Documenting the kinetic time course of lambda-cyhalothrin metabolites in orally exposed volunteers for the interpretation of biomonitoring data. Toxicol Lett. 276, 115—121, and others.

the brains of cats that died from overexposure to these insecticides.

Hughes et al. (2016) realized that humans are often exposed to multiple pyrethroids. Accordingly, they determined residue of several pyrethroids in blood and brain of rats and suggested that summed pyrethroid rat blood concentration could be used as a surrogate for brain concentration as an aid to study the neurotoxic effect of pyrethroids in a mixture. Tornero-Velez et al. (2012) proposed a pharmacokinetic model for *cis-* and *trans*-permethrin disposition in rats and humans with aggregate exposure application. In this investigation, the description of pharmacokinetics in humans was based on the properties of permethrin, Physiologically-Based Pharmacokinetic Modeling (PBPK) models of deltamethrin in rats, and permethrin in vitro clearance data. The model was adapted with a biomarker submodel to evaluate exposure estimation in probabilistic risk assessment applications. Starr et al. (2012) investigated cumulative risk assessment of pyrethroid pesticides (permethrin, cypermethrin, β-cyfluthrin, deltamethrin, and esfenvalerate) taking into account

pharmacokinetics, pharmacodynamics, and neurobehavioral assays. Findings supported the additive model of pyrethroid effect on motor activity and suggested that variation in the neurotoxicity of individual pyrethroids is related to toxicodynamic rather than toxicokinetic differences.

In addition to residue detection of pyrethrins and pyrethroids and their metabolites, hematological, biochemical, and histopathological alterations have been reported in target and nontarget tissues, and these changes can be used as biomarkers of pyrethrin/pyrethroid toxicity (Sayim et al., 2005; Yavasoglu et al., 2006).

AMITRAZ

Amitraz is a triazapentadiene compound of the formamidine pesticide family, which has a chemical formula of $C_{19}H_{23}N_3$ and a molecular weight of 293.41. Amitraz is a broad-spectrum insecticide and acaricide used in agriculture, horticulture, and veterinary medicine throughout the world since 1974. Amitraz is used to control ticks, mites, lice, and many other pests on dogs, sheep, cattle, and pigs. It persists on hair and wool long enough to control all stages of the parasite. Amitraz poisoning is frequently encountered in dogs and cats. With dogs, poisoning is most often associated with accidental ingestion of the flea and tick collar, resulting in severe toxicity and sometimes fatal poisoning. In humans, poisoning occurs because of oral ingestion of amitraz (Shitole et al., 2010). The major signs of acute poisoning are nausea, vomiting, coma, somnolence, miosis or mydriasis, bradycardia, hypo- or hyperthermia, polyuria, and respiratory failure. Amitraz should also not be used in diabetic animals, as it adversely affects the levels of glucose and insulin (Hsu and Schaffer, 1988).

Mechanism of Toxicity

Amitraz kills parasites by paralyzing their nervous system and sharp barbed mouth parts, thereby causing them to detach from animals. Unlike in insects, amitraz has been found to cause toxicity in animals by stimulating α_2-adrenergic receptors (α_2-AR), resulting in impairment of consciousness, respiratory depression, convulsions, bradycardia, hypotension, and hyperglycemia. Hypothermia occurs due to the inhibitory effect of amitraz on prostaglandin E2 synthesis. Amitraz acts centrally to influence blood pressure and heart rate by α_2-AR agonism, which causes a reduction in peripheral sympathetic tone (Cullen and Reynoldson, 1990). Marafon et al. (2010) observed significant declines in the heart rate and respiration rate of cats intoxicated with amitraz. Electrocardiography on an amitraz-

poisoned English bulldog revealed prolonged QT intervals (Malmasi and Ghaffari, 2010). In the peripheral vasculature, both α_1- and α_2-AR are involved in the vasopressor action of amitraz, which results in hypotension. It is suggested that the central α_2-AR agonist activity of amitraz is responsible for CNS depression (Cullen and Reynoldson, 1990). Amitraz is also a potent inhibitor of the enzyme monoamine oxidase (MAO), which is responsible for degrading neurotransmitters (norepinephrine and serotonin), resulting in neurotoxicity and behavioral toxicity (Moser, 1991).

Poisoning is most often encountered in dogs and cats and is generally acute in nature (Filazi and Yurdakok-Dikmen, 2018). Onset of clinical signs is noted within 30 min to 2 h after ingestion. Common clinical signs include gastrointestinal (GI) disturbance (i.e., prolonged gastric transit time), CNS and respiratory depression, bradycardia, hypotension, and hypothermia. Death usually occurs due to respiratory failure.

Biochemical changes include hyperglycemia, glucosuria, suppressed insulin release, and elevation of liver transaminases activities. Histopathological changes may include hepatic and renal cortical necrosis, hemorrhage, and renal failure. Clinical symptoms reported in humans were giddiness, vomiting, drowsiness, and gastric dilatation (Shitole et al., 2010). Unconscious patients' CT brain scans revealed brain edema. For a detailed mechanism of amitraz toxicity, refer to del Pino et al. (2015).

Biomarkers

Amitraz is a highly lipid-soluble compound that is rapidly absorbed following oral ingestion or dermal application, thus making exposure potentially dangerous for animals and humans. In the stomach, amitraz can be metabolized to as many as six different metabolites and some of them are potentially toxic. The two major metabolites of amitraz are 2,4-dimethylformamide and N-(2,4-dimethylphenyl)-N′-methylformamide. The former metabolite is a relatively weak methemoglobin former in dogs and humans. These metabolites are further catabolized to 2,4-dimethylaniline and ultimately to 4-amino-3-methylbenzoic acid, which is the principal metabolite found in the liver and urine. A pharmacokinetic study in dogs revealed that amitraz is significantly absorbed and has a long elimination half-life, which is responsible for most of the observed clinical signs (Hugnet et al., 1996). Marafon et al. (2010) reported similar findings in cats. In ponies and sheep, amitraz has a brief half-life after intravenous (IV) administration because it is hydrolyzed in the blood by formaminidases (Pass and Mogg, 1995).

The proposed biomarkers of amitraz exposure and its toxicosis include detection of the residue of amitraz and

its major metabolites in the plasma of poisoned animals or humans using GC with a nitrogen—phosphorus detector or thermionic specific detector (Marafon et al., 2010) or HPLC with a UV detector (Hugnet et al., 1996). Clinical signs of amitraz toxicity associated with α_2-AR agonism and biochemical and histopathological alterations can be used as biomarkers of amitraz toxicity. In a chronic study in rats, amitraz was reported to be embryotoxic and a teratogen at a maternally toxic dose of >10 mg/kg/day (Kim et al., 2007), and the no-observed-adverse-effect level (NOAEL) of amitraz for both dams and embryo fetal development was estimated to be 3 mg/kg/day. For further details on amitraz toxicity, see Filazi and Yurdakok-Dikmen (2018).

NEONICOTINOIDS

Neonicotinoids are a new class of insecticides, which includes imidacloprid, acetamiprid, thiacloprid, dinotefuran, nitenpyram, thiamethoxam, and clothianidin. These products are commonly used in agriculture and veterinary medicine. Neonicotinoids have a high target specificity to insects, a relatively low risk for nontarget mammalian species and the environment, and versatility in application methods (Ensley, 2018c). Among all neonicotinoids, imidacloprid is the most studied compound used as an insecticide for dermal application on animals, for grub control, and as an insecticide for crop protection. The neonicotinoids class accounts for about 20% of the current global insecticide market.

Mechanism of Toxicity

The neonicotinoids act on postsynaptic nicotinic acetylcholine receptors (nAChRs). In insects, these receptors are located entirely in the CNS. Mammalian tissue also contains multiple nAChRs subtypes, which are formed from different combinations of nine α, four β, and γ, δ, and ε subunits. In insects, there are binding sites in addition to nAChRs for neonicotinoids that are suggested to be used as mechanism-based biomarkers of exposure and effects (Badiou-Bénéteau et al., 2012). The selective toxicity of neonicotinoids in insects and mammals is attributed largely to the differential sensitivity of the insect and vertebrate nAChR subtypes. In insects, neonicotinoids act on at least three different subtypes of nAChRs and cause a biphasic response, i.e., an initial increase in the frequency of spontaneous discharge followed by a complete block to nerve propagation. In mammals, nAChRs are located in the brain, autonomic ganglia, skeletal muscle, and spinal cord. Neonicotinoids have a much lower activity in vertebrates as compared with insects because of the different

binding properties of the various receptor subtypes. Tomizawa and Casida (2011) suggested that the high affinity for neonicotinoids at the insect nAChR is related to a single dominant binding orientation, whereas relative insensitivity at vertebrate nAChRs is caused by multiple binding confirmations in the agonist-binding pocket. Acute toxicity of the neonicotinoids in mammals is related to the potency at the α_7 nicotinic receptor subtype with the activity at the α_4, β_2, α_3, and α_1 receptors having a decreased effect on toxicity. Toxicity in mammals involves complex interactions at multiple receptor sites with some of the receptor types even having a combination of agonist and antagonist effects on the synapse (Ensley, 2018b). Furthermore, neonicotinoids have relatively poor penetration of the blood—brain barrier (BBB) in mammals (Rose, 2012).

Following an acute exposure to imidacloprid, clinical signs and symptoms can be observed as early as 15 min, with recovery within 8—24 h. At low doses, neonicotinoids cause decreased activity and tremors, mydriasis or miosis, and incoordination; and at higher doses, they cause hypothermia, staggering gait, salivation, trembling, and spasms. At lethal doses, death is observed within 4 h. Humans, after deliberately ingesting imidacloprid, show symptoms of aspiration pneumonia, CNS effects (agitation, confusion, and coma), and respiratory failure. Cardiovascular effects include tachycardia, palpitation, and ventricular fibrillation. It needs to be emphasized that nicotinoid metabolites derived from some neonicotinoids (e.g., imidacloprid and thiacloprid) are more potent vertebrate nAChR agonists than their parent molecules and are likely to be more toxic (Rose, 2012). Additional mechanisms have been described in neonicotinoids-induced toxic effects, such as hepatotoxicity (Swenson and Casida, 2013; Arfat et al., 2014), nephrotoxicity (Arfat et al., 2014), respiratory toxicity (Pandit et al., 2016), hyperglycemia (Khalil et al., 2017), genotoxicity (Stivaktakis et al., 2016), endocrine disruption (Pandey and Mohanty, 2015), and obesity (Park et al., 2013).

Biomarkers

Pharmacokinetic studies of imidacloprid revealed its rapid and complete absorption and distribution following oral administration in rats. Peak plasma levels were achieved within 2 h and the initial and terminal half-lives in plasma were about 3 h and 26—118 h, respectively. The highest tissue residues after 48 h were found in the liver, kidney, lung, and skin. Low concentrations of imidacloprid were found in the brain due to poor penetration of the BBB, and a low concentration was found in fat due to low lipophilicity. Elimination of 90% of the dose occurred within 24 h (75%—80% in the urine and the remainder in the feces originating from

biliary excretion). Ensley (2018c) has described two pathways for imidacloprid metabolism in mammals. The first pathway involves oxidative cleavage of imidacloprid to imidazolidine and 6-chloronicotinic acid. The imidazolidine moiety is excreted in the urine. The 6-chloronicotinic acid is further degraded by glutathione conjugation to a derivative of mercapturic acid and then to methyl mercaptonicotinic acid. The mercaptonicotinic acid is then conjugated with glycine to form a hippuric acid conjugate, which is excreted. The second pathway involves hydroxylation of the imidazolidine ring, with two metabolites (5-hydroxyimidacloprid and 4-hydroxyimidacloprid) detected in the urine.

Residue detection of neonicotinoids and their metabolites in the body tissue/fluids serves as a biomarker of exposure. HPLC coupled with a UV or MS detector is commonly used to detect the residue of neonicotinoids and their metabolites. Signs and symptoms of toxicity and histopathological changes can also be used as biomarkers of neonicotinoid toxicity.

FIPRONIL

Fipronil is an insecticide of the phenylpyrazoles class and an active ingredient of one of the popular ectoparasiticide veterinary products, Frontline. Frontline is commonly used on dogs and cats to kill fleas and all stages of ticks, which may carry Lyme disease, and mites. Fipronil is also formulated as insect bait for roaches, ants, and termites; as a spray for pets; and as a granular form for turf and golf courses. The United States Environmental Protection Agency (USEPA) has determined fipronil to be safe for use on dogs and cats, with no harm to humans who handle these pets. Most of the time poisoning cases of fipronil occur in dogs and cats due to accidental ingestion of the product Frontline. In humans, poisoning is mainly due to accidental ingestions or suicide attempts. In agriculture, fipronil is widely used for soil treatment, seed coating, and crop protection.

Mechanism of Toxicity

The mechanism of action of fipronil is better understood in insects than it is in mammals. In insects, fipronil or its major metabolite (fipronil sulfone) noncompetitively binds to $GABA_A$-gated chloride channels, thereby blocking the inhibitory action of $GABA_A$ in the CNS. This leads to hyperexcitation at low doses and paralysis and death at higher doses. Fipronil exhibits a >500-fold selective toxicity to insects over mammals, primarily because of affinity differences in receptor binding between insect and mammalian receptors. In other words, fipronil binds more tightly to $GABA_A$ receptors in

insects than in mammals. Fipronil is more selective at this receptor through the β3 subunit in insects than in mammals. This selectivity is less pronounced with fipronil metabolites (sulfone and desulfinyl). It needs to be emphasized that fipronil sulfone is rapidly formed in humans and experimental animals and can persist much longer than fipronil; therefore the toxicological effects are also likely due to the sulfone metabolite. The toxicity of another metabolite, fipronil desulfinyl, is qualitatively similar to that of fipronil, but the dose—effect curve for neurotoxic effects appears to be steeper for fipronil desulfinyl. In addition, fipronil desulfinyl appears to have a much greater affinity to bind to sites in the chloride ion channel of the rat brain GABA receptor. This finding appears to be consistent with the greater toxicity of fipronil desulfinyl in the CNS of mammals. Narahashi et al. (2010) has explained the mechanism of action of fipronil in insects and mammals in detail.

In laboratory animals, fipronil administration by the oral route can produce the signs of neurotoxicity, including convulsions, tremors, abnormal gait, and hunched posture. Similar signs can be produced following inhalation exposure. Poisoned dogs and cats usually show signs of tremors, convulsions, seizures, and death (Gupta and Anadon, 2018). Following dermal exposure, fipronil toxicity is more pronounced in rabbits than in rats, mice, and dogs. Humans exposed to fipronil by ingestion may show symptoms of headache, tonic—clonic convulsions, seizures, paresthesia, pneumonia, and death. Neurotoxic symptoms of fipronil poisoning in humans are typically associated with the antagonism of central GABA receptors.

It has been suggested that fipronil is a developmental neurotoxicant. In an in vitro study using differentiating N2a neuroblastoma cells, Sidiropoulou et al. (2011) demonstrated that fipronil caused severe disruption of the developmentally important ERK (½) MAP kinase signal transduction pathway, as evidenced by significant reductions in the activation state of MAP kinase (MEK [½]), and particularly ERK (½). These findings supported the contention that fipronil is a developmental neurotoxicant and unrelated to GABA receptor inhibition. Recently, Roques et al. (2012) demonstrated that fipronil and fipronil sulfone induced thyroid disruption in rats. However, fipronil sulfone has greater potential than fipronil for thyroid disruption because it persists much longer in the organism than fipronil itself.

Recent reports indicate that fipronil and its metabolite(s) can cause toxicity in liver, kidney, and other vital organs by dysregulating mitochondrial bioenergetics (by inhibiting mitochondrial respiratory chain), calcium homeostasis, oxidative and nitrosative stress, as well as causing damage to DNA and proteins (reviewed in Wang et al., 2016, Gupta and Anadon, 2018). Cell death can occur due to apoptosis or autophagy.

Biomarkers

After topical application of Frontline, fipronil spreads and sequesters in the lipids of the skin and hair follicles and continues to be released onto the skin and coat, resulting in long-lasting residual activity against fleas and ticks. Jennings et al. (2002) reported the maximum concentration of fipronil on the canine hair coat 24 h after a single application of Frontline Top Spot. With a descending concentration trend, fipronil residue was detected on dog's hair coat for a period of 30 days. Fipronil is metabolized to fipronil sulfone in the liver by cytochrome P450 (Roques et al., 2012). Fipronil and its metabolites (primarily sulfone) can persist in the tissues, particularly in fat and fatty tissues, for 1 week after treatment. The long half-life (150–245 h) of fipronil in blood may reflect a slow release of metabolites from fat. Pharmacokinetic studies in rats suggest that fipronil excretes mainly in the feces (45%–75%) and very little in the urine (5%–25%). Detection and confirmation of residue of fipronil and its metabolites is usually performed using GC-MS.

Detection of residue of fipronil or its metabolites in the body tissue, urine, feces, or on skin or hair can be used as biomarkers of fipronil exposure. Clinical signs and symptoms and pathological changes in liver are not specific and are of little value in terms of toxicological biomarkers. For further details on toxicity of fipronil, readers are referred to Gupta and Anadon (2018).

IVERMECTIN AND SELAMECTIN

Ivermectin is a semisynthetic macrocyclic lactone (ML), which was first isolated from *Streptomyces avermitilis*. Ivermectin is a mixture of two homologs (80% B_{1a} and 20% B_{1b}), and it was introduced to the market as abamectin in 1981, a potent antiparasitic animal health drug. The drug is approved at a very low dosage for the control of parasites in many animal species (cattle, sheep, swine, horses, dogs, and cats) but not approved in lactating cows, sheep, and goats. Although ivermectin poisoning can occur in any animal species, dogs of certain breeds (Collies, Old English sheepdog, German Shepherd, and others), Murray Grey cattle, and young animals (with less developed BBB) are particularly more sensitive. In Japan, Crump and Ōmura (2011) described ivermectin as a "wonder drug" in humans against onchocerciasis and lymphatic filariasis. In agriculture, ivermectin is used for its insecticidal, miticidal, and acaricidal activities.

Selamectin is a novel semisynthetic avermectin, which is marketed as Revolution for topical application on dogs and cats 6 weeks of age and older. Selamectin is used to kill fleas, ticks, and ear mites in dogs and cats.

With ivermectin, selamectin, and other MLs (doramectin, eprinomectin, milbemycin, and moxidectin), poisoning in animals may occur because of overdosage or accidental exposure.

Mechanism of Toxicity

Ivermectin

Ivermectin is effective against nematodes and arthropods but not against cestodes and trematodes. This is because ivermectin acts as a GABA receptor agonist, and cestodes and trematodes lack a GABA system. In mammals, a GABA system is present only in the CNS. Ivermectin exerts toxicity by blocking the postsynaptic transmission of nerve impulses by potentiating the release and binding of GABA, thus blocking GABA-mediated transmission. In general, ivermectin does not cross the BBB in most animal species. The defective p-glycoprotein transporter (ABCB1) in the BBB has been found in at least 11 breeds of dogs (including Collies) and in many other animals. Therefore, when the p-glycoprotein transporter is defective or overwhelmed by ivermectin overdosage, the integrity of the BBB is compromised, leading to toxicosis in the animal. Some adverse effects of ivermectin in dogs, horses, and cattle also appear to be due to GABA-mediated cholinergic effects.

Both homologs of ivermectin are neurotoxicants and equally potent. The clinical signs and symptoms of ivermectin toxicosis, primarily involving the CNS, have been described in ivermectin-sensitive dogs. Further support for CNS involvement was the finding that the ivermectin concentrations in the brain were higher in dogs with p-glycoprotein defect displaying symptoms of ivermectin toxicosis than in nonsensitive dogs (Pullium et al., 1985). Clinical signs include dehydration, bradycardia, respiratory depression, cyanosis, mydriasis, and a diminished gag reflex. Toxic signs may also include vomiting, ataxia, tremors, hypersalivation, coma, and death. Ivermectin should not be given to kittens, as it can cross the BBB. At higher doses, other animals show similar signs of ivermectin toxicosis. In an experimental study in rats, abamectin has been found to cause testicular damage, thereby impairing male fertility (Celic-Ozenci et al., 2011).

Selamectin

In insects and parasites, selamectin binds to glutamate-gated chloride channels in the nervous system, causing them to remain open. This causes chloride ions to continuously flow into the nerve cell, changing the charge of the cell membrane. The continuous flow of chloride ions blocks neurotransmission, and transmission of stimuli to the muscle is prevented. Selamectin binding is irreversible, thereby causing prolonged

channel opening and permanent hyperpolarization. Selamectin has no such effect in the mammalian nervous system and, therefore, it is considered to be a safe insecticide. However, in acute cases, signs of toxicoses may include hair loss at the site of application, vomiting, diarrhea with or without blood, lethargy, salivation, tachypnea, pruritus, urticaria, erythema, ataxia, and fever. In rare instances, seizures followed by death occur with overt acute overdose. In our study, dogs treated with a single topical application of Revolution (6 mg/kg body wt) showed no signs of any poisoning, though detectable residue of selamectin persisted on the skin and hair coat for 1 month (Gupta et al., 2005). For more details on the toxicity of ivermectin, selamectin, and other MLs, readers are referred to Gwaltney-Brant et al. (2018).

Biomarkers

In general, these insecticides are well absorbed, distributed widely throughout the body (higher concentrations in fat and fatty tissues), and tend to have long tissue residence times. They undergo some metabolism and are excreted unchanged in the feces via the bile. Because of the enterohepatic recycling, the half-lives of these compounds are in the range of days to weeks. Interestingly, residues of these compounds are excreted in the milk. Residue analysis of ivermectin, selamectin, or any other MLs, along with clinical signs, can serve as biomarkers of exposure and effects. These compounds are analyzed using HPLC with UV, fluorescence, or photodiode array detector (Anastaseo et al., 2002; Gupta et al., 2005; Gwaltney-Brant et al., 2018).

ROTENONE

Rotenone is one of the naturally occurring insecticides present in a number of plants of the *Derris*, *Lonchocarpus*, *Tephrosia*, and *Mundulea* species. It has a molecular formula of $C_{23}H_{22}O_6$ and a molecular weight of 394.42. Rotenone is used worldwide because it has broad-spectrum insecticidal, acaricidal, and other pesticidal properties. Its formulations include crystalline preparations (about 95%), emulsifiable solutions (about 50%), and dust (0.75%). In veterinary medicine, rotenone is used in powder form to control parasitic mites on chicken and other fowl, and lice and ticks on dogs, cats, and horses. Rotenone dust is also used to control beetles and aphids on vegetables, fruits, berries, and flowers. Rotenone emulsions are used for eliminating unwanted fish in the management of bodies of water. It is also formulated, along with other pesticides, such as carbaryl, pyrethrins, piperonyl butoxide, and lindane, in products to control insects, mites, ticks, lice, spiders, and undesirable fish.

According to a survey conducted by the USEPA in 1990, rotenone was found to be one of the pesticides most commonly used in and around the home. Rotenone is a very safe compound when properly used, but in higher doses it is toxic to humans, animals, and fish. WHO classifies rotenone as a moderately hazardous Class II pesticide. It has been involved in suicide attempts, in which acute congestive heart failure was the characteristic feature at autopsy. During the past decade, rotenone has received enormous attention because of its link to Parkinson's disease (Pan-Montojo et al., 2010; Xiong et al., 2012; Terron et al., 2018). Currently, rotenone is used extensively by researchers as an experimental drug to cause mitochondrial complex I inhibition and reproduce Parkinsonian motor deficits in animal models (Drolet et al., 2009; Xiong et al., 2012; Terron et al., 2018).

Mechanism of Toxicity

In insects, rotenone is both a contact and a systemic insecticide. Rotenone inhibits the transfer of electrons from Fe—S centers in complex I to ubiquinone in the electron transport chain. This prevents NADH from being converted into usable cellular energy, i.e., ATP. In mammals and fish, rotenone inhibits the oxidation of NADH to NAD, thereby blocking the oxidation of NAD and the substrates such as glutamate, α-ketoglutarate, and pyruvate. Rotenone causes inhibition of mitochondrial respiratory chain complex I, which can cause oxidative stress and lead to selective degeneration of striatal-nigral dopamine neurons. Besides complex I inhibition, mitochondrial dysfunction, nitrosative stress, increased nitric oxide and malondialdehyde levels, impaired proteostasis, aggregation of α-synuclein and polyubiquitin, activation of astrocytes and microglial cells, neuroinflammatory reaction, glutamate excitotoxicity, and degeneration of dopaminergic neurons in rotenone evoked Parkinsonism (reviewed in Xiong et al., 2012; Terron et al., 2018). In an in vitro study, Mundhall et al. (2012) demonstrated that 30 min superfusion of horizontal slices of rat midbrain with 100 nM rotenone caused significant injury to tyrosine hydroxylase—positive proximal dendrites in dorsal and ventral regions of the substantia nigra zona impacta and ventral tegmental area. Rotenone toxicity has been studied using various in vitro and in vivo models (reviewed in Xiong et al., 2012; Terron et al., 2018).

Rotenone exerts selective toxicity, as it is highly toxic to fish because of its rapid absorption from the GI tract in comparison with mammalian species in which it is poorly absorbed. The selective toxicity of rotenone in insects and fish versus mammals can also be explained by

its metabolism. Rotenone converts to highly toxic metabolites in large quantities in insects and fish, while it converts to nontoxic metabolites in mammals.

Rotenone has been proven to be a neurotoxicant in all species tested. In mammals, acute rotenone exposure can produce vomiting, incoordination, muscle tremors, and clonic convulsions. Cardiovascular effects include tachycardia, hypotension, and impaired myocardial contractility. Death occurs due to cardiorespiratory failure. Chronic exposure to rotenone exerts Parkinson's disease—like neuropathology in experimental lab animals (Drolet et al., 2009; Pan-Montojo et al., 2010). A NOAEL of 0.4 mg/kg/day has been determined in rats and dogs. For further details on rotenone toxicity, readers are referred to Gupta (2012).

Biomarkers

In animals, rotenone has been found to be hundred times more toxic via the IV route than by the oral route because of its poor absorption from the GI tract. Rotenone is metabolized in the liver by NADP-linked hepatic microsomal enzymes. Several metabolites of rotenone have been identified as rotenoids, such as rotenolone I and II, hydroxyl and dihydroxyrotenone, etc. Approximately 20% of a rotenone dose is excreted in the urine within 24 h of oral administration in rats and mice. Unabsorbed rotenone from the GI tract is excreted in the feces. Residue detection of rotenone and/or its metabolites in blood, urine, feces, or liver can serve as a biomarker of rotenone exposure. Rotenone residue can be determined using HPLC with a fluorescence detector or Liquid Chromatograph-Mass Spectrometer-Mass Spectrometer (LC-MS-MS) (Caboni et al., 2008). Characteristic toxicological symptoms and histopathological changes can be used as biomarkers of rotenone toxicity.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The majority of insecticides are of chemical origin, and the rest are of biological origin. They are used worldwide in agriculture, horticulture, forestry, residential areas, gardens, homes, offices, and aircrafts. Insecticides are of diverse chemical structures, and therefore their mechanism of action, pharmacokinetics, and toxicity vary significantly. Most insecticides are neurotoxicants in insects and nontarget mammalian (including humans) species, wildlife, and aquatic species. In nontarget species, the insecticides appear to be of lesser toxicity than that in insects, but their toxic effects involve other body organs and systems, in addition to the nervous system. In general, detection of the residue of insecticides and/or their metabolites in body fluids (urine, blood serum, plasma, and milk), tissue, or hair is often used as a biomarker of exposure. Alterations in behavioral, biochemical, molecular, and histopathological endpoints are used as biomarkers of effects. In insecticide toxicity, very little is understood regarding biomarkers of genetic susceptibility and this needs to be explored in future studies. Future research will explore novel biomarkers with greater sensitivity, reliability, and reproducibility, preferably nondestructible and noninvasive for chemical toxicity and chemical-related long-term illnesses, such as neurodegenerative, metabolic, and carcinogenesis.

Herbicides and Fungicides

P.K. Gupta

Director Toxicology Consulting Group, Former Principal Scientist and Chief Division of Pharmacology and Toxicology, IVRI, Advisor, World Health Organization (Geneva), Bareilly, India

INTRODUCTION

Ever since the dawn of civilization, it has been the major task of man to engage in a continuous endeavor to improve his living conditions. One of the main tasks in which human beings have been engaged is securing relief from hunger, one of the basic needs. Food production capacity is faced with an ever-growing number of challenges, including a world population expected to grow to nearly 10 billion by 2050 and a falling ratio of arable land to population. Food plays a vital and strategic role in a growing global population, but food production is encountering limits. For example, there is a limit to new areas to cultivate; therefore, we must increase agricultural production from the areas available. In fact, herbicides have significantly increased crop yields by reducing the strong competition of weeds with important and essential food crops. Along with improved crop varieties, both herbicides and fungicides have increased crop yields, decreased food costs, and enhanced the appearance of food. These benefits include increased crop and livestock yields, improved food safety, human health, quality of life and longevity, and reduced drudgery, energy use, and environmental degradation. A complex matrix of benefit interactions is explored for a range of beneficiaries at three main levels—local, national, and global—and in three main domains: social, economic, and environmental (Cooper and Dobson, 2007). Although the use of biopesticides is increasing (Gupta, 2006a), the use of chemical pesticides is still the mainstay in large-scale control of most insects, weeds, fungi, and other pests of economic or public health importance. Among pesticides, herbicides and fungicides have found extensive use in the eradication of unwanted plants and control of plant diseases (Gupta, 1989, 2004, 2010a, 2016).

On the other side, acute and long-term exposures to these chemicals and residues that remain on foods have given rise to many health effect issues (Gupta, 1986, 1988; 2006b). The toxic effects of some of these pesticide chemicals on animals (Gupta, 2018a,b,c,d) and their effects on developmental and reproductive abnormalities have been reviewed previously (Gupta, 2017). However, many point to health or environmental problems from accidental or deliberate exposure to pesticides. Because of the wide environmental dispersive uses of pesticides, regulatory agencies around the world have implemented intensive and robust product registration requirements that require state-of-the-art animal and environmental species testing that assures the safe use of modern pesticides. When pesticides are used rationally and carefully, in conjunction with other technologies in integrated pest management systems, it is more likely that their use will be justifiable (Cooper and Dobson, 2007).

The application of biological markers has been considered a major opportunity for assessing exposure and risk in determining health outcomes that are associated with exposures and for evaluating the success of risk mitigation strategies (Gupta, 2010b). Biomonitoring is an important tool that can be used to evaluate human exposure by measuring the levels of herbicides and fungicides and/or their metabolites or altered biological structures or functions in biological specimens or tissue. These measurements in biological media reflect human exposure (not the risk) to these chemicals through all relevant routes and can therefore be used to monitor aggregate and cumulative exposures (Barr et al., 1999; Barr and Angerer, 2006). Thus, with the availability of validated biomarker data, there are opportunities to reconstruct the exposure of an individual(s) at risk (Sachana et al., 2017). However, careful interpretation

of biomarkers and biomonitoring data related to toxicant exposures is necessary to accurately assess human exposure to chemicals and the associated health risks. Biomonitoring studies should be carefully designed to minimize inappropriate interpretation.

BACKGROUND

It is well known that human biomonitoring provides an efficient way to identify and quantify exposure to chemical substances. Once the toxicological effects have been identified in animal studies (and the mechanism of toxic effects has been elucidated), an adequate margin of safety is established by comparing with human exposure. Herbicides and fungicides are the most widely and commonly used pesticides worldwide. As such there is a likelihood of higher risk of exposure to these hazardous chemicals that may lead to adverse effects on health (Kapka-Skrzypczak et al., 2011). In view of these findings, the detection of populations at risk constitutes a very important topic. Therefore, the main focus of this chapter is to summarize the latest information on biomarkers and other widely used biomonitoring methods for studies on herbicides and fungicides or their metabolites levels, so as to assess the health risks associated with these chemicals.

TOXICOKINETICS

Toxicokinetics is associated with the absorption, distribution, metabolism, and excretion (ADME) of drugs and xenobiotics. Toxicokinetic studies provide important data on the amount of toxicant delivered to a target, as well as species-, age- and gender-specific influences on ADME properties. Human beings are exposed to herbicides or fungicides of different chemical classes. These chemicals may be ingested through food pesticide residues or absorbed through the skin or the respiratory system. Different factors regulate their ADME (Gupta, 2014). In general, liver is the primary site for biotransformation and may include activation and detoxification reactions through the cytochrome P450-dependent monooxygenase system, the flavin-containing monooxygenase, esterases, and a variety of transferases, most notably the glutathione (GSH) S-transferases (Hodgson and Meyer, 1997). Liver can serve as an important "first-pass metabolism" barrier to systemic distribution of pesticides, and particularly so with low-dose real-world oral (dietary residue) exposures encountered for most pesticides. The measurements of specific biomarkers after the absorption step, or during each subsequent step of the ADME process, are used to assess exposure by estimating the internal dose, which is defined as the amount of chemical absorbed into the body after an exposure has occurred. Biomonitoring of exposure to pesticides involves the measurement of an exposure biomarker, which can be pesticide(s), its metabolite(s), or reaction product(s) in biological media such as urine, blood or blood components, exhaled air, hair or nails, and tissues (Barr et al., 2006; Ngo et al., 2010). The knowledge of toxicokinetic values is, therefore, important to determine their biomarkers and for biomonitoring the chemicals in various body tissues or metrics used for this purpose. This also helps in the design of urine or other biological sampling time, which is of great relevance in a biomonitoring study, and sufficient collection time (i.e., spot samples vs. longer term continuous collection) will differ depending on the pesticide and other factors such as the route of exposure and chemical form. For example, in the case of herbicides such as 2,4-D, where they are essentially rapidly excreted unchanged in human urine, collection of a 24 h urine sample provides a very accurate estimate of total exposed dose of 2,4-D. Therefore, in planning biomonitoring, appropriate timings of the sampling are very important. This procedure can be difficult to perform among farm workers or pesticide sprayers because they are constantly undergoing occupational exposure, and this poses logistical and organizational problems with collecting samples (Kimata et al., 2009), and the procedure becomes more complex when the human and environmental biomarkers are the same for a particular chemical. Some of the herbicides or fungicides are very popular because they do not accumulate appreciably in humans and are rapidly metabolized and excreted in the urine, which means that the urinary metabolites of those pesticides can be measured up to a limited period only after an exposure has occurred. These measurements represent only a snapshot in time; thus, only exposures that occurred during the previous few hours or days can be captured. In that case, a single urinary measurement may not reflect the average exposure (Barr and Angerer, 2006). However, in the case of chronic exposure to those pesticides having prolonged systemic half-lives, urinary elimination may reach a steady state, which means that the chemical or metabolite present in the urine stays at a relatively constant level and reflects the average exposure. The specificity of urinary measurements is equally as high as blood measurements, but only in the case when the parent compound is excreted in urine (e.g., 2,4-dichlorophenoxyacetic acid (2,4-D), glyphosate, sulfonyl ureas). In another study, it was shown that variability in detection for each urinary metabolite within and across individuals indicates that any single measure of urinary metabolites cannot be considered a credible indicator of exposure for an individual. Furthermore, exposure

estimation based on a urinary metabolite collected at a single time in an agricultural season is not a good indicator of population pesticide exposure, especially if the systemic half-life is very short. Results from these studies suggest that to provide a reliable characterization of pesticide exposure it is necessary to measure numerous pesticide urinary metabolites and collect multiple samples from each participant across a single agricultural season (Arcury et al., 2009). Therefore, ADME information for a chemical helps in careful design of biomonitoring studies.

MECHANISM OF ACTION

There are a number of biochemical changes that may act as indicators of biological response, such as enzyme changes due to exposure to herbicides and fungicides, which may be used as an internal marker of exposure; however, these types of biomarkers must be considered in the context of dose response, i.e., high-dose animal biomarkers are unlikely to be useful for low-dose human exposures. Likewise, specific biological effects of a chemical can be measured very early at the cellular level and may serve as indicators of exposure to that particular chemical. In most situations, it is difficult to pinpoint the exact mechanism of action. The mechanism of action of phenoxy derivatives, triazines, triazolopyrimidines, imidazolinones, dinitroaniline, and many other classes of herbicides is not precisely known in humans, especially at environmental exposure dose levels. However, at high-dose levels, phenoxy compounds are known to depress ribonuclease synthesis, uncouple oxidative phosphorylation, and increase the number of hepatic peroxisomes in animal studies. Oxadiazon causes hepatic porphyria in both mice and rats. The phenylurea herbicides linuron and monuron are rodent liver carcinogens. Chloroacetanilide and metolachlor have shown weak hepatocarcinogenicity in female rats and are nongenotoxic, suggesting a tumor-promoting action. The dinitro compounds markedly stimulate respiration while simultaneously impairing adenosine triphosphate synthesis. The main toxic action is uncoupling of oxidative phosphorylation, converting all cellular energy into the form of heat and causing extreme hyperthermia. In addition, the gut flora in ruminants is able to further reduce the dinitro compounds to diamine metabolites, which are capable of inducing methemoglobinemia (Gupta, 2018b). The available information on substituted anilines indicates that there is a nongenotoxic mechanism of action and lack of relevance to humans for the nasal turbinate, stomach, and/or thyroid oncogenic effects produced in rats. Glyphosate, a member of the phosphonomethyl amino acid group, selectively inhibits the enzyme

5-enolpyruvylshikimate 3-phosphate synthetase. The enzyme plays a key role in the biosynthesis of the intermediate, chorismate, which is necessary for the synthesis of the essential amino acids phenylalanine, tyrosine, and tryptophan. This aromatic amino acid biosynthesis pathway is found in plants, as well as in fungi and bacteria, but not in insects, birds, fish, mammals, and humans, thus providing a specific selective toxicity to plant species (Franz et al., 1997); this highlights that if an herbicide mode of action operates by a pathway not present in mammals, then this type of mode of action provides no basis for establishing a human biomarker. In mammalian systems, glyphosate can cause disruptions of mitochondrial and membrane integrity, and endocrine, reproductive, and developmental systems (Gasnier et al., 2009; Williams et al., 2012). Glyphosate can also induce apoptosis and necrosis in human umbilical, embryonic, placental, and testicular cells, and a testosterone decrease (Benachour and Seralini, 2009; Clair et al., 2012). Another compound of this group, glufosinate, acts by inhibiting the enzyme glutamine synthetase in animals. Glutamine synthetase in mammals is involved in ammonia homeostasis in many organs and the glutamine–glutamate shunt between γ-aminobutyrate and glutamate in the central nervous system (CNS). However, the enzyme normally works at a small fraction of its capacity, and considerable inhibition is required in mammals before ammonia levels increase. Hence, this does not lead to a problem in ammonia metabolism; the mammals obviously compensate by using other metabolic pathways (Hack et al., 1994; JMPR, 2000). Therefore, knowledge of mechanism of action may provide insight into selection of potential human biomarkers; however, particular attention must be directed at understanding dose response for such biomarkers to be effectively translated to actual real-world human applications. High-dose animal biomarkers are unlikely to be useful for real-world applications.

BIOMARKERS AND BIOMONITORING OF EXPOSURE

The expansion of knowledge at the molecular and cellular level has provided an opportunity to consider the addition of a myriad of new endpoints to toxicological evaluations utilizing the in vitro and in vivo animal models for better characterization of hazard potential of a chemical. This includes an array of new molecular biomarkers that have received substantial attention. Although biomarkers are frequently discussed as new approaches, it is well known to the clinician and toxicologist that biomarkers have been used in human medicine for centuries. In most cases, urine is the matrix for

pesticides used for biomonitoring. A few biomarkers of herbicides and fungicides or their metabolites, along with selectivity of the measurement, are summarized in Table 27.1.

In some cases, the biomarkers to be measured are present in body fluids other than urine, such as exhaled breath or tears, which can serve as an indicator of exposure or, even, dose of a toxicant. In other cases, for example, the biomarker is an indicator of a disease process, such as individuals being evaluated for prostate

cancer based on an elevated level of prostate-specific antigen in serum samples. New biomarkers of exposure will continue to be proposed. For each potential biomarker of exposure, it will be necessary to conduct experiments to validate the utility of the biomarker. The potential list of biomarkers for toxic responses is seemingly endless. Therefore, the application of biological markers has been considered as a major opportunity for exposure assessment to identify populations exposed to herbicides and fungicides. The biological

TABLE 27.1 Biomarkers of Selective Herbicides and Fungicides or Their Metabolites and Specificity of the Measurement

		Potential Biomarker[a]	Specificity[b]
Herbicide Class	**Herbicide**		
Phenoxy acid derivative	2,4-D	2,4-D	1
	2,4,5-T	2,4,5-T	1
	MCPA	MCPA	1
Triazines and triazoles	Atrazine	Atrazine and atrazine mercapturate	2,3
Phenyhirea herbicide	Diuron	Diuron and N-(3,4-dichlorophenyl)-urea	1,2
Protoporphyrinogen oxidase inhibiting herbicide		Porphyrin accumulation	3
Substituted anilines	Alachlor	Alachlor and alachlor mercapturate	2
	Metolachlor	Metolachlor and metolachlor mercapturate	2
Bipyridyl derivatives	Paraquat	Paraquat	1
	Diquat	Diquat	1
	Imazapyr	Imazapyr	1
Imidazolinones	Imazapic	Imazapic	1
	Imazethapyr	Imazethapyr	1
	Imazamox	Imazamox	1
	Imazaquin	Imazaquin	1
	Imazamethabenz-methyl	Imazamethabenz-methyl and Ester to imazamethabenz	1,2
Fungicide Class	**Fungicide**		
Dialkyldithiocarbamates		Common metabolite ETU	3,4
Anilinopyrimidines	Cyprodinil	4-cydopropyl-5-hydroxy-6-methyI-N-(4-hydroxy)-phenyl-2-pyrimidinamine	2
Chloroalkylthiodicarboximides (phthaiimides)	Captan	1,2,3,6-tetra-hydrophthalimide (THPI) and Thiazolidine-2-thione-4-carboxylic acid (TTCA)	2,3
	Folpet	THPA, phthalimide, and phthalic acid	2,3
Halogenated substituted monocyclic aromatics	Chlorothalonil	Thiol-derived metabolities	2

[a]Urine is the matrix for analysis unless otherwise stated
[b]1, Parent pesticide measured; 2, Metabolite or contaminant measured but is reflective of the parent pesticide; 3, Reflective of class exposure to pesticides; 4, Reflective of exposure to pesticide and nonpesticide chemicals (e.g., other chemicals or degradates).

markers can include a broad range of techniques that are designed to provide information on "an exogenous substance or its metabolite or a product of an interaction between a xenobiotic agent and some target molecule or cell that is measured in a compartment within an organism." Thus, biomarker measurements can provide quantitative information that can identify prior exposure or link exposures to an adverse effect/disease outcome. In most cases of exposure, the type of techniques needed do not exist, especially those needed to provide a direct linkage to disease. Such a situation is also true for various herbicides and other chemicals because we still only touch the tip of the iceberg of available active ingredients that can be measured (Barr and Angerer, 2006). A special challenge relates to recognizing the dynamics of the toxicokinetics and their mechanisms of action and establishing quantitative relationships between exposure and dose at any particular time over the course of the intoxication. Therefore, it is pertinent to discuss these topics, which are very important for biomarkers and biomonitoring of chemicals.

Herbicides

Herbicides are phytotoxic chemicals used for controlling various weeds. They have variable degrees of specificity. For example, paraquat kills all green plants, whereas phenoxy compounds are specific for certain groups of broadleaf plants. The worldwide consumption of herbicides is almost 48% of the total pesticide usage. Herbicides represent a plethora of chemically diverse structures and are inclusive of modes of action that are unique to plants or overlap with human biology. Most of the human or animal health problems that result from exposure to herbicides are due to their improper use or careless disposal of containers. Very few cases occur when these chemicals are used properly. However, there is increased concern about the effects of herbicides on human health because of runoff from agricultural applications and entrance into the drinking water supply (Gupta, 1986).

A large number of chemicals are used as herbicides (Gupta, 2018b) but, due to limited space, only those herbicides which are in active use and for which sufficient information on biomonitoring and biomarkers is available are discussed in greater detail in this chapter.

Phenoxy Acid Derivatives

This class of herbicides has been in continuous, extensive, and uninterrupted use since 1947. A combination of 2,4-D and 2,4,5-T, popularly known as "Agent Orange," was teratogenic in mouse. In the rat, this combination did not result in malformations, but behavioral effects were seen postnatally in some offspring. Because it was contaminated with the highly toxic and persistent 2,3,7,8-tetrachlorodibenzo-p-dioxin, along with other chlorinated dioxins and furans, 2,4,5-T has been banned for most applications. Although 2,4-D contains very small amounts of persistent chlorinated dioxins and furans, it is not expected to produce any adverse effects. In its ester or salt forms, it is commonly found in home and garden stores in combination with other herbicides such as dicamba or mecoprop for application on lawns. Absorption of 2,4-D occurs rapidly from the gastrointestinal tract (GIT), and plasma half-lives range from 3.5 to 18 h approximately. Dermal absorption was reported to occur rapidly but usually is less than 6%. The compound is extensively protein bound in vivo and distributed to the liver, kidneys, and lungs. 2,4-D has also been reported to cross the placental barrier in laboratory animals and pigs. 2,4-D is not metabolized to reactive intermediates, does not accumulate in tissues, and is excreted predominantly as the parent compound in urine. However, the rate of excretion via urine is inversely proportional to dose. 2,4-D has been detected in milk of lactating rats dosed with 2,4-D. The salts and esters of 2,4-D undergo acid and/or enzymatic hydrolysis to form 2,4-D acid, and possibly small amounts are conjugated with glycine or taurine. Excretion can be markedly enhanced by ion trapping using alkaline agents, as most of these herbicides are organic acids (Gupta, 2018b).

In addition to 2,4-D, mecoprop, MCPA (2-methyl-4-chloro-phenoxyacetic acid), and 2,4,5-T have been measured in urine (Kennepohl et al., 2010). Their mechanism of action indicates that they act as peroxisome proliferators. In addition, biomonitoring data for 2,4-D in urine samples are now available from a number of studies of both the general population (including preschool-age children) and farm applicators and their family members. Such data provide an integrated measure of absorbed dose from all pathways and routes of exposure (Alexander et al., 2007).

Using various toxicological information and monitoring data available in the literature, the hazards of 2,4-D were recently assessed by the US Environmental Protection Agency and the Canadian Pest Management Regulatory Agency (EPA, 2004; PMRA, 2007). The US EPA-derived reference doses (RfDs) for acute and chronic exposure to 2,4-D are based on external exposure metrics (administered dose), which are not directly useful for evaluating biomonitoring data. However, Biomonitoring Equivalent (BE) values (BEs are defined as an estimate of pesticide or its key metabolite in urine and/or blood of humans exposed to a regulatory standard health-protective dose, e.g., RfD) corresponding to RfDs for acute and chronic exposure scenarios are now available (Aylward and Hays, 2008). The use of BEs is a more scientific tool for performing exposure risk assessment while comparing with the

biomonitoring data, as has been done for 2,4-D in Figs. 27.1 and 27.2, respectively, for the general population and field applicators (Aylward et al., 2010).

The available biomonitoring data for 2,4-D from the United States and Canada were compared with BE values. The biomonitoring data indicated margins of safety (ratio of BE value to biomarker concentration) of ~200 at the central tendency and 50 at the extremes in the general population. Median exposures for applicators and their family members during periods of use appear to be well within acute exposure guidance values. Biomonitoring data from these studies indicate that current exposures to 2,4-D are below applicable exposure guidance values (Hays et al., 2012). This example demonstrates the value of biomonitoring data in assessing population exposures in the context of existing risk assessments using the BE approach.

In conclusion, the extensive database of metabolic, toxicological, and epidemiological studies on 2,4-D has provided no evidence that 2,4-D poses any adverse health risk to humans. Furthermore, there is no credible or plausible evidence for any increased risk of cancer or noncancer outcomes in humans associated with 2,4-D exposure (Burns and Swaen, 2012).

Triazines and Triazoles

Another class of pesticides extensively used as herbicides are the triazines and triazoles. These herbicides have been extensively used in agriculture in the United States and other parts of the world for more than 50 years. These herbicides include both the asymmetrical and symmetrical triazines. Examples of symmetrical triazines are chloro-S-triazines (simazine, atrazine, propazine and cyanazine); the thiomethyl-S-triazines (ametryn, prometryn, terbutryn); and the methoxy-S-triazine (prometon). The commonly used asymmetrical triazine is metribuzin. These herbicides have low oral toxicity and are unlikely to pose acute hazards in normal use and do not produce developmental toxicity, except for ametryn, metribuzin, atrazine, and cyanazine, which may be slightly to moderately hazardous. Atrazine induced no structural malformations in either rats or rabbits. Another herbicide, simazine, provided contradictory results of developmental toxicity in different studies carried out in different species using different dose levels (Dilley et al., 1977).
FIGURE 27.1 Urinary 2,4-D concentrations (µg/L) in general population studies presented in the context of the BE value corresponding to the US EPA RfD for general population chronic exposures. The symbol for data from NHANES (CDC, 2005) represents the 95th percentile for all tested participants (median values were below the LOD). The symbols for data from Morgan et al. (2008) (in key, Morgan) represent the median values for the children and adults from two states; bars extend to the 95th percentile for each group. The shaded regions represent concentration ranges associated with low, medium, and high priority for risk assessment follow-up based on the criteria described in the BE communications guidelines (LaKind et al., 2008) (Aylward et al., 2010).
FIGURE 27.2 Urinary 2,4-D concentrations (µg/L) in applicators on the day after application of 2,4-D presented in the context of the human-equivalent BEPOD and target BE values associated with the occupational risk assessment in the United States (EPA, 2004). Symbols represent the median (or, in the case of Curwin et al., 2005 and Thomas et al., 2010, the geometric mean), and the bars extend to the maximum measured value in each study (not reported for Curwin et al., 2005). The description of shaded regions is shown by abbreviations: BEPOD, Chronic exposure at the human equivalent (Aylward et al., 2010); POD, Point of departure.

Extensive use of atrazine has resulted in widespread contamination of surface, ground-, and drinking water with this herbicide and its dealkylated and hydroxylated degradation products (Konstantinou et al., 2006). For this reason, atrazine has progressively been restricted or banned in the European countries over the last 20 years. The structurally related but more hydrophobic terbuthylazine is often used as a substitute. Contrary to the European countries, the United States continues to heavily use atrazine (LeBaron et al., 2008). Some of the symmetrical triazines are reported to produce mammary tumors specifically in the Sprague—Dawley strain of rats; however, a recent review on mode of action indicates that these tumors are of nonrelevance to humans (Breckenridge et al., 2010). Recent reviews on toxicology data from animal studies and human epidemiological data concluded that there is no scientific basis for inferring the existence of a causal relationship between triazine exposure and the occurrence of cancer in humans (Jowa and Howd, 2011; Sathiakumar et al., 2011). The metabolic studies of atrazine revealed that chemical structures of the compound are permutations of alkyl substituted 2,4-diamines of chlorotriazine. On entering the body, they are metabolized via the glutathione detoxification pathway or by simple dealkylation. For glutathione detoxification, the chlorine atom on the triazine herbicide is subject to an enzymatic catalyzed

substitution by the free —SH on the internal cysteine residue of the glutathione tripeptide. The terminal peptides are enzymatically cleaved and the cysteine is N-acetylated. The mercapturate and dealkylation metabolites are then excreted into the urine. These metabolites are not specific for a single triazine but provide class exposure information. Triazines, as parent molecules, can also be measured as the intact pesticide in blood products (Sachana et al., 2017). The proposed metabolic pathways for atrazine are presented in Fig. 27.3 (Barr et al., 2007a,b). Animal versus human urine and/or blood metabolites from different studies are summarized in Table 27.2. Atrazine mercapturate appeared to be the major metabolite in humans after dermal or oral exposure to atrazine, which seems not to be the case in animal studies.

This table highlights the importance of understanding metabolic pathways of a compound in humans for selecting appropriate biomarkers for exposure. In a recent biomonitoring study for atrazine, atrazine mercapturate (Fig. 27.4) accounted for a major proportion of metabolites found in urine of atrazine applicators and measuring atrazine mercapturate plus atrazine could be used as a specific biomarker for the atrazine exposure (Mendas et al., 2012).

Another compound of this group is cyanazine. Cyanazine is more acutely toxic and resulted in developmental

toxicity, presumably because of the presence of the cyano moiety. Effects noted at doses that were toxic to the mothers were cyclopia and diaphragmatic hernia in rabbits and an apparent increase in the incidences of skeletal variations in rats (Hodgson and Meyer, 1997; Gupta, 2018b).

Phenylurea Herbicides

Ureas and thioureas are a group of herbicides used for general weed control in agricultural and nonagricultural practices. The first urea herbicide, N, N-dimethyl-N0-(4-chlorophenyl)-urea was introduced in 1952 by DuPont under the common name of monuron. In subsequent years, many more derivatives of this class of compounds have been marketed. There are more than 20 polyureas available under different names such as diuron, fluometuron, isoproturon, linuron,

FIGURE 27.4 Chemical structure of atrazine mercapturate (N-acetyl-S-{4-(ethylamino)-6-[(1-methylethyl)amino]-1,3,5-triazine- 2-yl}-L-cysteine).

buturon, chlorbromuron, chlortoluron, chloroxuron, difenoxuron, fenuron, methiuron, metobromuron, metoxuron, monuron, neburon, parafluron, siduron, tebuthiuron, tetrafluron, and thidiazuron. Diuron, the most common phenylurea, has been among the top 10 pesticides in use in the United States. The acute toxicity potential for all phenylureas appears to be low, but at high acute or repeated exposures, neurobehavioral alterations, body weight reductions, hematotoxicity, and hepatotoxicity have been reported. In general, ureas and thioureas do not cause developmental and reproductive toxicity, but monolinuron, linuron, and buturon are known to cause some teratogenic abnormalities in experimental animals. Linuron produced a high incidence of malformations in rat fetuses when given by gavage, but the chemical had no teratogenic potential in the rabbit under dietary regimen. A related chemical, monolinuron, caused cleft palate in mice (Matthiaschk and Roll, 1977; Liu, 2010).

Absorption and excretion studies have revealed that polyureas are readily absorbed through the GI tract in rats and dogs and are mainly metabolized by dealkalization of the urea methyl groups (Boehme and Ernst, 1965). Hydrolysis of diuron to 3,4-dichloroaniline and oxidation to 3,4-dichlorophenol, as well as dihydroxylation at carbon 2 and/or 6 of the benzene ring, have also been reported. The predominant metabolite of diuron in urine is N-(3,4-dichlorophenyl)-urea. Diuron is partially excreted unchanged in feces and urine. The storage of diuron does not occur in tissues (Hodge et al., 1968; Hodgson and Meyer, 1997).

Protoporphyrinogen Oxidase—Inhibiting Herbicides

Protoporphyrinogen oxidase (Protox)—inhibiting herbicides have been used since the 1960s and now represent a relatively large and growing segment of the herbicide market. Nitrofen was the first Protox-inhibiting herbicide to be introduced for commercial use, in 1964. This diphenyl ether (DPE) herbicide was eventually recognized as a relatively weak inhibitor of Protox but was a lead compound of an entire class of structurally related herbicides that were much more active. Subsequently several DPE herbicides have been successfully commercialized (Nandihalli et al., 1992; Anderson et al., 1994). Nitrofen is a developmental toxicant and produced varying results in different species. It produced a high incidence of diaphragmatic hernias and harderian gland alterations in mice following oral treatment, and hydronephrosis and respiratory difficulties in rats. In hamsters, the compound when administered orally during gestation resulted in abnormal development of the para- and mesonephric ducts and ureteric bud, which was occasionally accompanied by renal agenesis in female offspring and predominantly left-sided agenesis of vas or epididymis and seminal vesicles in males. It was concluded that the teratogenic activity of nitrofen is mediated by alterations in maternal and fetal thyroid hormone status (Manson et al., 1984; Dayan and Duke, 2010).

After the first generation of Protox inhibitors (with the exception of oxadiazon), which was based on the DPE, numerous other non—oxygen-bridged compounds (non-DPE Protox inhibitors) with the same site of action (carfentrazone, JV 485, and oxadiargyl) have been commercialized. These compounds have little acute toxicity and are unlikely to pose any acute hazard in normal use. The developmental toxicity studies conducted on rats and rabbits indicate that the majority of the compounds did not show any reproductive, developmental, or teratogenic abnormalities, except at very high doses that elicit maternal toxicity. The developmental toxicity correlates with Protox accumulation (JMPR, 2004).

The Protox class of oxidase inhibitor herbicides is either not readily absorbed and/or are rapidly degraded by metabolism and/or excreted. The mammalian metabolites are similar to photochemical degradation products. In mammals, there are remarkable species differences in the levels of porphyrin accumulation resulting from exposure to Protox inhibitors. There is no bioaccumulation risk in animals. Metabolism of Protox inhibitors has been studied in a number of species, including rats, rabbits, goats, sheep, cattle, and chicken. In general, the metabolic degradation of these compounds by animals includes nitroreduction, deesterification, and conjugation to GSH, cysteine, and carbohydrates. Most of the metabolites are excreted in urine, with small amounts excreted in feces and milk. In chickens, ~95% of the metabolites are eliminated in excreta, with small amounts (0.09%) eliminated in the eggs (Hunt et al., 1977; Leung et al., 1991).

Substituted Anilines

Substituted aniline, an alachlor herbicide, was registered and introduced in 1967 for the preplant or preemergent control of a broad spectrum of grass, sedge, and broadleaf weeds (Heydens et al., 2010). The commonly used herbicides are alachlor, acetochlor, butachlor, metolachlor, and propachlor. This class of herbicides is slightly hazardous, except butachlor, which is not likely to pose any hazard. Based on various toxicity studies, the data support grouping alachlor, acetochlor, and butachlor with respect to a common mechanism of toxicity for nasal turbinate and thyroid tumors, and alachlor and butachlor for stomach tumors. The results from the reproductive and developmental toxicity studies indicate that these herbicides are not reproductive toxicants, developmental toxicants, or teratogens. However, in the rabbit study with butachlor, a slight increase in postimplantation loss and decreased fetal weights were observed at maternally toxic doses, but at dietary concentrations over two successive generations, no adverse effects on reproductive performance or pup survival was observed (Wilson and Takei, 1999).

Substituted anilines are well absorbed in rats orally. The dermal penetration in monkeys is relatively slow. The metabolism of alachlor in rats is complex because of extensive biliary excretion, intestinal microbial metabolism, and enterohepatic circulation of metabolites. The main route of excretion is urine and feces, and nearly 90% of the dose is eliminated in 10 days. The metabolism in rats and mice is similar; however, there are significant quantitative differences between the two species. These herbicides undergo o-demethylation with the release of formaldehyde; however, the relationship between metabolism-mediated formaldehyde release and nasal tumors induced was not established. In contrast, alachlor is metabolized in monkeys to a limited number of GSH and glucuronide conjugates, which are excreted primarily via kidney. Excretion in monkeys is more rapid than rodents with ~90% being excreted in the urine within 48 h. Alachlor metabolites undergo biliary excretion and hepatic circulation in rodents, whereas biliary excretion is limited in monkeys. In rats, acetochlor is rapidly metabolized to several polar metabolites and more than 95% are quickly excreted in urine and feces. The metabolites are the result of the mercapturic acid pathway formed by initial GSH

conjugation. As in case of alachlor, acetochlor, butachlor, and propachlor also undergo glucuronide/glutathione conjugation and enter the hepatic circulation, leading to the formation of tertiary amide methylsulfide metabolite, which further undergo metabolism in liver and nasal tissue to form the putative carcinogen, diethyl quinoneimine (DEIQ) in rats (Feng et al., 1990; Heydens et al., 2010). In humans, the major urinary metabolites of alachlor, metolachlor, and acetachlor have been identified as their mercapturates. Alachlor mercapturate equivalent and metolachlor mercapturate equivalent were detected in more than half (n = 15) of the applicator preseason urine samples and in about 2% in the reference population (n = 46), whereas during the spraying season, the geometric mean amount of alachlor mercapturate equivalent and metolachlor mercapturate equivalent excreted in 24 h was 17 and 22 nmol, respectively. In addition, some of the intact chloroacetanilide herbicides have been measured in serum and plasma (Driskell et al., 1996; Driskell and Hill, 1997; Barr et al., 2007a,b). From these studies, it may be concluded that these metabolites are not inconsistent with the suggested metabolic pathways; however, the parent, plus the respective mercapturate metabolite in urine, can be used as a biomarker to monitor human exposure to substituted anilines (Sachana et al., 2017).

Bipyridyl Derivatives

This chemical class of herbicides includes paraquat and diquat. Paraquat was first described as a chemical redox indicator in 1882 by Weidel and Russo. In 1933, Michaelis and Hill discovered its redox properties and called the compound methyl viologen. It became commercially available as a herbicide in 1962 (Smith, 1997). It is a fast-acting, nonselective contact herbicide, absorbed by the foliage with some translocation in the xylem. Paraquat is the most toxic of the commonly used herbicides and the toxicity varies in different animals depending on the formulation and species used.

The compound is apparently nonteratogenic under standard testing regimens. High doses injected into pregnant rats and mice on various gestation days caused significant maternal toxicity but did not produce teratogenic effects (Bus and Gibson, 1975). At lower doses, gross soft tissue and slight increases in skeletal anomalies have been reported. In rats, costal cartilage malformations were reported. Diquat had no effect on fertility, was not teratogenic, and only produced fetotoxicity at doses that were maternally toxic. In the multigenerational study, cataract has been observed in rats at high doses (Lock and Wilks, 2010).

Paraquat is rapidly but incompletely absorbed from the GIT of laboratory animals and humans, with plasma concentration of 30−90 min, and poorly absorbed through contact skin. It has been reported that the dog absorbs more paraquat compared with rats, resulting in greater susceptibility of dogs toward paraquat toxicity. Distribution studies show higher radioactivity in Type I and Type II epithelial cells and the Clara cells of the rodent and human lungs, which are the major target cells for paraquat toxicity (Smith, 1997; Dinis-Oliveira et al., 2008). Paraquat is taken up into the brain via the neural amino acid transporter and thus may be a factor in the etiology of Parkinson's disease. The amount of paraquat excretion in feces corresponds to 60%−70% of the ingested dose. Paraquat is very poorly metabolized, and the bulk is excreted unchanged in the urine and feces (Van Dijck et al., 1975). The mechanism of action of paraquat and diquat is very similar at the molecular level and involves cyclic reduction−oxidation reactions, which produce reactive oxygen species and depletion of NADPH. However, the critical target organ differs for the two compounds, so the mammalian toxicity is quite different.

Although both herbicides affect kidneys, paraquat is selectively taken up in the lungs. Paraquat causes pulmonary lesions as a result of type I and type II pneumocytosis. The primary event in the mechanism of toxicity within cells is paraquat's ability to undergo a single electron reduction from the cation to form a free radical that is stable in the absence of oxygen. If oxygen is present, a concomitant reduction of oxygen takes place to form superoxide anion (O_2^-). Superoxide radical, in turn, is nonenzymatically converted to singlet oxygen, which attacks polyunsaturated lipids associated with cell membranes to form lipid hydroperoxides. Lipid hydroperoxides are normally converted to nontoxic lipid alcohols by the selenium-containing GSH-dependent enzyme, GSH peroxidase. Selenium deficiency, deficiency of GSH, or excess lipid hydroperoxides allow the lipid hydroperoxides to form lipid-free radicals. Lipid hydroperoxides are unstable in the presence of trace amounts of transition metal ions and decompose to free radicals, which in turn cause further peroxidation of polyunsaturated lipid in a process that is slowed by vitamin E. Peroxidation of the membranes could in turn cause cellular dysfunction and hence lead to cell damage or death, as summarized in Fig. 27.5 (Smith, 1997). For further details on mechanisms, toxicokinetics, clinical features, and treatment of paraquat poisoning, readers are referred to Dinis-Oliveira et al. (2008).

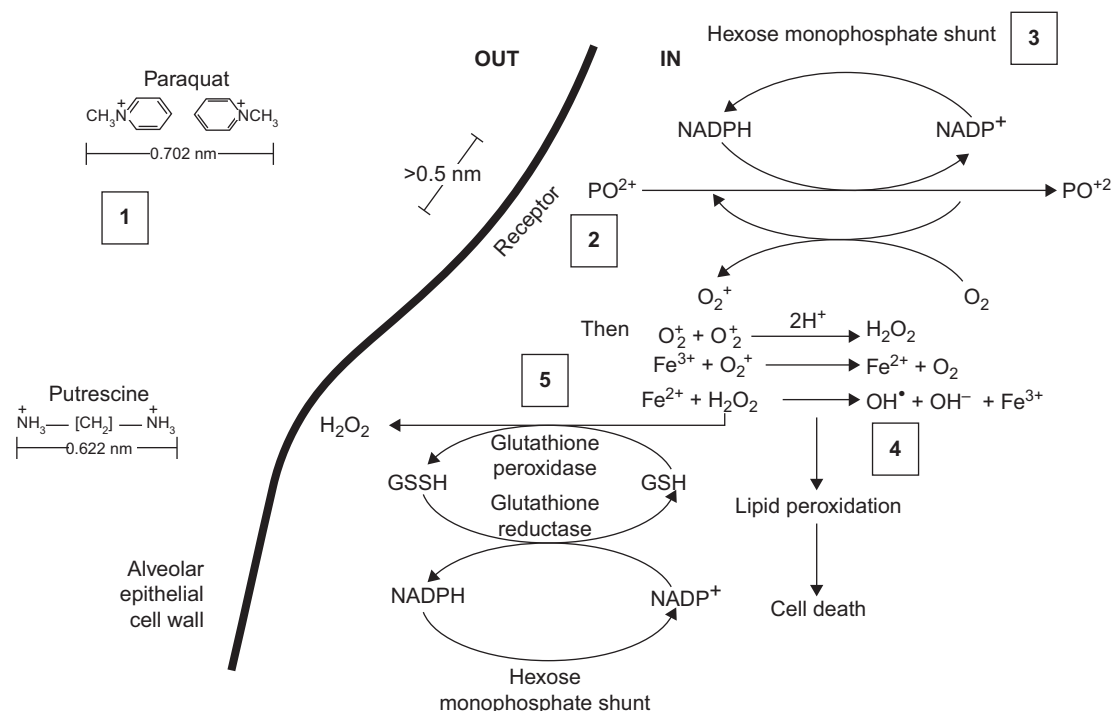
Unlike paraquat, diquat does not accumulate in the lungs; however, its presence is observed in the liver, kidney, plasma, and adrenal gland. Diquat does not enter the brain (Rose et al., 1976). Following oral administration, 90%−98% of the dose is eliminated via the urine. Metabolism studies indicate some unidentified metabolites of diquat in the urine of rabbits and guinea pigs. In rats, diquat monopyridone has been identified


FIGURE 27.5 Schematic representation of mechanism of toxicity of paraquat. (1) Structure of paraquat and putrescine; (2) putative accumulation receptor; (3) redox cycling of paraquat, utilizing NADPH; (4) formation of hydroxyl radical (OHᵒ), leading to lipid peroxidation; and (5) detoxication of H_2O_2 via GSH reductase peroxidase couple, utilizing NADPH. *Reproduced with permission from Smith, L.L., 1997. Paraquat. In: Sipes, I.G., McQueen, C.A., and Gandolfi, A.J. (Eds.), Comprehensive Toxicology: Toxicology of the Respiratory System, vol. 8. Pergamon, New York, pp. 581–589.*

in the feces, at about 5% of an oral dose, whereas diquat-dipyridone has been detected in urine. These results indicate that diquat is probably metabolized by GI bacteria (Daniel and Gage, 1966; JMPR, 1993).

Amides and Acetamides

The commonly used herbicides include bensulide, dimethenamid-P, and propanil. They are slightly to moderately hazardous in normal use. Dimethenamid is a racemic mixture of the M and P stereoisomers, whereas the P isomer has useful herbicidal activity. Dimethenamid can reduce fetal body weights but is not teratogenic (Gupta, 2018b). Dimethenamid is slowly but well absorbed after oral administration (90% in rats) and is extensively metabolized in rats. The maximum concentration in blood is not achieved until about 72 h. Excretion is primarily via bile. By 168 h after treatment, an average of 90% of the administered dose is eliminated. In rats, the concentration of radioactivity in blood decreases more slowly than in other tissues and is associated with specific binding to globin (not in humans). Metabolism is primarily via the GSH conjugation pathway, but racemic dimethenamid is also metabolized by cytochrome P450 enzymes via reductive dechlorination, oxidation, hydroxylation, o-demethylation, and cyclization pathways, as well as conjugation with glucuronic acid. Unchanged dimethenamid in excreta accounts for only 1%–2% of the administered dose; more than 40 metabolites have been detected (JMPR, 2005).

Imidazolinones

Imidazolinone herbicide was discovered in the 1970s, with the first US patent awarded in 1980 for imazamethabenz-methyl. Imidazolinone herbicides include imazapyr, imazapic, imazethapyr, imazamox, and imazaquin. These herbicides are relatively nontoxic. The relatively high ADIs suggest that this class of compounds does not pose a concern for chronic dietary exposure to humans. Imidazolinone herbicides are not reproductive toxicants, developmental toxicants, or teratogens. Following single oral doses of imazapyr, imazapic, imazethapyr, imazamox, or imazaquin, these imidazolinone herbicides are rapidly absorbed and excreted. Although imazamethabenz-methyl is also rapidly absorbed in the rat, greater than 60% becomes metabolized via hydrolysis of the ester to imazamethabenz acid, which is rapidly excreted in the urine within 24 h. The presence of a significant amount of unchanged parent or metabolite in the urine within 24–48 h indicates a low potential for bioaccumulation of parent compound or acid metabolite in mammalian tissues (Hess et al., 2010).

Triazolopyrimidine

Triazolopyrimidine herbicides include cloransulammethyl, diclosulam, florasulammethyl, flumetsulam, and metosulam. In general, they exhibit very low mammalian toxicity. In repeat-dose toxicity studies, the liver and kidneys have been identified as target organs with effects that were often adaptive in nature. This group of herbicides did not affect reproduction or fetal development or multigenerational reproduction. No evidence of maternal toxicity, embryo-fetotoxicity, or teratogenicity has been observed in experimental animals (EPA, 1997a,b; Billington et al., 2010). Triazolopyrimidines are rapidly absorbed, and the excretion is mainly through urine with small amounts being excreted in feces. They have a low potential for bioaccumulation. The only metabolite present is the 4-OH phenyl derivative and/or oxidation product. In metosulam toxicity, demethylation of the 3-methyl moiety of the phenyl ring and of the 3-methoxy moiety of the pyridine ring and other conjugation products of the parent material has been observed. Other minor metabolites include hydroxylated products of the pyridine ring, though the position of hydroxylation has not been identified. Because of rapid elimination, there is little potential for accumulation in the tissues (Billington et al., 2010).

Phosphonomethyl Amino Acids or Inhibitors of Aromatic Acid Biosynthesis

Inhibitors of aromatic acid biosynthesis (organic phosphorus), broad-spectrum, nonselective, postemergent, systemic herbicides with activity on essentially all annual and perennial plants have been developed. Monsanto discovered the herbicidal properties of glyphosate in 1970, and the first commercial formulation was introduced in 1974, under the brand "Roundup." Another compound, glufosinate (Basta), is marketed as the isopropyl amine. Trimethylsulfonium salts of glyphosate and the ammonium salt of glufosinate have low acute oral toxicity in mice and rats and are unlikely to pose acute hazard in normal use. No adverse effects on reproduction or development toxicity have been reported. These compounds are poorly absorbed both orally and via the dermal route. These herbicides are rapidly eliminated, and they are neither biotransformed nor accumulated in tissues. More than 70% of an orally administered dose of glyphosate is rapidly eliminated through feces and 20% through urine. The main metabolite of glyphosate is aminomethylphosphonic acid (AMPA); the AMPA is of no greater toxicological concern than its parent compound (JMPR, 2004).

Others

Carbamates, thiocarbamates, and dithiocarbamate compounds include derivatives of carbarnic acid (asulam, barban, chlorpropham, chlorbufam, karbutilate, and phenmedipham), derivatives of thiocarbarnic acid (butylate, cycloate, diallate, EPTC, molinate, and triallate), and derivatives of dithiocarbarnic acid (methamsodium). These herbicides have low-to-moderate toxicity in rats and do not pose acute hazards, but chlorpropham at high oral doses given during the organogenesis period caused malformations and various types of development toxicity (Gupta, 2018b).

There are several other herbicides that may cause various types of severe abnormalities or lead to developmental and reproductive abnormalities in animals. As such, most of them either have been banned or have restricted use. For example, aminotriazole or amitrole causes fetal thyroid lesions, as it is also an antithyroid agent (Shalette et al., 1963). Butiphos was reported to be teratogenic in the rabbit but was not so in the rat (Mirkhamidova et al., 1981). Chloridazon caused only resorptions in the rat but caused rib and tail anomalies in hamster fetuses of several litters. Prometryn produced head, limb, and tail defects in rat fetuses following daily administration during gestation (Schardein, 2000). Dinitrophenol compounds such as DNP (2,4-dinitrophenol), DNOC, dinoseb, and dinoterb are highly hazardous to animals and may cause developmental toxicity. Dinoseb is known to have teratogenic effects in several species. The compound when given by gavage to rats at maternally toxic doses reduced fetal body weight and increased the frequency of extra ribs. In rabbits, after dermal exposure, eye defects and neural malformations accompanied by maternal toxicity have been reported. With dinitro compounds, abortions have been reported in sows (Lorgue et al., 1996). Most of these chemicals have been banned from use in the United States. Dinoterb, another chemical of the same group, induced skeletal malformations by both oral and dermal administration in the rat, and skeletal, jaw, head, and visceral malformations in the rabbit (Schardein, 2000).

Compound such as astridiphane, a dinitroaniline compound, was a potent developmental toxicant in the mouse, and induced cleft palate and other toxicity at maternally toxic doses, but under the same conditions in the rat the compound increased the frequency of minor skeletal variations (Hanley et al., 1987).

Fungicides

Fungicides are agents that are used to prevent or eradicate fungal infections from plants or seeds. In agriculture, they are used to protect tubers, fruits, and vegetables during storage or are applied directly to ornamental plants, trees, field crops, cereals, and turf grasses. Numerous substances having widely varying chemical constituents are used as fungicides. Fungicides

have been classified according to chemical structures or have been categorized agriculturally and horticulturally according to the mode of action (Ballantyne, 2004). According to the mode of application, fungicides are grouped as foliar, soil, and dressing fungicides. Foliar fungicides are applied as liquids or powders to the aerial green parts of plants, producing a protective barrier on the cuticular surface and systemic toxicity in the developing fungus. Soil fungicides are applied as liquids, dry powders, or granules, acting either through the vapor phase or by systemic properties. Dressing fungicides are applied to the postharvest crop as liquids or dry powders to prevent fungal infestation, particularly if stored under less than optimum conditions of temperature and humidity. With a few exceptions, most of the newly developed chemicals have a low order of toxicity to mammals. Public concern has focused on the positive mutagenicity tests obtained with some fungicides and the predictive possibility of both teratogenic and carcinogenic potential. The quantity of fungicides used on major crops is estimated to have increased 2.3-fold between 1964 and 1997. Use of inorganics such as sulfur, lime, copper, and mercury compounds has declined since the 1960s, but captan, chlorothalonils, and other organic materials account for 90% of fungicide use. Newer groups, such as benzimidazoles, conazoles, dicarboximides, and metal organic compounds, account for $\sim$10% of fungicide use (Osteen and Padgitt, 2002).

Dialkyldithiocarbamates

Ethylenebisdithiocarbamate (EBDCs) fungicides are commonly used to control about 400 fungal pathogens on more than 100 crops. All members have an ethylenebisdithiocarbamate backbone, with different metals associated with the individual compounds. Out of five (mancozeb, maneb, metiram, zineb, and nabam), mancozeb, maneb, and metiram are the most widely used EBDCs. Zineb is used to a lesser degree, and nabam is no longer used in agriculture. The EBDCs have very low acute toxicity by the oral, dermal, and respiratory routes. Mancozeb, maneb, and metiram are unlikely to present an acute exposure hazard under conditions of normal use (Freudenthal et al., 1977).

Toxicokinetics and metabolism of mancozeb, maneb, and metiram in laboratory animals have indicated that the EBDCs are only partially absorbed, then rapidly metabolized, and excreted with no evidence of long-term bioaccumulation. Absorption of oral doses is rapid. Most of the administered dose is excreted within 24 h, with about half eliminated in the urine and half in the feces. Biliary excretion is minimal, indicating that only $\sim$50% of oral doses are absorbed.

Only low level residues are found in tissues, principally in the thyroid.

Ethylenethiourea (ETU) is the major metabolite. On average $\sim$7.5% of an EBDC dose administered to rats is metabolized to ETU on a weight basis. The spectrum of metabolites produced in laboratory animals points to two common metabolic pathways (Fig. 27.6), both leading ultimately to the formation of glycine and incorporation into natural products. In the predominant pathway quantitatively, the dithiocarbamate linkages are hydrolyzed to produce ethylenediamine (EDA) directly, and EDA is oxidized to glycine, joining the intermediary metabolic pool at this point. The other pathway is responsible for the toxic effects of the EBDCs and involves oxidation to ethylenebisisothiocyanate sulfide and then to ETU, various derivatives of ETU, and ethyleneurea (EU) before rejoining the main pathway with conversion to EDA, glycine, and other natural products (Hurt et al., 2010).

ETU reversibly inhibits thyroid peroxidase-catalyzed iodination and coupling of tyrosine residues into the thyroid hormone. The correlation of thyroid hormonal changes with hypertrophy, hyperplasia, and neoplasia has been clearly demonstrated in specific studies of ETU in rats (Chhabra et al., 1992).

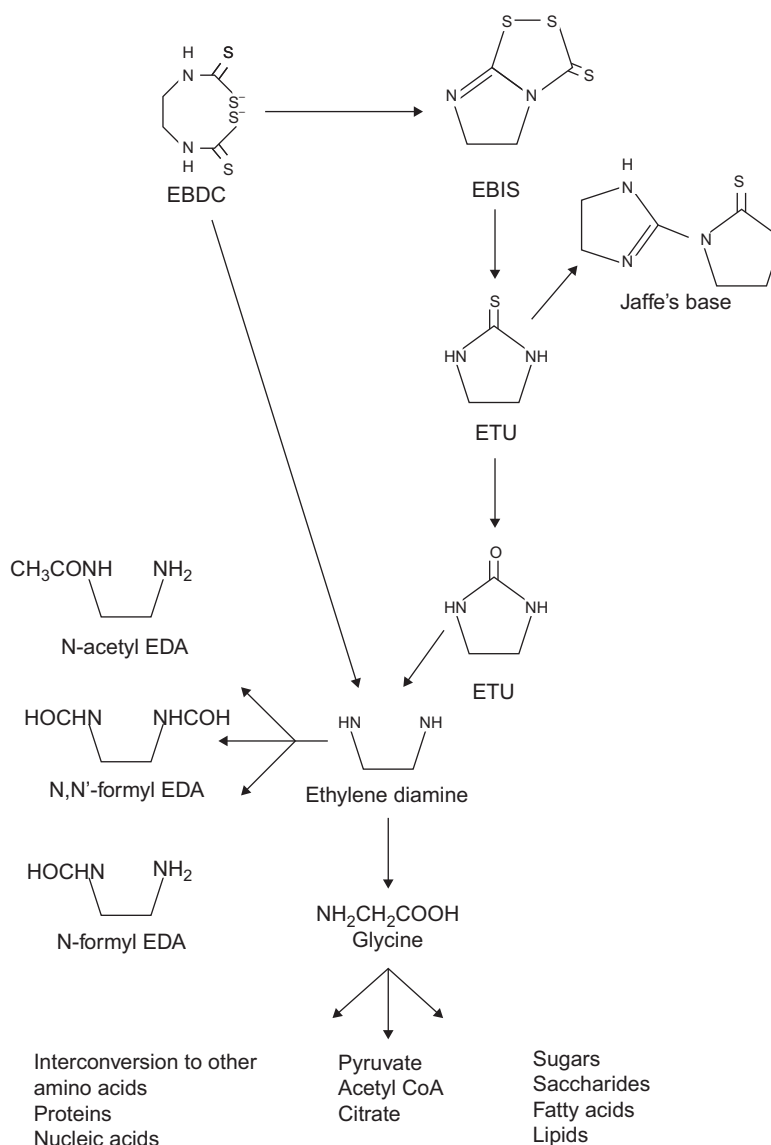
Based on various parameters, using individual toxicology databases for the respective EBDCs, mancozeb, maneb, and metiram, and their ETU metabolite, indicate an overall NOAEL of 5.0 mg/kg bw/day for the group (Fig. 27.7). Application of a standard 100-fold overall safety factor leads to a recommended acceptable daily intake (ADI) of 0.05 mg/kg/day. The factors discussed above for ETU, and the unusual reliability of the database, reflecting the combined results of four individually comprehensive databases, confirm that no additional uncertainty factors need be applied. This aggregate assessment produces a comparable, if slightly higher, estimate of the ADI than the FAO/WHO recommendation. The WHO panel reviewed the data for each of the actives individually and established ADIs of 0.05 mg/kg/day for mancozeb and maneb, and 0.03 mg/kg/day for metiram, resulting in the allocation of a group ADI of 0.03 mg/kg/day for the EBDCs collectively, including mancozeb, maneb, metiram, and zineb. The basis for the establishment of a group ADI was the similarity of the chemical structures of the EBDCs, the comparable toxicological profile of the EBDCs based on the toxic effects of ETU, and the fact that the parent EBDC residues cannot be differentiated using presently available regulatory analytical procedures (FAO/WHO, 1994). Because of their importance to worldwide agriculture, the EBDCs and ETU have been thoroughly tested over many years. Collectively, the data demonstrate that the use of the


FIGURE 27.6   Metabolic pathway of ethylenebisdithiocarbamate. Hurt et al. (2010).

EBDCs results in essentially negligible exposure to consumers and low risk to farm workers, production workers, and people who are exposed through recreational activities (Hurt et al., 2010).

As ETU is the major and common metabolite of EBDCs, it can be used as a biomarker for EBDC exposures. Colosio et al. (2002) used ETU and mancozeb as an indicator of mancozeb exposure to vineyard workers. In this study, urine levels of ETU were significantly increased in workers after the work shift. However, the number of workers considered in this study was low. In another study with a comparatively larger group of workers, the authors concluded that, altogether, the

differences between exposed and controls were not consistently correlated to any clinical impairment and suggested that the seasonal application of mancozeb does not pose a significant health risk to exposed subjects (Colosio et al., 2002).

Anilinopyrimidines

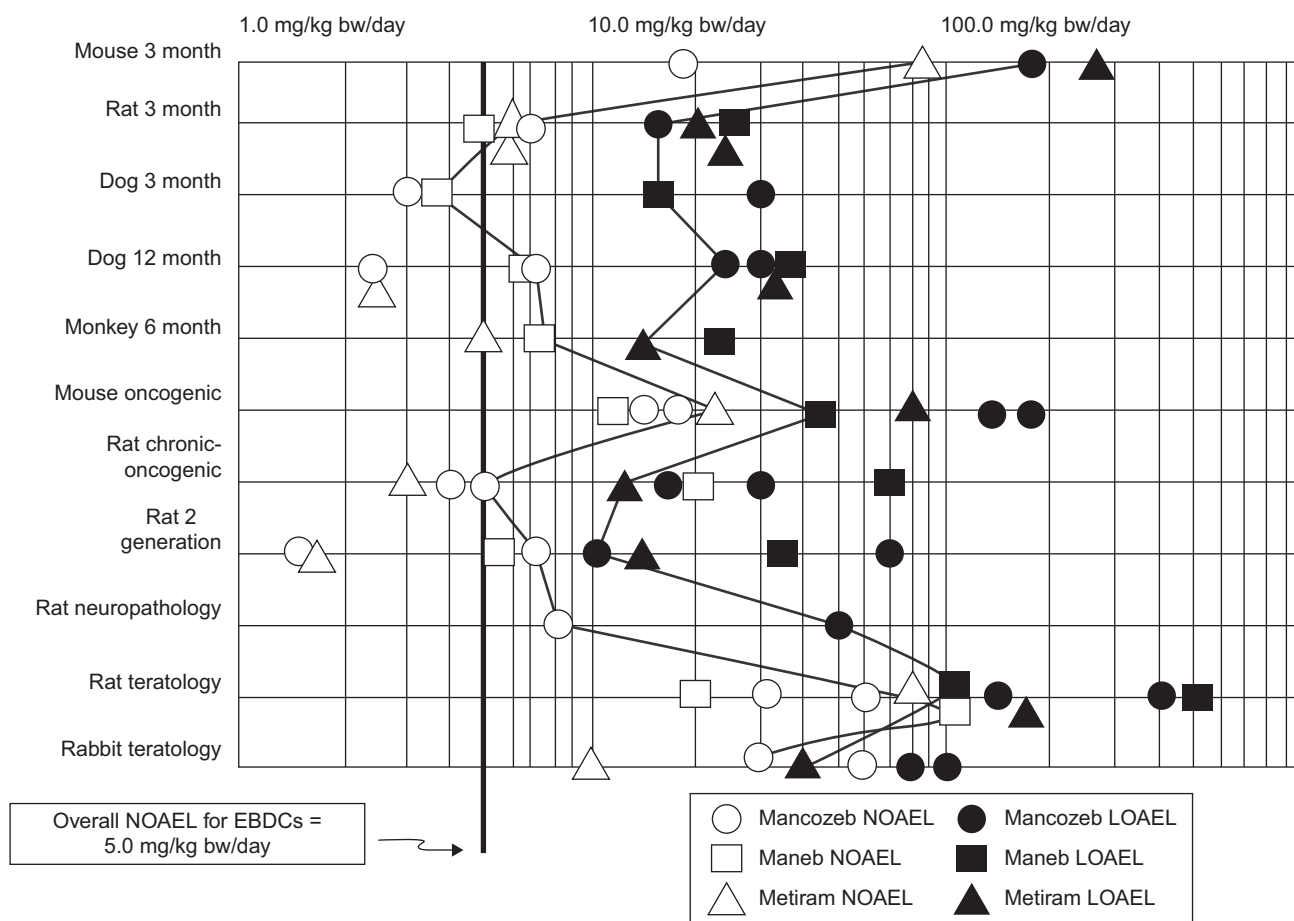
Anilinopyrimidines are a new chemical class of fungicides that are highly active against a broad range of fungi. The anilinopyrimidine class of fungicides includes cyprodinil, mepanipyrim, and pyrimethanil. The compounds have low toxicity and are unlikely to present acute hazards in normal use. Cyprodinil


FIGURE 27.7 Summary of critical doses (NOAELs) for different EBDCs from various toxicology studies. Hurt et al. (2010).

produces hepatomegaly with hepatocellular hypertrophy and increased thyroid weights associated with follicular cell hypertrophy and hypochromasia in rats. Mepanipyrim causes hepatocellular fatty vacuolation and lipofuscin deposition in Kupffer cells and hepatocytes of dogs, whereas such changes are not observed in cyprodinil-treated rats (Terada et al., 1998). Pyrimethanil produces thyroid follicular cell tumors in rats and enhancement of hepatic thyroid hormone metabolism, which may be responsible for thyroid tumorigenesis (Hurlety, 1998). The findings in the thyroid were considered to be secondary to liver changes. Enhancement of hepatic thyroid hormone metabolism and excretion are considered to be the mode of action of thyroid tumorigenesis. Cyprodinil induced microsomal protein and cytochrome P450 contents along with ethoxyresorufin O-deethylase, pentoxyresorufin O-depentylase, and lauric acid 11- and 12-hydroxylase, and cytosolic glutathione S-transferase activities in rats. Cyprodinil and mepanipyrim induce the opposite effects on liver and blood lipid parameters in rats. In general, anilinopyrimidines do not have adverse effects on developmental toxicity. They are neither genotoxic nor have any carcinogenic potential (Waechter et al., 2010).

In rats, cyprodinil was almost completely metabolized. No unchanged parent molecule could be found in urine, whereas minor amounts of unchanged cyprodinil were found in feces. Most of the administered cyprodinil was metabolized by sequential oxidation of the phenyl and pyrimidine ring. The major phase 1 metabolite was identified as 4-cyclopropyl-5-hydroxy-6-methyl-N-(4-hydroxy)-phenyl-2-pyrimidinamine (metabolite 2). This metabolite was excreted in the urine as β-glucuronic acid conjugate, as well as mono- and disulfuric acid conjugates. Although female rats formed the monosulfate almost exclusively, the males excreted equal amounts of the mono- and disulfate. Further oxidation of the methyl group led to the formation of 4-cyclopropyl-5-hydroxy-6-hydroxymethyl-N-(4-hydroxy)-phenyl-2-pyrimidinamine (metabolite 3), which was excreted in the urine in unconjugated form.

Alternative pathways proceeded either by sequential oxidation of the phenyl ring to the 4-hydroxy and 3,4-dihydroxy derivatives (metabolites 4 and 5), followed by oxidation of the methyl group (metabolite 6), or started with hydroxylation of the methyl group as the first oxidation step (metabolite 9). Urinary and biliary metabolites were found to be conjugated with β-glucuronic acid and sulfuric acid. The major metabolites identified in feces were the 5-hydroxypyrimidine derivative of cyprodinil (metabolite 1) and metabolite 4. Metabolites 1 and 4 also were present in conjugated form in urine and bile.

Two additional metabolites were found in liver and/or kidney tissue but not in excreta. Metabolite 7 was identified as ring-hydroxylated N-phenyl-guanidine, a breakdown product of the pyrimidine ring moiety. Metabolite 8 (i.e., 4-cyclopropyl-6-methyl-pyrimidine-2-ylamine) demonstrated a cleavage of the parent molecule between the pyrimidine and the phenyl ring. Metabolite 7 was found exclusively in the liver, where

it represented the major metabolite. Minor amounts of metabolite 8 were found in the liver and kidneys. It seems the metabolism of cyprodinil in humans has not been documented in the scientific literature.

The metabolism of cyprodinil in rats is summarized in Fig. 27.8.

Chloroalkylthiodicarboximides (Phthalimides)

This class of chemicals contains broad-spectrum fungicides (captan, folpet, captafol, etc.) used as surface protectants on many crops. Captan and folpet have been in use for over 55 years. They are usually nontoxic to mammals. Some compounds of this class cause developmental effects, whereas others do not, perhaps because of, and/or masked by, maternal toxicity and possible nutritional deficits (Costa, 1997). Captan induces hyperplasia of the crypt cells. Following treatment with folpet, immune function is reduced, villi length is reduced, and crypt compartments are expanded, thereby reducing the villi-to-crypt ratio in
FIGURE 27.8 Phase I metabolism of cyprodinil in rats. Waechter et al. (2010).

mice (Tinston, 1995; Waterson, 1995). Captafol differs from captan and folpet in a number of ways, including structure and chemical activity. Both of them have low acute toxicity. They are not carcinogenic, mutagenic, or teratogenic. They are neither selective developmental toxicants nor reproductive toxicants. They are irritant to mucus membranes, especially of skin after repeated exposures (Gordon, 2010). Recently, the National Toxicology Program (NTP) judged that captafol is reasonably anticipated to be a human carcinogen based on sufficient evidence of carcinogenicity from studies in experimental animals and supporting data on mechanisms of carcinogenesis (NTP, 2011).

The captan is rapidly degraded to 1,2,3,6-tetrahydrophthalimide (THPI) and thiophosgene (via thiocarbonyl chloride) in the stomach before reaching the duodenum. THPI has a half-life of $1-4$ s, and thiophosgene is detoxified by reaction with cysteine or glutathione and is rapidly excreted. The metabolic pathway of captan is presented in Fig. 27.9.

No captan is detected in blood or urine. It is therefore unlikely that these compounds or even thiophosgene would survive long enough to reach systemic targets such as the liver, uterus, or testes. Because of rapid elimination, meat, milk, or eggs from livestock/poultry would be devoid of the parent materials. Humans appear to metabolize captan in a similar manner to other mammals (Krieger and Thongsinthusak, 1993). THPI and thiazolidine-2-thione-4-carboxylic acid (TTCA) have been used as biomarkers in urine for captan exposure via either oral or dermal routes in animals and humans (van Welie et al., 1991; Heredia-Ortiz and
FIGURE 27.9 Metabolic pathway of captan according to available in vivo experiments in animals and in vitro studies (Heredia-Ortiz and Bouchard, 2012).
FIGURE 27.10 Metabolic pathway of folpet according to available in vivo experiments in animals and in vitro studies (Heredia-Ortiz et al., 2011).

Bouchard, 2012; Berthet et al., 2012a). Similarly, along with THPI, phthalimide (PI) and phthalic acid (PA) could be used as biomarkers for human exposure to folpet (Heredia-Ortiz et al., 2011; Berthet et al., 2012b). As stated earlier, these compounds degrade extremely rapidly when thiols are present (Fig. 27.10). In human blood, captan's t1/2 is less than 1 s and folpet's is less than 5 s. Thiophosgene, the reactive degradate that is formed from the trichloromethylthio side chain, reacts not only with thiols but also with other functional groups and its t1/2 is less than 0.6 s. Due to rapid degradation systemic exposure to captan, folpet, or

their common degradate, thiophosgene, is absent. This, along with the low estimated dermal absorption rate of 0.5% per hour, assures that adverse systemic risk in agricultural workers is absent (Gordon, 2010).

Halogenated Substituted Monocyclic Aromatics

This class of chemicals includes chlorothalonil, dicloran, HCB, quintozene, PCP, dichlorophen, dinocap, tecnazene, and chloroneb. Chlorothalonil is a nontoxic halogenated benzonitrile fungicide with broad spectrum activity against vegetable, ornamental, orchard, and turf diseases. Repeated administration of

chlorothalonil causes hyperplasia in the forestomach of rats and mice.

In dogs, there is no evidence of either neoplastic development or the occurrence of preneoplastic lesions in the kidney or stomach. The absence of stomach lesions in dogs is attributable to the anatomical differences between rodents and dogs (dogs do not possess a forestomach). Continued administration of chlorothalonil leads to the development of a regenerative hyperplasia within the renal proximal tubular epithelium. Continued regenerative hyperplasia ultimately results in progression of the kidney lesion to tubular adenoma and carcinoma. Initial cytotoxicity and regenerative hyperplasia within the proximal tubular epithelium are essential prerequisites for subsequent tumor development. The proposed mode of action for the induction of renal toxicity in rodents is outlined in Fig. 27.11. Human relevance to these stomach and kidney tumors is discussed in a review (Wilkinson and Killeen, 1996). Considering that chlorothalonil has been marketed for about 30 years, the reports of adverse effects are very rare.

Chlorothalonil is a reactive molecule toward thio(-SH) groups. It is a soft electrophile with a preference for sulfur nucleophiles rather than nitrogen/oxygen nucleophiles. Such chemicals tend to show reactivity toward protein containing critical S electrophiles rather than toward DNA (containing critical O and N nucleophiles). Following oral administration thiol-derived metabolites were identified in urine; only 3% of the dose appeared in urine with lower proportions excreted as thiol-derived metabolites, indicating that gut microflora may play a role in the disposition and metabolism of chlorothalonil in the rat. At least 80% of the administered dose has been shown to be excreted in feces within 96 h. Bile cannulation studies have confirmed that chlorothalonil undergoes enterohepatic circulation in the rat. A relatively high concentration of about 0.1% was observed in rat kidneys, one of the target organs for chlorothalonil toxicity (Parsons, 2010).

Mechanistic studies have been conducted to determine if a relationship exists between the ability to excrete urinary thiol-derived metabolites of chlorothalonil and to induce renal toxicity. Inhibition of γ-glutamyltranspeptidase using Acivicin (Syngenta, 1985) and renal organic anion transport using probenecid (Syngenta, 1986) decreased urinary thiol-derived metabolite excretion in rats. Administration of the monoglutathione conjugate to rats was shown to produce a qualitatively similar pattern of metabolite excretion to
FIGURE 27.11 Schematic outlining potential pathways of chlorothalonil metabolism in the rat that leads to formation of toxic metabolites within the kidney. Following absorption from the GI tract, chlorothalonil is conjugated to glutathione in the liver. Further metabolic processing results in the formation of cysteine conjugates that may be detoxified via N-acetylase or activated to toxic thiol-derived species. *GIT*, gastrointestinal tract; *GSH*, glutathione. *Reproduced with permission from Parsons, P.P., 2010. Mammalian toxicokinetics and toxicity of chlorothalonil. In: Krieger, R. (Ed.), Hayes' Handbook of Pesticide Toxicology, third ed. vol. 2. Elsevier, New York, NY, pp. 1951–1966.*

that seen following administration of chlorothalonil itself (Syngenta, 1987a,b). These studies indicate that excretion of thiol-derived metabolites of chlorothalonil requires glutathione conjugation and then subsequent enzymatic processing of glutathione-derived conjugates that are selectively accumulated within the kidney. By analogy with other chemicals that undergo extensive glutathione conjugation, it is reasonable to presume that metabolism proceeds via cysteine conjugates and N-acetyl cysteine conjugates ("mercapturates") as outlined in Fig. 27.12 (Parsons, 2010).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

To recognize whether a subject is exposed to herbicides and fungicides, or even accidental poisoning, standardized analytical procedures for diagnostic investigation of biological materials have become established. Accurately assessing exposure to these chemicals is critical in determining health outcomes that are associated with exposures and for evaluating the success of risk mitigation strategies. Biomonitoring is an important tool that can be used to evaluate human exposure to such xenobiotics by measuring the levels of these chemicals, their metabolites, or altered biological structures or functions in biological specimens or tissue. These measurements in biological media reflect human exposure to xenobiotics through all relevant routes and can therefore be used to monitor aggregate and cumulative exposures. Therefore, biomonitoring is a systematic continuous or repetitive activity of collection of biological samples for analysis of concentrations of xenobiotics, their metabolites, or specific nonadverse biological effect parameters for immediate application, with the objective to assess exposure and health risk to exposed subjects.

Although the biomonitoring data are not without their limitations, they still remain a viable tool and there is still much work left to be done. With existing data gaps, we may have more uncertain estimates of risks or health outcomes, but the biomonitoring data at least give us a starting point for our endeavors. We must continue and strive hard to fill in these gaps so that we can better interpret the data we generate.

Polychlorinated Biphenyls, Polybrominated Biphenyls, and Brominated Flame Retardants

Prasada Rao S. Kodavanti[1], Bommanna G. Loganathan[2]

[1]Neurotoxicology Branch, Toxicity Assessment Division, National Health and Environmental Effects Research Laboratory, Office of Research and Development, U.S. Environmental Protection Agency, Research Triangle Park, NC, United States; [2]Department of Chemistry and Watershed Studies Institute, Murray State University, Murray, KY, United States

INTRODUCTION

Polychlorinated biphenyls (PCBs), polybrominated biphenyls (PBBs), and brominated flame retardants (BFRs) belong to a group of chemicals known as organohalogens. Organohalogens are organic compounds that contain chlorine, bromine, or fluorine atoms and the molecules are named as chlorinated, brominated, or fluorinated hydrocarbons, respectively. These compounds share common characteristics such as persistence in the environment, bioaccumulate in living organisms, long-range transport beyond the geographical regions of their use, and long-term health effects in wildlife and humans. Even though some of these compounds (e.g., PCBs and PBBs) have been banned or severely restricted in use in developed countries for more than three decades, they are still found in every component of the global ecosystem and pose a threat to human health (Kodavanti and Loganathan, 2017). Following the ban on production and usage, levels of regulated organohalogens have declined in the environment (Loganathan and Lam, 2012; Loganathan et al., 2016a,b). However, newly discovered organohalogens such as BFRs have taken their place and continue to be manufactured for commercial use. BFRs are widely used as flame retardants in a variety of consumer products and are considered to be emerging chemicals of concern with regard to human health and sustainability of the ecosystem (Guo et al., 2012; Kodavanti and Loganathan, 2016). These persistent organic chemicals have been shown to cause a variety of effects in humans including neurotoxic effects in children (Berghuis et al., 2015). This chapter focuses on physicochemical properties, environmental contamination and human exposure, health effects, and mode of action with particular emphasis on biomarkers of exposure and effects for two well-known and already regulated persistent chemical groups such as PCBs and PBBs, and the emerging persistent chemical group such as BFRs, which are partially regulated in some countries.

POLYCHLORINATED BIPHENYLS

The commercial production of PCBs began in 1929. PCBs were introduced under a number of trade names and sold in many different countries. Aroclor was the most common trade name for PCBs in the United States. PCB mixtures were named according to their chlorine content, Aroclor 1254 containing 54% chlorine by weight, and Aroclor 1260 containing 60%. PCB mixtures were produced for a variety of uses, including fluids in electrical transformers and capacitors, heat transfer fluids, hydraulic fluids, lubricating and cutting oils, and as additives in plastics, paints, copying paper, printing inks, adhesives, and sealants.

Physicochemical Properties and Environmental Levels

PCBs are colorless to light yellow, have no odor, and are a tasteless oily liquid or solids (Table 28.1). Some PCBs are volatile and may exist as a vapor in air. The physicochemical properties of PCBs depend on the number and positions of chlorine atoms in the biphenyl

TABLE 28.1 Physical and Chemical Properties of Polychlorinated biphenyls (PCBs), polybrominated biphenyls (PBBs), and Polybrominated Dipheny Ethers (PBDEs)

Property	PCBs	PBB (Hexa-, Octa-, and Deca-BB	PBDEs (Penta, Octa, and Deca)
CAS Numbers	Aroclor 1016−12674-11-2 Aroclor 1254−11097-69-1 Aroclor 1260−11096-82-5	HexaBB − 36355-01-8 OctaBB − 27858-07-7 DecaBB − 13654-09-6	Penta − 32534-81-9 Octa − 32536-52-0 Deca − 1163-19-5
Physical state at room temperature	Oil to viscous liquid	White solid	Viscous liquid to powder
Molecular weight (g/mol)	188 to 498	627 to 943	Up to 959.22
Water solubility (µg/L at 25°C)	0.0027 to 0.59	3 to 30	<0.1 to 13.3
Boiling point (°C)	275 to 450	Not applicable	300 to >400
Melting point (°C)	1	72 to 386	−7 to 306
Vapor pressure at 25°C (mm Hg)	10^{-12} to 10^{-4}	5.2×10^{-8}	2.2×10^{-7} to 3.47×10^{-8}
Octanol-water partition coefficient (log Kow)	4.7 to 6.8	5.53 to 9.10	6.265 to 6.97
Soil organic carbon-water coefficient (Koc)	No data	3.33 to 3.87 (HexaBB)	4.89 to 6.80
Henry's Law Constant (atm m^3/mol)	2.9×10^{-4} to 4.6×10^{-3}	1.38×10^{-6} to 5.7×10^{-3}	1.2×10^{-5} to 4.4×10^{-8}

rings (Fig. 28.1). PCBs resist both acids and alkalis and are thermally stable. These properties made them useful in a wide variety of industrial applications but contribute to their persistence in the environment. Generally, PCBs are relatively insoluble in water, with solubility decreasing with increasing chlorination (Table 28.1). However, PCB congeners are readily soluble in nonpolar organic solvents and biological lipids. PCBs entered the earth's ecosphere primarily during their manufacture and use in a variety of applications. PCBs also entered the environment from accidental spills and leaks during the transport of PCB-containing materials.

Once in the environment, PCBs do not readily break down and therefore remain for very long periods. PCBs can easily cycle between air, water, and soil. For example, PCBs can enter the air by evaporation from both water and soil. In air, PCBs can be carried long distances from where these compounds are released and have been found in snow and seawater as far away as the Arctic and Antarctic (Macdonald et al., 2000; Corsolini, 2012). This has resulted in extended contamination and distribution throughout the global environment. Because of their persistent and lipophilic properties, PCBs bioaccumulate in various lower trophic organisms plankton, moving up the food chain through plankton, bivalve mollusks, fish, reptiles, marine mammals, birds, terrestrial mammals and including humans (Loganathan and Kannan, 1994; Loganathan and Lam,

2012). In concurrence with these findings, these compounds have been detected in fish and other food products. The primary route of human exposure to PCBs is through consumption of contaminated foods such as freshwater fish, dairy products, and meat. Unexpectedly, high levels of these compounds have been found in human adipose tissues, and blubber of marine mammals (Loganathan et al., 1993, Loganathan and Kannan, 1994).

Human Health Effects and Modes of Action

Information on health effects of PCBs first became available from studies of people accidentally exposed by consumption of contaminated rice oil in Japan in 1968 ("Yusho" incident) and Taiwan in 1979 ("Yu-Cheng" incident). Major symptoms of Yusho disease included acne form eruptions, pigmentation of the skin, nails, and conjunctivae, increased discharge from the eyes, and numbness of the limbs (Yusho Support Center, 2007). PCB exposures have been associated with low birth weight and learning and behavioral deficits in children of women who consumed PCB-contaminated fish from Lake Michigan (Jacobson and Jacobson, 1996). Health effects that have been associated with general environmental exposure to PCBs in humans and/or animals include histopathological and metabolic changes in liver, thyroid, dermal and ocular tissues/organs, immunological alterations, neurodevelopmental
FIGURE 28.1 Generalized structure of polychlorinated biphenyls (PCBs) and structures of selected PCB congeners. The numbers in the generalized structure indicate the position for chlorines. The letters (*o*), (*m*), and (*p*) indicate *ortho*-, *meta*-, and *para*-substitutions for chlorine side groups. Predominant non–dioxin-like (PCB 47 and PCB 153) and dioxin-like (PCB 77) are shown here as examples.

changes, reduced birth weight, reproductive toxicity, and cancer. Our studies have shown neurobehavioral changes in adult animals and in animals that were exposed to PCBs during development (Kodavanti et al., 2000, 2010). Animals that were prenatally, postnatally, or perinatally exposed to PCBs showed many of the behavioral characteristics indicative of attention deficit hyperactivity disorder.

Apart from effects on motor activity, PCBs have been shown to decrease cognitive function in rats, nonhuman primates, and mice. Gender differences have been reported in a study where developmental exposure to PCBs significantly interfered with acquisition of the spatial alternation task in females, but not in males. Studies also indicated that perinatal exposure to Aroclor 1254 impaired radial arm maze performance in male rats and affected long-term potentiation in the dentate gyrus of the hippocampus. In nonhuman primates, developmental exposure to Aroclor 1016 or Aroclor 1248 resulted in long-term changes in cognitive function (Kodavanti et al., 2008). Other effects seen with developmental exposure to PCBs include sensory deficits. The most significant effect seen with developmental exposure to PCBs was deficits in hearing; the auditory threshold at low frequency (1 kHz) was significantly

increased. PCB exposure during development has no significant effect on visual-, somatosensory-, or peripheral nerve-evoked potentials. These animal studies clearly indicated that developmental exposure to PCBs resulted in cognitive dysfunction, motor deficits, and hearing loss.

With regard to mode of action, coplanar PCBs (chlorine substitutions in *para* and *meta* positions in the biphenyl molecule) seem to elicit dioxin-like toxicity via AhR-mediated toxicity leading to the development of cancer. However, planar non–dioxin-like PCBs seem to exert neurotoxicity through their effects on thyroid hormones (THs) and intracellular signaling processes (Kodavanti and Tilson, 1997; see section "Perturbed Calcium Homeostasis and Kinase Signaling as Biomarkers of Effect" for details on the mode of action).

POLYBROMINATED BIPHENYLS

PBBs are a class of brominated hydrocarbons consisting of a central biphenyl structure to which 1–10 bromine atoms are attached (see Fig. 28.2). PBBs are a synthetic chemical mixture, not found in nature. Commercial scale production of PBBs was carried out using

Generalized structure of PBB

2,2',4,4',5,5'-Hexabromobiphenyl

2,2',3,4,4',5,5'-Heptabromobiphenyl

FIGURE 28.2 Structural features of polybrominated biphenyls (PBBs). Generalized structure and selected PBB congeners of scientific interest are presented here. The numbers in the generalized structure indicate the position for bromines.

Kingdom until 1977, in Germany until the mid-1980s and in France until 2000. It has not been possible to find information on production volumes in Europe. In the United States, total production of PBBs during 1970—76 was estimated to be 6000 tons, of which 98% was FireMaster FF-1 and FireMaster BP-6.

Physicochemical Properties

PBBs are colorless to off-white solids. Based on the number and position of the bromine atoms attached to the two phenyl rings, there are 209 possible individual compounds, referred to as PBB congeners. PBBs have same number of congeners and the bromine substitution pattern and are identical to the PCB congeners (Ballschmiter et al., 1993; Kodavanti and Loganathan, 2016). Therefore, the PBBs share the same IUPAC numbering system as used for PCBs. PBB congeners have a molar mass range from 233 g/mole (for monoBBs) to 943 g/mole (decaBBs) (EFSA, 2010). PBBs are lipophilic and chemically stable compounds with low water solubility and low vapor pressures, which decreases with increasing degree of bromination. The octanol—water partition coefficients (log Kow) and volatility also vary between congeners (Table 28.1). These values are much higher than PCBs and this may contribute to the higher environmental mobility of PBBs as compared with PCBs. In general, PBBs are chemically recalcitrant and are resistant to heat, acids, bases, and oxidation (EFSA, 2010). These unique properties make PBBs highly desirable for industries that produce a variety of consumer products. The same properties make these compounds highly persistent in the environment and bioaccumulative in organisms and contribute to their toxic effects.

PBBs have been detected in air, dust, soil, fish and other seafood, meat and meat products, and milk and dairy products. PBBs were released into the air during manufacture and during incineration of PBB-containing materials. Because PBB-containing materials are no longer in circulation, it is unlikely that incineration is a significant source of PBBs into the atmosphere in recent years. The major former sources of PBBs in soil were production operations and disposal of PBB-containing products. At one point, PBB concentrations in soils near bagging and loading areas of the Michigan Chemical Corporations were 3500 and 2500 mg/kg, respectively (Di Carlo et al., 1978). As studies have shown that root uptake of PBBs in plants is extremely low, the intake by grazing animals might be due to soil ingestion during grazing (EFSA, 2010). The contamination levels of PBBs in biota are generally low. Gotsch et al. (2004) reported <10 ng/g wet weight of PBB-153 in egg sample of a white-tailed eagle in Norway. Von der Recke and Veter (2008) studied PBBs in the blubber

bromination of biphenyl, a process that results in a smaller number of product mixtures than the corresponding chlorination seen in PCBs (Sundström et al., 1976). Worldwide production of PBBs was estimated in 1994 to be 11,000 tons. However, the production statistics were not available in some countries known to have produced this compound (IPCS, 1994). PBBs were used as fire retardant additives in plastics that were used in a variety of consumer products, including furniture, textiles, electronic devices such as computer monitors and televisions, plastic foams, and other household products (ATSDR, 2004; US EPA, 2012). Because of their stability, lipophilic properties, and toxic biological effects, the production of PBBs has been banned in the United States since 1973 (US EPA, 2012). According to Hardy (2002), PBBs were manufactured in the United

of seals and harbor porpoises from the North Sea, the Baltic Sea, and the coastal waters of Iceland and North America. The authors observed hexaBBs dominated in most samples, followed by pentaBBs, heptaBBs, and octaBBs. NonaBBs and DecaBBs were not detected. Jaspers et al. (2005) investigated the occurrence of BB-153 in 39 egg samples from little owls (*Athene noctua)* from Belgium. They reported the concentrations of BB-153 ranged from 1 to 6 ng/g fat (mean 2 ng/g fat, $n = 39$ samples). For comparison, the corresponding levels of polybrominated dipheny ethers (PBDEs) were 10−94 ng/g fat (mean 32 ng/g fat). Recently, detailed studies conducted by the European Food Safety Authority (EFSA, 2010) reported levels of PBBs in fish and other seafood, meat and meat products, milk and dairy products. They found the highest frequency of detectable levels with the lowest proportion of nondetects in the food category of "fish and other seafood (including amphibians, reptiles, snails, and insects)". In a specific study on "fish meat," 9 out of 10 analyzed congeners (BB-15, 49-, 52-, 77-, 80-, 101-, 126-, 153-, and 169) showed increased fat content corresponding with increasing PBB contamination levels (except for BB-209). Shen et al. (2008) reported PBB contamination of human milk from Denmark and Finland indicating that BB-153 is the most frequently found and most abundant congener, with mean levels of 200 pg/g fat ($n = 65$) and 134 pg/g ($n = 65$) fat, respectively. These studies provide evidence of PBBs' widespread contamination and exposure to wildlife and humans.

Human Health Effects and Modes of Action

Humans are exposed to PBBs mainly via consumption of contaminated foods such as fish, dairy, and meat products. As PBBs are lipophilic, these compounds dissolve and accumulate in fat. PBBs have been detected in breast milk of exposed mothers, making mothers' milk a source of exposure to infants. PBBs are known to cross the placenta and to reach the fetuses before birth (ATSDR, 2004). Shen et al. (2008) analyzed PBBs in Danish and Finnish placenta samples and reported over 13 PBB congeners in the samples. BB-153 and BB-155 were the two most commonly detected congeners (detected in 100% and 77% of the samples, respectively). Mean concentrations of BB-153 were 304 and 83 pg/g fat for Danish ($n = 168$) and Finnish ($n = 112$) samples, respectively. The Michigan long-term study (Joseph et al., 2009) reported serum PBB concentrations in 145 mother/child pairs. In serum samples ($n = 112$) from mothers, collected between 1976 and 1979, PBB concentrations ranged from <LOD to 933 µg/L (median 2 µg/L), where LOD is the lowest detectable level of <1 µg/L. Analysis of serum samples of children ($n = 145$), born between 1973 and 1982, during infancy to 17 years old,

showed that 73% of children had PBB levels <1 µg/L (LOD), whereas the remaining 27% of children had PBB concentrations at or >LOD (median 2.9 µg/L). In an another study, Wang et al. (2010) correlated serum PBB levels with TH levels in occupationally exposed people from electronic waste recycling and dismantling activity sites and in nonoccupationally exposed people. Median range of the sum of BB-77, BB-103, and BB-209 was 510.35 (<LOQ−4695) ng/g fat for the occupationally exposed group ($n = 239$). For people living around the electronic waste recycling site (nonoccupational exposure group, $n = 93$), the concentrations were 614 (<LOQ−4050) ng/g fat. For the control (people working in green plantations) group ($n = 116$), the serum contained 246 (<LOQ−5833) ng/g fat. The authors noted, in all three groups, the congener BB-77 was found to be the most abundant with median levels of 340, 440, 180 ng/g fat, respectively, for the three groups. The occurrence of PBBs was also investigated in tissues taken from cancer patients (Zhao et al., 2009). The authors measured 23 PBB congeners in the kidney ($n = 19$), liver ($n = 55$), and lungs ($n = 7$) tissue samples from cancer patients living near electronic waste-dismantling sites. Median (range) of concentrations for the total PBBs was 194 (39−1140), 193 (42−560), and 150 (102−677) ng/g fat for the kidney, liver, and lungs tissue samples, respectively. Fifty-nine percent of the total PBB was contributed by the lower brominated congeners such as PBB-2, BB-10, PBB-15, and PBB-30, whereas PBB-153 alone accounted for over 12% of the total.

PBB congeners have been reported to elicit liver toxicity, liver hyperplasia, and interference with thyroid function, cause endocrine-mediated reproductive effects, and have immunotoxicity, teratogenicity, and developmental and neurobehavioral effects (Roth and Wilks, 2014). Because of their structural similarity with PCBs, PBBs share many structure activity relationships and toxicological properties. Safe (1984) stated that binding to the AhR, induction of AhR-mediated gene expression, and subsequent dioxin-like behavior is the major toxic mode of action of non-*ortho* PBBs (BB-77, BB-126, and BB-169), and mono-*ortho*-brominated congeners in PBB mixtures. Molecular mechanisms are discussed in detail in the section "Induction of Cytochrome P450 Enzymes as a Biomarker of Exposure and Effect."

BROMINATED FLAME RETARDANTS

In the early 1970s, accidental brominated biphenyls (PBBs) poisoning occurred on Michigan farms. Inadvertent mixing of PBBs (trade name: FireMaster) in the production of feed (trade name: NutriMaster) for dairy cattle resulted in the destruction of 1.5 million chickens,

5 million eggs, 29,800 cattle, 34,000 pounds of milk products, 5920 hogs, and 1470 sheep, which cost approximately 75−100 million US dollars (Fries, 1985). After this poisoning episode, PBBs were removed from the market and, as previously mentioned, the United States has banned PBBs since 1973 (US EPA, 2012). Among the BFRs still in the market are brominated bisphenols, diphenyl ethers, and cyclododecanes (Fig. 28.3). These three classes are still produced in large volumes (Shaw and Kannan, 2009) and it is estimated that over 1 million metric tons of PBDEs have been produced. Although the manufacture of penta- and octa-bromo mixtures has ceased, the production of decabromodiphenyl ether

(decaBDE) is still continuing in some countries (Guo et al., 2012). DecaBDE was banned in Sweden in 2007, followed by partial bans in four US states (Washington, Maine, Oregon, and Vermont), the European Union in 2008, and Canada in 2009. The REACH (Registration, Evaluation, Authorization, and Restriction of Chemical substances) program in the European Union announced on February 17, 2011 was the banning of hexabromocyclododecane (HBCD) for all polystyrene used in building insulation (http://ec.europa.eu/environment/chemicals/reach/reach_intro.htm).

PBDEs and other brominated and chlorinated flame retardants still in use are HBCD, decabromodiphenyl
FIGURE 28.3 Chemical structures comparing selected brominated flame retardants (BFRs) with thyroxine (T_4). The numbers in the generalized structure of polybrominated dipheny ethers (PBDE) indicate the position of bromine. The letters (*o*), (*m*), and (*p*) indicate *ortho-, meta-*, and *para*-substitutions for bromine side groups.

ether, tetrabromobisphenol-A (TBBPA), tris(1-chloro-2-propyl) phosphate (TCPP), tris(2-chloroethyl)phosphate, and dechlorane plus. These compounds are used to meet fire safety standards for furniture, textiles, polyurethane foam, plastics used in electric and electronic equipment, printed circuit boards, curtains, carpets, etc. (Alaee et al., 2003; Stapleton et al., 2009; de Wit et al., 2010; Guo et al., 2012). The high production volume and the structural similarities of these brominated chemicals to other well-known toxic environmental contaminants such as DDTs and PCBs are the main concerns for environmental and human/animal health. Furthermore, polybrominated dioxins (PBDDs)/dibenzofurans (PBDFs), formed during heating or incineration of BFRs, have toxicological profiles similar to those of their chlorinated homologs (Birnbaum et al., 2003; DiGangi et al., 2010) but are more toxic than PBDEs. Like other organohalogens, BFRs are ubiquitous in the environment, bioaccumulate, and are toxic to animals and humans (Dye et al., 2007; Kodavanti et al., 2008; Kierkegaard et al., 2009; Guo et al., 2012; Shaw et al., 2012).

Low levels of PBDDs/PBDFs detected in the environmental samples suggest relatively lower exposure of biota (fish) and humans to these compounds.

PBDEs constitute an important group of flame retardants. PBDEs are added to consumer products so the products will not catch fire or will burn more slowly if exposed to flame or heat. PBDEs are added to plastics, upholstery, fabrics, and foams and are in common products such as computers, television sets, mobile phones, furniture, and carpet pads. In contrast to PCBs, PBDEs are currently being produced and used in household goods. PBDEs are primarily indoor pollutants. PBDEs leach into the environment when household wastes decompose in landfills or are incompletely incinerated. PBDE concentrations are rapidly increasing in the global environment and in human blood, breast milk, and liver. Although these chemicals are ubiquitous in the environment and bioaccumulate in wildlife and humans, potential toxic properties are still under investigation (Kodavanti, 2005; Shaw et al., 2010). New alternative flame retardants emerged to replace PBDEs, and Jin et al. (2016) reported species-specific accumulation of PBDEs and other emerging flame retardants in several species of birds from Korea. Human health concerns stem from the fact that PBDEs are persistent, bioaccumulative, and structurally similar to PCBs (see Figs. 28.2 and 28.3).

Physicochemical Properties

Tetrabromobisphenol-A (TBBPA; Fig. 28.3), the highest volume flame retardant worldwide, is primarily (90%) a reactive BFR covalently bound to the polymer structure and less likely to be released into the environment than are additive flame retardants (Birnbaum and Bergman, 2010). It is used mainly for the production of circuit board polymers. TBBPA is highly lipophilic (log $Kow = 4.5$) and has low water solubility (0.72 mg/mL). TBBPA has been measured in the air (Zweidinger et al., 1979), soil, and sediment (Watanabe et al., 1983) but is generally not found in water samples. TBBPA is found in eggs of birds, human milk, and umbilical cord serum. TBBPA derivatives such as ethers are reported to be biologically active, which also may lead to adverse health effects (Birnbaum and Bergman, 2010).

Hexabromocyclododecane (HBCD; Fig. 28.3) is a nonaromatic brominated cyclic alkane with a molecular weight of 641.7 and is mainly used as an additive flame retardant in thermoplastic polymers with final applications in styrene resins (National Research Council, 2000). Like other BFRs, HBCD is highly lipophilic with a log Kow of 5.6 and has low water solubility (0.0034 mg/L) (MacGregor and Nixon, 1997). The melting point is at 185−195°C and vapor pressure is 4.7×10^{-7} mm Hg. Studies have shown that HBCD is highly persistent, with a half-life of 3 days in air and 2025 days in water (Lyman et al., 1990), and is bioaccumulative with a bioconcentration factor of ∼18,100 in fathead minnows (Veith and Defoe, 1979).

PBDEs comprise two phenyl rings linked by an oxygen molecule (thus the designation as "ether"; Fig. 28.3). The phenyl rings may have 1 to 10 bromine atoms, leading to formation of 209 possible congeners. PBDEs take the form of viscous liquid to powder and they are hydrophobic in nature (see additional details in Table 28.1).

The exact identity and pattern of various congeners in various commercial mixtures depends on the manufacturer and the specific product. Among these, the commercial "penta" mixture generally consists of PBDE congeners 99 (pentaBDE) and 47 (tetraBDE) as the major constituents (Fig. 28.3), which make up about 70% of the mixture (Huber and Ballschmiter, 2001). PBDE congener 100 (pentaBDE) is present at less than 10%, with PBDE congeners 153 and 154 (hexaBDEs) at less than 5% each. The commercial "octa" mixture is 10%−12% hexaBDE, 43%−44% heptaBDE, 31%−35% octa-BDE, 9% −11% nona-BDE, and 0%−1% decaBDE. The "deca" commercial mixture consists of 98% decaBDE, with a small percentage of nona-BDEs (World Health Organization, 1994; Hardy, 2000).

Human Health Effects and Modes of Action

TBBPA is of high ecotoxicologic concern because of its acute and chronic toxicity in several biota (US EPA, 2008; Lyche et al., 2015). Although rapidly metabolized by mammalian liver and eliminated in bile, urine, and feces

(Schauer et al., 2006), TBBPA has been detected in various environmental media and biota, including air, soils, water, sediment, and bird muscle, from electronic waste regions of China (Shi et al., 2009; Liu et al., 2016) and in bottlenose dolphins and bull sharks from the Florida Coast (Johnson-Restripo et al., 2008). TBBPA is cytotoxic, immunotoxic, a TH agonist and has the potential to disrupt estrogen signaling (Birnbaum and Staskal, 2004). TBBPA has also been shown to be toxic in rat brain cells in vitro where it causes oxidative stress and calcium influx and inhibits dopamine uptake (Reistad et al., 2007). Recent in vivo studies indicated that neonatal TBBPA exposure causes hearing deficits in rat offspring, similar to those observed following developmental exposure to PCBs (Lilienthal et al., 2008). Nakajima et al. (2009) correlated behavioral alterations following acute treatment with the presence of TBBPA in brain. Disruption of TH homeostasis is proposed to be the primary toxic effect of TBBPA and other BFRs. TBBPA has a closer structural relation to thyroxine (T_4) than PCBs and binds to transthyretin (TTR) with greater affinity than that of the naturally occurring ligand, T_4 (Meerts et al., 2000). The detailed mechanism by which BFRs can disrupt TH homeostasis is illustrated in the next section (Fig. 28.4).

Studies showed that HBCD, the second most used flame retardant, also has endocrine disrupting and reproductive effects (Birnbaum and Staskal, 2004). Many effects of HBCDs seem to occur during development. During developmental exposure, HBCDs have been shown to decrease bone density and retinoids and enhance immune response to sheep red blood cells (van der Ven et al., 2009). HBCD isomers are endocrine disruptors with antiandrogenic properties that inhibit aromatase and interact with steroid hormone receptors (Hamers et al., 2006). Like other BFRs, HBCDs may disrupt TH homeostasis resulting in decreased T_4 levels and increased thyroid-stimulating hormone (TSH) (Ema et al., 2007). Recent studies indicated that low-dose HBCD potentially can disrupt TH hormone receptor—mediated transactivation and impairs cerebellar Purkinje cell dendritogenesis (Ibhazehiebo et al., 2011).

Exposure to PBDEs in domestic/pet animals and humans may occur via multiple sources (air, water, dust, and food; Sjodin et al., 2008; Kodavanti and Loganathan, 2016). There are a few reports indicating high levels of serum PBDEs in household cats because of their high exposure to house dust (Dye et al., 2007). Studies show levels of PBDEs in animal, and human tissues have increased exponentially since the 1970s in the United States, Canada, and Sweden (Schecter et al., 2005; Guo et al., 2012). Elevated levels of PBDEs in North America were attributed to the greater use of the penta BDE mixture compared with the rest of the world. Like other lipophilic compounds, PBDEs readily cross

the placenta into the fetus, providing an opportunity for PBDEs to interfere with human and animal developmental processes. Epidemiological studies indicate that childhood exposure to PBDEs results in neurodevelopmental changes in two cognitive assessments at 6 years of age (Chevrier et al., 2016; see review Linares et al., 2015). Fernie et al. (2017) reported spatiotemporal patterns and relationships among the diet, circulating THs, and exposure to flame retardants in an apex avian predator, the peregrine falcon. The results indicate that rural nestlings had significantly lower circulating TH levels, α-tocopherol, and oxidative status, but higher retinol levels and PBDE-153 when compared with the urban nestlings.

Laboratory studies with animals have indicated that commercial PBDE mixtures and the individual PBDE congeners that compose them affect the nervous, endocrine, reproductive, and immune systems. Regarding neurotoxic effects, several studies indicated that PBDEs, along with HBCDs, cause permanent aberrations in spontaneous behavior and habituation capability in mice after a single exposure at postnatal day (PND) 10 (a period of rapid brain growth and development). It is interesting to note that the effects seen on this behavioral paradigm with PBDEs are identical to those produced by PCBs (Eriksson and Fredriksson, 1996). Recent studies indicated that developmental exposure to a commercial pentabrominated mixture (DE-71) resulted in multiple effects. Although maternal or male body weights were not altered, female offspring were smaller compared with controls from PND 35—60. Exposure to DE-71 also resulted in accumulation of PBDE congeners in various tissues, including the brain, suggesting that PBDEs cross blood—placenta and blood—brain barriers (BBBs). Subtle changes in some parameters of neurobehavior, dramatic changes in circulating TH levels, and changes in both male and female reproductive endpoints were also observed (Kodavanti et al., 2010). In female Wistar rats exposed to DE71 (penta-PBDE mixture), deficits in reference memory have been described without alteration of working memory and hyperactivity (de-Miranda et al., 2016).

In addition to the effects on TH, there is evidence that PBDEs affect the cholinergic neurotransmitter system (Viberg et al., 2003a,b), with roles in memory and motor function. The effects of several PBDE congeners have been compared to PCBs for their ability to affect intracellular signaling in a cerebellar (brain) culture system (Kodavanti and Ward, 2005; Fan et al., 2010). The Ca/protein kinase C signaling pathways have been proposed as an additional mechanism of neurotoxicity for a number of chemicals, including PCBs and PBDEs. The order of potency for their effects on intracellular signaling was DE-71 (a commercial mixture of tetra-, penta-, and hexa-BDEs)>PBDE 47 > PBDE 100 > PBDE

Thyroid Hormone Disruption as a Biomarker of Exposure and Effect
FIGURE 28.4 Schematic representation of thyroid hormone disruption as a biomarker of exposure and effect for polychlorinated biphenyls (PCBs), polybrominated biphenyls (PBBs), and brominated flame retardants (BFRs). Sequential processes by which these compounds may disrupt thyroid hormone homeostasis are illustrated by numbers. (1) PCBs, PBBs, and BFRs enter the circulation from gastrointestinal (GI) tract following exposure. (2) Parent compounds or hydroxylated metabolites can displace thyroxine (T_4) from serum binding proteins such as transthyretin (TTR). The resulting free T_4 will be eliminated following hepatic metabolism. (3) Reduced circulating T_4 levels stimulate the hypothalamic—pituitary axis to synthesize and secrete more T_4 by the thyroid gland. (4) Chemicals that were bound to TTR, along with T_4, will reach target organs, including the brain. (5) These chemicals activate nuclear receptors in liver cells (hepatocytes) initiating transcription of xenobiotic metabolizing enzymes (XMEs) for T_4 elimination. (6) XMEs consequently conjugate T_4 by phase II enzymes, uridine diphosphate glucuronyl transferase (UGT), and sulfotransferase (SULT). (7) Hepatic deiodinase (DI) deiodinates T_4 to its metabolites. (8) Influx transporters (Oatp1a4) further increase the T_4 uptake and metabolism. Efflux transporters eliminate T_4 or its conjugates from hepatocytes into either the serum (Mrp3) or the bile (Mrp2). These compounds do not have any effect on T_4 synthesis in the thyroid gland. *Adapted from Szabo D.T., Richardson V.M., Ross D.G., et al., 2009. Effects of perinatal PBDE exposure on hepatic phase I, phase II, phase III, and deiodinase 1 gene expression involved in thyroid hormone metabolism in male rat pups. Toxicol. Sci. 107, 27—39; Kodavanti P.R.S., Curras-Collazo M.C., 2010. Neuroendocrine actions of organohalogens: thyroid hormones, arginine vasopressin, and neuroplasticity. Front. Neuroendocrinol. 31, 479—496.*

99. On a molar basis, DE-71 was equipotent with Aroclor 1254; the most widely used commercial PCB mixture. A Swedish study found that PBDE 99 and PCB 52 produced effects on behavior when given together but not at the same dose given alone (Eriksson et al., 2006).

The results suggest that there is little difference in neurotoxic potency between PBDEs and PCBs, and that effects of PCBs and PBDEs are additive. This implies that body burdens of PCBs and PBDEs in humans may be combined during the risk assessment of these compounds.

THYROID HORMONE DISRUPTION AS A BIOMARKER OF EXPOSURE AND EFFECT

PBDEs affect the TH system both in vivo and in vitro. In vivo studies show reductions in serum thyroxin (T_4) levels following exposure to PBDEs, both after acute and subacute exposure (Fowles et al., 1994) and after developmental exposure (Kodavanti et al., 2010). The negative correlation between these organohalogens and serum T4 levels has also been demonstrated in a North American human cohort (Makey et al., 2016). Hallgren et al. (2001) showed that PCBs are more potent compounds in reducing circulating T_4 levels than are PBDEs. Interaction studies with human TTR showed that PBDEs have to undergo metabolic activation before the compounds are able to competitively inhibit the binding of T_4 (Hamers et al., 2006). This interaction between PBDEs and TTR, however, appears to vary with species because several PBDE congeners (BDE-47, BDE-99) bind the piscine form of TTR with high affinity (Morgado et al., 2007). These species differences in PBDE interaction with TTR are likely due to differences in the structural properties of mammalian and piscine TTRs (Eneqvist et al., 2004). Zhou et al. (2001) concluded that short-term exposure to some commercial PBDE mixtures interferes with the TH system via upregulation of uridine diphosphate glucuronyl transferases (UGTs) and TH metabolizing enzymes. Richardson et al. (2008) indicated that although there was induction of hepatic UGTs, the decreases in circulating T_4 levels by PBDE 47 exposure might involve other mechanisms. In support of alternative mechanisms, several other reports indicated a good correlation between the degree of TH reduction by PCBs and PBDEs with a decrease in the ex vivo binding of ^{125}I-labeled T_4 to TTR and a lack of correlation with UGT induction (Hallgren et al., 2001; Hallgren and Darnerud, 2002). Further studies indicated that decabromodiphenyl ether (PBDE 209) decreased serum triiodothyronine (T_3) levels, but not T_4 levels, in the absence of any induction of UGTs (Tseng et al., 2008). These studies with PBDEs are similar to the reports on PCBs and support the conclusion that UGTs may not play a significant role in decreasing circulating TH levels by these groups of chemicals. Displacement of T_4 and binding of PCBs or PBDEs with the TTR transport protein might be a critical event in decreasing circulating TH levels.

Szabo et al. (2009) conducted extensive studies on different mechanisms involved in TH disruption after exposure to the PBDE mixture, DE-71. Developmental exposure resulted in significant increases both in hepatic cytochrome P450 enzyme activities and gene expression with significant decreases in hepatic deiodinase I (D1) activity and gene expression. The results from this study indicated that deiodination, active transport, and sulfation, in addition to glucuronidation, may be involved in the disruption of TH homeostasis (Szabo et al., 2009, Fig. 28.4). In addition to the effects on circulating TH levels, PBDEs also interfere with TH receptor (TR)—mediated TH signaling. Schriks et al. (2007) reported that hydroxyl-PBDEs increased T_3-induced thyroid receptor (TR)α-activation, but not T_3-induced TRβ-activation while 2,2′,3,3′,4,4′,5,5′,6-brominated diphenyl ether (PBDE 206) was antagonistic on both TRs. Lema et al. (2008) recently reported depressed plasma T_4 levels in flathead minnows exposed to PBDE 47 and this was accompanied by elevated mRNA levels for TSHβ in the pituitary. PBDE-47 exposure also elevated transcription of TRα in the brain of females and decreased mRNA levels for TRβ in the brain of both sexes of fathead minnows (Lema et al., 2008). The PBDE effects on TR would have physiological implications such as alterations in the development of neuronal cells as reported by Schreiber et al. (2010).

Based on the literature, the possible mechanism(s) of disruption of TH by exposure to PCBs, PBBs, and BFRs are shown in Fig. 28.4. These chemicals enter circulation through gastric absorption. T_4 is synthesized and released into circulation by the thyroid gland. These compounds did not interfere with the synthesis of T_4 by this gland. In circulation, PBDEs displace T_4 from serum binding proteins such as TTR. The resulting free T4 released from TTR will be subjected to hepatic metabolism and elimination.

The reductions in circulating T_4 levels increase TSH production via reduced negative feedback on the hypothalamic—pituitary axis (Lema et al., 2008), which induces increased synthesis and secretion of T_4 by the thyroid gland. PBDEs bound to TTR along with T_4 will reach target organs, including the brain, to elicit their effects. PBDEs activate nuclear receptors initiating transcription of xenobiotic metabolizing enzymes (XMEs) in the liver for T_4 elimination. XMEs consequently conjugate T_4 by phase II enzymes, UGT, and sulfotransferase (SULT). Deiodinase 1 (D1) can deiodinate T_4 to its metabolites. Influx transporters (Oatp1a4) further increase the T_4 uptake for metabolism. Efflux transporters eliminate T_4 or its conjugates from hepatocytes either into the serum (Mrp3) or the bile (Mrp2). Thus, TH disruption by PBDEs involves multiple mechanisms, including phase II glucuronidation and sulfation, TTR displacement, decreased hepatic deiodinase I activity, and increases in hepatic transporter phase III elimination (Fig. 28.4).

PERTURBED CALCIUM HOMEOSTASIS AND KINASE SIGNALING AS BIOMARKERS OF EFFECT

Studies with prototypic *ortho* (2,2′-dichlorobiphenyl, DCB) and non-*ortho* (3,3′,4,4′,5-pentachlorobiphenyl; PeCB or 4,4′-DCB) PCBs followed by extensive structure−activity relationships with more than 35 PCB congeners indicated alterations in intracellular calcium signaling. Increases in free Ca^{2+} ($[Ca^{2+}]_i$) with a fluorescent dye (Fluo-3AM) were reported for the first time; the *ortho*-substituted 2,2′-DCB was more effective than the non-*ortho*-substituted 3,3′,4,4′,5-PeCB (Kodavanti et al., 1993). The increase in $[Ca^{2+}]_i$ was slow, and a steady rise was observed with time (Kodavanti et al., 1993). The follow-up studies confirmed these observations in cerebellar granule neurons (Mundy et al., 1999; Bemis and Seegal, 2000), cortical neurons (Inglefield et al., 2002), and in human granulocytes (Voie and Fonnum, 1998). Studies characterizing the mechanisms of $[Ca^{2+}]_i$ increase indicated that 2,2′-DCB was an inhibitor of $^{45}Ca^{2+}$ uptake by mitochondria and microsomes with IC_{50} (concentration which inhibits control activity by 50%) values of 6−8 μM. 3,3′,4,4′,5-PeCB inhibited Ca^{2+} sequestration, but the effects were much less than those produced by equivalent concentrations of 2,2′-DCB. Synaptosomal Ca^{2+}-ATPase, involved in the Ca^{2+} extrusion process, was only inhibited by 2,2′-DCB, but not by 3,3′,4,4′,5-PeCB (Kodavanti et al., 1993). Further structure−activity relationship (SAR) studies indicated that congeners that are noncoplanar inhibited $^{45}Ca^{2+}$-uptake by microsomes and mitochondria, whereas coplanar congeners did not (Kodavanti et al., 1996a).

The disruption of Ca^{2+} homeostasis may have a significant effect on other signal transduction pathways (e.g., inositol phosphate [IP] and AA second messengers) regulated or modulated by Ca^{2+}. The congener 2,2′-DCB, but not 3,3′,4,4′,5-PeCB, affected basal and carbachol (CB)-stimulated IP accumulation in cerebellar granule cells (Kodavanti et al., 1994). Further studies indicated that any modulation of CB-stimulated IP accumulation is due to Ca^{2+} overload, but not due to activation of PKC activity (Kodavanti et al., 1994). AA is released intracellularly following activation of membrane phospholipases, and AA is an important second messenger in releasing Ca^{2+} from endoplasmic reticulum (Striggow and Ehrlich, 1997). Aroclor 1254 (a commercial mixture of PCBs) and 2,2′-DCB increased $[^3H]$-AA release in cerebellar granule cells, whereas 4,4-DCB did not (Kodavanti and Derr-Yellin, 1999); this is in agreement with previous structure−activity relationship studies on Ca^{2+} buffering and PKC translocation (Kodavanti and Tilson, 1997). A similar increase

in $[^3H]$-AA was observed with structurally similar chemicals such as PBDE mixtures (Kodavanti and Derr-Yellin, 2002). Further studies indicated that the $[^3H]$-AA release caused by these chemicals could be due to activation of both Ca^{2+}-dependent and -independent phospholipase A_2 (PLA_2).

One of the downstream effects of perturbed Ca^{2+}-homeostasis is translocation of PKC from the cytosol to the membrane where it is activated (Trilivas and Brown, 1989). $[^3H]$-Phorbol ester ($[^3H]$-PDBu) binding has been used as an indicator of PKC translocation. The congener 2,2′-DCB increased $[^3H]$-PDBu binding in a concentration-dependent manner in cerebellar granule cells, whereas 3,3′,4,4′,5-PeCB had no effect on in concentrations up to 100 μM. The effect of 2,2′-DCB was time-dependent and also dependent on the presence of external Ca^{2+} in the medium. Sphingosine, a PKC translocation blocker, prevented 2,2′-DCB-induced increases in $[^3H]$-PDBu binding (Kodavanti and Tilson, 2000). Experiments with several pharmacological agents revealed that the effects are additive with glutamate, and none of the channel (glutamate, calcium, and sodium) antagonists blocked the response of 2,2′-DCB (Kodavanti et al., 1994).

Immunoblots of PKC-alpha and epsilon indicated that noncoplanar ortho-PCB decreased the cytosolic form and increased the membrane form significantly at 25 μM (Yang and Kodavanti, 2001). Subsequent SAR studies indicated that congeners that are noncoplanar increased PKC translocation, whereas coplanar congeners did not (for review, see Kodavanti and Tilson, 1997, 2000). This was further strengthened by observations with structurally similar chemicals such as polychlorinated diphenyl ethers (Kodavanti et al., 1996b). Nitric oxide (NO), which is produced by NOS, is a gaseous neurotransmitter. NO has an important role as a retrograde messenger in LTP, learning and memory processes, and endocrine function (Schuman and Madison, 1994). The congener 2,2′-DCB, but not 4,4′-DCB, inhibited both cytosolic (nNOS) and membrane (eNOS) forms of NOS (Sharma and Kodavanti, 2002).

These in vitro studies clearly demonstrated that second messenger systems, involved in the development of the nervous system, LTP, and learning and memory, are sensitive targets for the *ortho*-substituted PCBs and related chemicals. Fig. 28.5 illustrates the intracellular signaling events affected by these chemicals (ortho-PCBs and commercial PCB mixtures) at low micromolar concentrations and shorter exposure periods, where cytotoxicity is not evident. These signaling pathways include calcium homeostasis and PKC translocation. The rise of intracellular free Ca^{2+} is slow but steady following exposure. This free Ca^{2+} rise could be due to

FIGURE 28.5 Schematic representation of calcium and kinase signaling as a biomarker of effect for polychlorinated biphenyls (PCBs), polybrominated biphenyls (PBBs), and brominated flame retardants (BFRs). The processes by which these compounds disrupt calcium homeostasis and kinase signaling are as follows. First, chemicals bind to the cell surface receptors and activate membrane phospholipases such as phospholipase C (PLC), phospholipase A2 (PLA$_2$), and phospholipase D (PLD). This will result in several second messengers such as arachidonic acid and inositol trisphosphate (IP$_3$), which will release calcium from intracellular stores such as endoplasmic reticulum. Following blockage of calcium sequestration mechanisms in mitochondria and endoplasmic reticulum, cytosolic free calcium levels rise. Increased cytosolic calcium translocates protein kinases from cytosol to the membrane where they are activated. This will result in the activation of kinase cascade triggering transcription of genes, which will result in a morphological change. *Adapted from Kodavanti, 2004.*

increased calcium influx, inhibited Ca^{2+} buffering mechanisms, and/or calcium release from intracellular stores by the products of membrane phospholipases. This increase in free Ca^{2+} could cause translocation of PKC. The coplanar non–ortho-PCBs have marginal effects on calcium homeostasis and no effects on PKC translocation. Literature reports indicate that at slightly higher concentrations, commercial PCB mixtures (Aroclors 1221 and 1254) have been seen to alter neurite outgrowth in PC12 cells (Angus and Contreras, 1995) and in hypothalamic cells (Gore et al., 2002). The possible mode of action for this structural change could be due to changes in intracellular signaling by these chemicals.

In vivo effects of PCBs have been studied with a commercial PCB mixture, Aroclor 1254, given orally from gestational day 6 through PND 21. Aroclor 1254 treatment did not alter maternal body weight or percent mortality, but caused a small and transient decrease in body weight gain of offspring. Both calcium homeostasis and

PKC activities were significantly affected following developmental exposure to Aroclor 1254 (Kodavanti et al., 2000). Developmental exposure to PCBs also caused significant hypothyroxinemia and age-dependent alterations in the translocation of PKC isozymes; the effects were significant at PND 14 (Yang et al., 2003). Immunoblot analysis of PKC-alpha (α), -gamma (γ), and -epsilon (ε) from both cerebellum and hippocampus revealed that developmental exposure to Aroclor1254 caused a significant decrease in cytosolic fraction and an increase in particulate fraction. For some isozymes, the ratio between the two fractions was increased in a dose-dependent manner. Thus, the patterns of subcellular distributions of PKC isoforms following a developmental PCB exposure were PKC isozyme- and developmental stage-specific. The changes in PKC and other second messengers were associated with changes in transcription factors such as Sp1 and NF-κB, indicating changes in gene expression

following developmental exposure to PCBs (Riyaz Basha et al., 2006). Considering the significant role of PKC signaling in motor behavior, learning, and memory, it is suggested that altered subcellular distribution of PKC isoforms at critical periods of brain development may be associated with activation of transcription factors and subsequent gene expression and may be a possible mechanism of PCB-induced neurotoxic effects. PKCα, γ, and ε may be among the target molecules implicated in PCB-induced neurological impairments during developmental exposure.

Further studies focused on the structural outcome for changes in the intracellular signaling pathway following developmental PCB exposure. Detailed brain morphometric evaluation was performed by measuring neuronal branching and spine density. Developmental exposure to PCBs affected normal dendritic development of Purkinje cells and CA1 pyramids (Lein et al., 2007). The branching area was significantly smaller in the PCB-exposed rats. When the rats became adults, there was continued neurostructural disruption of the CA1 dendritic arbor following PCB exposure, however, the branching area of the Purkinje cells returned to normal level. Developmental exposure to PCBs also resulted in a significantly smaller spine density in hippocampus, but not in cerebellum. This dysmorphic cytoarchitecture could be the structural basis for long-lasting neurocognitive deficits in PCB-exposed rats (Lein et al., 2007).

Previously, Pruitt et al. (1999) reported a reduced growth of intra- and infrapyramidal mossy fibers following developmental exposure to PCBs. These studies indicate that developmental exposure to a PCB mixture resulted in altered cellular distribution of PKC isoforms, which can subsequently disrupt the normal maintenance of signal transduction in developing neurons. The perturbations in intracellular signaling events could lead to structural changes in the brain. These findings suggest that altered subcellular distribution of PKC isoforms may be a possible mode of action for PCB-induced neurotoxicity. Fig. 28.5 illustrates the intracellular signaling events, transcription factors, and brain morphometry affected by these chemicals.

INDUCTION OF CYTOCHROME P450 ENZYMES AS A BIOMARKER OF EXPOSURE AND EFFECT

The adaptive response found in most organisms for a chemical insult is the induction and expression of genes for xenobiotic metabolizing enzymes (Denison and Nagym, 2003). One of the most potent and comprehensively studied properties of PCBs is their effect on mixed function oxidase (MFO) activity. The MFO system is located in the endoplasmic reticulum of many mammalian cells (Fig. 28.6). It has its terminal oxidase cytochrome P450 (CYP), which is responsible for the metabolism of many xenobiotics and endogenous compounds (Conney, 1967). Many drugs, pesticides, and herbicides cause changes in the activity of the MFO system by induction of cytochrome P450 and the enzyme activity associated with it (Parke, 1975). There are two major classes of cytochrome P450 inducing agents: (1) phenobarbital (PB) type and (2) 3-methylcholanthrene (3MC) type, which induces cytochrome P-448. Aroclor 1254 has been reported to have the inducing properties of both PB and 3MC (Alvares et al., 1973).

The suggestion that PBBs have similar toxic properties to PCBs was supported by the study by Dent et al. (1976) that dietary exposure to a mixture of PBBs containing mostly hexaBB induced the activities of the monoxygenase enzymes in rat liver microsomes. It has been reported that BB-52 is a weak "phenobarbital-like" inducer of CYP enzymes (Robertson et al., 1983). The authors further affirmed that BB-52 is an agonist of constitutive androstane receptor (CAR)/pregnane X receptor (PXR) transcription factors, responsible for gene expression of CYP2B, CYP3A, and other drug metabolizing enzymes and adverse effects connected with incorrect activation of CAR and PXR. Arneric et al. (1980) observed that metabolism of progesterone was accelerated in liver microsomes containing CYP enzymes from rats exposed to various concentrations of PBBs; simulation of hydroxylation of progesterone in positions 16α- and 6β-resembled the effects of phenobarbital, a prototype inducer of CAR- and PXR-dependent gene expression. The authors' observation confirmed induction effects of non−dioxin-like PBBs; certain effects of PBBs on the endocrine system are probably a consequence of enhanced steroid sex hormone catabolism, which might have led to a decrease in progesterone, 17β-estradiol, and testosterone levels, as well as THs.

Coplanar congeners such as non-*ortho* and mono-*ortho*-substituted PBBs elicited AhR-mediated gene expression and benzo[a]pyrene hydroxylase activity and depletion of thymus in immature male Wistar rats (Robertson et al., 1982, 1983). The authors further confirmed the AhR inducing potency of non-*ortho* PBBs using a rat hepatoma H4IIE Luc cell line with luciferase reporter system (DR CALLUX). BB-77, BB-126, and BB-169 were shown to be potent inducers of AhR-dependent luciferase and 7-ethoxyresorufin-O-deethylase activities (Fig. 28.6) and were calculated relative to 2,3,7,8-TCDD as a reference toxicant. The toxic equivalent (TEF) values were 0.0800, 0.16, and 0.0047, respectively (Behmisch et al., 2003). The TEF values were comparable with TEFs for coplanar PCBs.

Chen et al. (1992) studied PBB congeners for their ability to reduce serum retinol levels in male

Induction of Cytochrome P450 as a Marker of Exposure and Effect
FIGURE 28.6 Schematic representation of functioning of the AhR (aryl hydrocarbon receptor) pathway. After entering the cell, the dioxin-like compounds bind to a protein complex in the cytoplasm consisting of AhR, Hsp90, AIP. On ligand binding AIP is released, exposing nuclear localization signal on AhR and leading to translocation of AhR from the cytoplasm to the nucleus. Within the nucleus, Hsp90 is released and AhR heterodimerizes with the Aryl Receptor Nuclear Translocator (ARNT). The AhR–ARNT complex then binds to multiple enhancer elements in the promotor region of the responsive genes in the AhR battery such as CYP1A. *Adapted from Denison, M.S., Nagym S.R., 2003. Activation of the aryl hydrocarebon receptor by structurally diverse exogeneous and endogenous chemicals. Annu. Rev. Pharmacol. Toxicol. 43, 309334.*

Sprague–Dawley rats. The authors noted an interesting observation that BB-169 had no effects on retinol levels, suggesting that a mechanism other than AhR activation is involved in this adverse effect. BB-77 and BB-126 significantly induced the retinyl ester hydrolase activity in the liver. Furthermore, high dietary levels of retinyl acetate produced some inhibitory effect on the promotion of hepatic altered foci induced by BB-169 in initiated rats (Rezabek et al., 1989). These studies showed that PBBs induce impairment of vitamin A and possibly also retinoid signaling and suggested that these effects result from different modes of action.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Human activities are responsible for the environmental input of many classes of chemicals through industrial, agricultural, and domestic sources. Biomonitoring studies have clearly shown a wide distribution of PCBs, PBBs, and PBDEs in the biosphere, resulting in exposures to almost all trophic level organisms with consequent adverse biological effects. This chapter presents biomarkers of response to environmental stressors, specifically in relation to the man-made synthetic organic chemicals PCBs, PBBs, and BFRs. Although other biochemical effects such as oxidative stress (Lee and Opanashuk, 2004; Mutlu et al., 2016) and neurotransmitter changes (Bell, 2014; Costa et al., 2014) have been reported for these chemicals, this chapter concentrates on the current three best prospects of early biomarkers of toxicity. Thyroid hormone disruption, perturbed calcium homeostasis and kinase signaling, and induction of cytochrome P450 enzymes are described as potential biomarkers of exposure and effect in exposed organisms. Data show that toxicity to these compounds appears at the subcellular level before being observed at individual or population levels. Further research, particularly for the BFRs, on initiating events, common molecular mechanisms, and the consequences of exposure, will improve our ability to determine earlier and better biomarkers of exposure. The relevant use of early biomarkers will improve our ability to assess both ecosystem and human risk.

INTRODUCTION

Cancer risk assessment based on the 2-year rodent tumor bioassay is becoming obsolete because of the complexities associated with polycyclic aromatic hydrocarbon (PAH) exposures from occupational, dietary, and environmental settings. In addition to the costs and time factors involved, the relationship at best infers the relationship between the measured event (PAH exposure) and the tumor response. This approach, however, misses several endpoints that represent the various causal pathways involved in carcinogenesis. Additionally, the bioassay results could predict risk in the case of individuals but not at a population level. Therefore, to predict "at risk populations" from PAH exposure, appropriate biomarkers need to be employed for rapid screening of vulnerable populations and deploy appropriate preventive measures.

Biomarkers are cellular, biochemical, or molecular alterations that are measureable in biological media such as human tissues, cells, or fluids (Hulka, 1990). This definition has been extended to embrace biological parameters that could be measured and evaluated as an indicator of normal biological and pathogenic processes (Naylor, 2003). Biomarkers could be indicators of exposure, effect, or susceptibility (Links et al., 1995). These three categories of biomarkers are explained below (Links and Groopman, 2010). In the context of toxicology, biomarker of exposure indicates previous exposure to an environmental toxicant. This biomarker could be an exogenous chemical and interactive product (formed between a toxicant and endogenous compound) that could change the identity or status of target molecule. On the other hand, the biomarker of effect reports the nature and magnitude of biological (functional) response on exposure to an environmental pollutant. The third category, biomarker of susceptibility, outlines the heightened sensitivity of a subpopulation to the effects of a xenobiotic.

Biomarkers have power to be indispensable tools for preventing environmentally induced disease. The rising incidence of human exposure to persistent environmental pollutants necessitated use of biomarkers for disease detection and prevention at an early stage (Suk and Wilson, 2002). One such family of compounds that garnered a great deal of interest in the last century is PAHs. Being products of incomplete combustion they are prevalent in several environmental media (IARC, 2010; Ramesh et al., 2004, 2011, 2012) and through long-range atmospheric transport are carried over to places far away from point source areas (Shen et al., 2012). In addition, these toxicants are released from automobile exhaust, cigarette smoke, and industrial emissions. Several diseases such as cancer (lung, breast, colon, prostate), neurotoxicity, atherosclerosis, and infertility have been attributed to PAH exposure (IARC, 2010; Ramesh et al., 2011). Over the years, several biomarkers have been employed to detect susceptible populations from PAH-induced diseases. Some of the commonly employed biomarkers of PAH exposure, effect, and susceptibility are presented schematically in Fig. 29.1.

BIOMARKERS OF EXPOSURE

Hydroxylated Metabolites

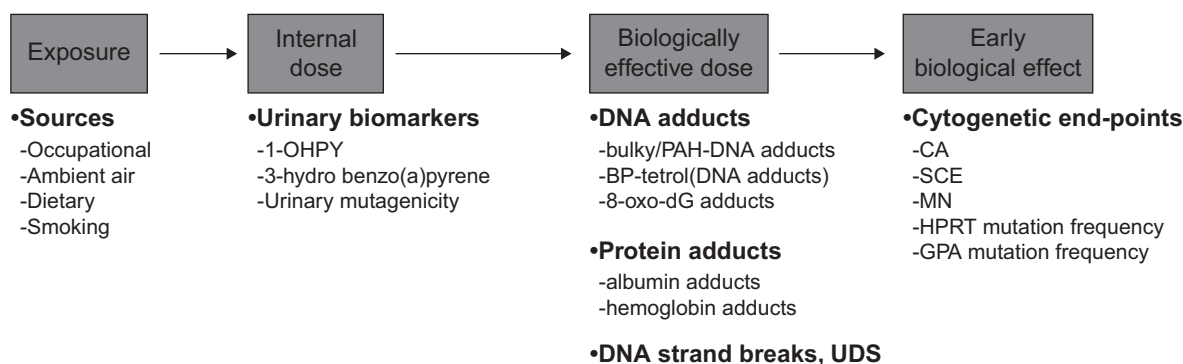
As products of incomplete combustion, PAHs are prevalent in the environment, and exposure of people to PAHs in domestic, outdoor, and occupational settings


FIGURE 29.1 Overview of PAH exposures and biomarkers. *1-OH-PY*, 1-hydroxypyrene; *8-oxo-dG*, 8-oxo-2′-deoxyguanosine; *CA*, chromosome aberrations; *GPA*, glycophorin A; *HPRT*, hypoxanthine-guanine phosphoribosyltransferase; *MN*, micronuclei; *PAH*, polycyclic aromatic hydrocarbon; *SCE*, sister chromatid exchange. *Adopted from* Gyorffy E., Anna, L., Kovács, K., et al., 2008. Correlation between biomarkers of human exposure to genotoxins with focus on carcinogen-DNA adducts. Mutagenesis 23, 1–18; *with permission from Oxford University Press, UK.*

is inevitable. Hydroxylated metabolites of PAHs (OH-PAHs) generated through biotransformation have widely been used as biomarkers of exposure. Urinary concentrations of these metabolites have been employed in several studies. It is reported that urinary 1-hydroxypyrene (1-OHP) concentrations are higher for outdoor workers exposed to polluted air in urban setting than their unexposed counterparts (Ciarrocca et al., 2014). Similar observations were made in volunteers experimentally exposed to wood smoke (Li et al., 2016). Interestingly, the urinary concentrations of 1-nitropyrene are elevated in the United States–Mexico border residents, who tend to cross the border frequently, which is indicative of the higher urban pollution south of the border (Galaviz et al., 2017). Increased concentrations of 1-OHP glucuronide were reported in inner city Baltimore children from the home of cigarette smokers and children who more time spent outdoors (Peters et al., 2017). Children and elderly residents living near emission sources such as oil refineries and coal-fired power plants were also found to have elevated urinary concentrations of 1-OHP (Chen et al., 2017). Furthermore, restaurant workers exposed to fumes from repeated frying oil and restaurant waste oil were found to have higher urinary concentrations of 1-OHP (Ke et al., 2016). Another instance of occupation exposure to PAHs was reported in metallurgy workers in aluminum electrode production plant, who had high levels of urinary PAHs, the half-lives of which were estimated to range from 12 to 18 h (Lutier et al., 2016).

DNA Adducts

PAHs undergo biotransformation. As a result of this process, highly reactive metabolites are generated, which interact with cellular DNA and form PAH-DNA adducts. Measurement of these adducts serve an important purpose of human biomonitoring for exposure to

PAH carcinogenesis and are also used as tools in molecular epidemiology studies (Farmer et al., 2003; Perera, 2000, 2011).

PAH-DNA adducts have been used as biomarkers to assess human exposure to mixtures of toxicants in Poland (Perera, 2000). Peripheral blood samples collected from residents of high-exposure regions revealed an association between environmental pollution and significant increases in levels of PAH-DNA adduct, sister chromatid exchanges (SCEs), chromosomal aberrations, and c-ras oncogene expression.

Another molecular epidemiology study that deserves mention was conducted by Taioli et al. (2007). The PAH-DNA adducts and oxidative DNA damage was measured in PAH-exposed populations from Prague (Czech Republic), Kosice (Slovakia), and Sofia (Bulgaria). The occupationally exposed individuals (policeman and bus drivers) were subjected to personal exposure monitoring, and the exposure of general population was monitored by measuring the levels of carcinogenic PAHs (c-PAHs) in ambient air. In the occupational category, policemen were exposed to PAHs to a greater extent than bus drivers. The average personal exposure to c-PAHs was found to be highest in Bulgaria, followed by Slovakia and the Czech Republic.

Further studies in this direction were undertaken by the SRAM research group in the Czech Republic (Rossner et al., 2013a). This study compared exposure of general public to contaminated air in Ostrava, a heavily polluted region, and Prague, a relatively clean region. The bulky PAH-DNA adducts in peripheral blood lymphocytes were used as biomarkers. A significant correlation between personal exposure to benzo(a)pyrene and BaP-DNA adduct levels were found in subjects from Ostrava, but not Prague.

Several analytical techniques have been employed for detection and quantitation of PAH-DNA adducts. The sources, types of samples used for analysis, and the methods used are summarized in Table 29.1.

TABLE 29.1 Sample Matrices and Methods Employed for Biomonitoring of Polycyclic Aromatic Hydrocarbon (PAH) DNA Adducts in Susceptible Populations

Exposure Route	Biological Matrix	Population	Analytical Method	References
Inhalation (cigarette smoke)	White blood cells	Healthy smokers and nonsmokers	Enzyme linked immunosorbent assay (ELISA)	Perera et al. (1987)
Inhalation (cigarette smoke)	White blood cells	Lung cancer patients	^{32}P-postlabeling	van Schooten et al. (1992)
Inhalation (cigarette smoke)	Peripheral leukocytes	Lung cancer patients	ELISA	Tang et al. (1995)
Inhalation (cigarette smoke)	Oral cavity (mouth floor and buccal mucosa)	Healthy subjects	Immunoperoxidase assay	Besaratinia et al. (2000)
Inhalation (cigarette smoke)	White blood cells	Smokers	Immunoassay	Funck-Brentano et al. (2006)
Inhalation (cigarette smoke)	Cervical mucosa	HPV-infected patients	Chemiluminescence assay	Pratt et al. (2007)
Inhalation (environmental tobacco smoke)	Maternal and umbilical cord blood	Pregnant mothers	?	Perera et al. (2007)

Inhalation (occupational)	White blood cells	Coke oven workers	ELISA	van Schooten et al. (1990)
Inhalation (occupational)	White blood cells	Iron foundry workers	ELISA	Santella et al. (1993)
Inhalation (occupational)	Peripheral blood lymphocytes	Aluminum plant workers	ELISA	Schoket et al. (1999)
Inhalation (occupational)	Peripheral blood lymphocytes	Coke oven workers	^{32}P-postlabeling High performance liquid chromatography (HPLC)	Brescia et al. (1999)
Inhalation (occupational)	Lymphocytes	Coke oven, aluminum plant workers, chimney sweeps	HPLC	Pavanello et al. (1999)
Dermal (coal tar)	White blood cells	Psoriasis patients	ELISA	Santella et al. (1995)
Dietary (charbroiled beef eaters)	White blood cells	Fire fighters who consumed barbecued food	ELISA	Rothman et al. (1993)
Dietary (charbroiled beef eaters)	White blood cells	Healthy subjects	ELISA	Kang et al. (1995)
Dietary (red meat eaters)	Leukocytes	Nonsmokers	Chemiluminescence assay	Gunter et al. (2007)
None specified	Colon tissue	Colon cancer patients	^{32}P-postlabeling	Al-Saleh et al. (2008)
None specified	Breast tissue	Breast cancer	ELISA	Sagiv et al. (2009)
None specified	Follicular cells	Infertile women	^{32}P-postlabeling	Al-Saleh et al. (2010)
None specified	Spermatozoa	Infertile men	Immunofluorescence assay	Ji et al. (2010)
None specified	Prostate	General population	Immunohistochemistry	Tang et al. (2013)

Protein Adducts

The formation of protein adducts is fundamentally similar to that of DNA adducts, i.e., reaction of a diol epoxide metabolite with a protein molecule (Autrup et al., 1999). Because of this property, protein adducts have been used as surrogates for DNA adducts, as metabolites of PAH carcinogens bind to both DNA and protein with similar dose-response kinetics (Poirier et al., 2000; Links and Groopman, 2010). Of all the proteins, hemoglobin and albumin have become the proteins of choice for molecular dosimetry studies. The characteristics that made protein adducts preferable over DNA adducts are that protein adducts are relatively more stable and are not removed by repair processes unlike DNA. Although protein adducts, when compared with DNA adducts, are considered as precise dosimeters (Links and Groopman, 2010), interpretation of results from protein adduct studies is limited by the techniques employed, which vary highly among laboratories (Castaño-Vinyals et al., 2004). Additionally, compared with DNA adducts, not many studies have measured protein adducts, and the data on PAH-protein adducts in humans are inconclusive owing to lack of sensibility in the assays used (Käfferlein et al., 2010).

Hemoglobin adduct concentrations of benzo(a)pyrene diol epoxide (BPDE) were reported to be high in newspaper vendors exposed to traffic exhaust (Pastorelli et al., 1996), compared with nonsmokers. On the other hand, BaP-albumin adducts did not show any significant difference between iron foundry workers and nonsmokers when serum samples were evaluated as an exposure measure (Omland et al., 1994). Similar results were reported from coke oven plant workers and nonoccupationally exposed individuals in an industrial area in Poland (Kure et al., 1997). The techniques employed for detection and quantitation of

PAH-protein (albumin and/or globin) adducts for biomonitoring purposes are summarized in Table 29.2.

OTHER BIOMARKERS OF EXPOSURE

Aside from hydroxylated metabolites and PAH-DNA adducts, serum levels of liver enzymes such as alanine aminotransferase, aspartate aminotransferase, and superoxide dismutase, which are associated with liver function, have been used as indicators of PAH exposure in workers from occupational settings such as coke oven plants (Wu et al., 1997), brick kilns (Kamal et al., 2014), and petrochemical industry (Min et al., 2015). Additionally, in some instances markers of inflammation such as C-reactive protein and activated leukocyte cell adhesion molecule showed a positive correlation with hydroxylated metabolites of PAHs in coke oven workers (Yang et al., 2016). On the other hand, some studies do not provide conclusive evidence to establish a relationship between PAH exposure and some of these biomarkers (Clark et al., 2012; Alhamdow et al., 2017)). There are other caveats that limit the utilitarian value of the above-mentioned markers, which include the exposure dose, duration (time spent on assigned task), and other confounding factors such as smoking, diet, and BMI status. Therefore, the lack of robustness associated with these markers discourages their use for routine monitoring purposes.

BIOMARKERS OF EFFECT

Genetic Alterations

Some of the cytogenetic biomarkers that are currently being used as biomarkers of effect include chromosome

TABLE 29.2 Sample Matrices and Methods Employed for Biomonitoring of PAH-Protein Adducts in Susceptible Populations

Exposure Route	Biological Matrix	Population	Analytical Method	References

Diet and inhalation (smoking)	Globin and albumin	Healthy subjects	GC-MS	Scherer et al. (2000)

aberrations (CAs), SCEs, and micronuclei (MN). The CAs are characterized by structural alterations and rearrangements in chromosomes. Gu et al. (2008) observed BPDE (a carcinogenic metabolite of BaP)—induced chromosome 9p21 aberrations in bladder cancer cases. These studies suggest 9p21 as a marker for PAH-induced bladder cancers. The above-mentioned BaP metabolite has also been implicated in chromosome 3p deletions, which serves as a marker of an individual's susceptibility to renal cell carcinoma (Zhu et al., 2008).

MN are formed after mitosis from lagging chromatids. Cells bearing MN if enter mitosis produce daughter cells without MN. The formation of MN is linked to genetic damage. Increased frequencies of MN were found in coal-tar workers, who may have been exposed to PAHs in tar (Giri et al., 2012). In addition to occupational exposures, MN levels were monitored in mothers and newborns from a region in Czech Republic impacted by severe air pollution, whose BaP levels were found to be elevated in air samples (Rossnerova et al., 2011).

SCEs are exchanges of DNA segments between sister chromatids of a duplicated metaphase chromosome. Asphalt workers exposed to bitumen fumes registered a significant increase in SCEs (Karaman and Pirim, 2009). In addition, results of a metaanalysis study revealed statistically significant SCE frequencies in peripheral blood lymphocytes and peoples occupational exposure to PAHs (Wang et al., 2012a,b).

Glycophorin A (GPA) assay, which detects and quantifies erythrocytes with variant phenotypes at the autosomal locus, is a marker for population exposure to genotoxicants. A slight increase in GPA mutations was noticed in iron foundry workers exposed to PAHs (Perera et al., 1993). Additionally, a strong association between urinary PAH metabolites and GPA mutation frequencies was seen in incineration workers (Lee et al., 2002a,b).

The hypoxanthine-guanine phosphoribosyltransferase (HPRT) is used to denote transgene expression in T lymphocytes. Smoking (rich source of PAHs)—associated mutations at the HPRT locus was deleted in T lymphocytes of lung cancer patients (Hackman et al., 2000). Results of a metaanalysis study also revealed that children who are exposed to mothers' smoke registered a higher frequency of HPRT mutations as well (Neri et al., 2006).

In addition to chromosomal alterations, oncogenes and tumor suppressor genes have been used as markers of PAH exposure. Alguacil et al. (2003) used k-ras mutations to find out whether occupational exposure to PAHs had any effect on exocrine pancreatic cancer in factory workers. A weak association was noticed which cannot provide a definitive link between exposure and disease etiology.

It could be possible that some k-ras mutations are present at relatively high frequencies in some human tissues, but the methods applied may not have been able to detect those. Using an allele-specific competitive blocker polymerase chain reaction assay, Parsons et al. (2010) found k-ras mutations in normal human colon mucosa samples at high frequencies. A dose response for k-ras mutations caused by BaP has already been reported (Meng et al., 2010). Given the fact that dietary intake of PAHs contributes to colon cancers, oncomutations could be used as potential biomarkers for measuring PAH exposures in humans from occupational, environmental, and dietary settings.

The tumor suppressor gene p53 has also been used as a biomarker of PAH exposure. This gene regulates cell proliferation, differentiation, apoptosis, and DNA repair (Levine, 1997). Mordukhovich et al. (2010) reported an association between PAH exposure and p53 mutations subgroups in participants from the Long Island Breast Cancer Study Project. Other studies also have found positive association between PAH sources and p53 mutations in colon and lung cancers (Diergaarde et al., 2003; Harty et al., 1996).

Rossner et al. (2013b) studied the biomarkers of effect in Czech population exposed to PAHs through inhalation of polluted air in a highly contaminated region (Ostrava) and clean region (Prague). Samples collected from exposed humans were analyzed for oxidative stress markers (8-oxo-7,8-dihydro-2′-deoxyguanosine [8-oxodG], 15-F(2t)-isoprostane [15-F2t-ISOP]) and cytogenetic parameters (stable and unstable chromosomal aberrations). Lipid peroxidation measured by isoprostanes was elevated in subjects from Ostrava region compared with inhabitants of Prague. Other markers such as urinary excretion of 8-oxodG and unstable chromosomal aberrations were mostly comparable in both locations.

BIOMARKERS OF SUSCEPTIBILITY

Polymorphisms in PAH-metabolizing enzymes serve as markers of susceptibility. The PAH bioactivation enzyme, cytochrome P4501A1 (CYP1A1) gene polymorphism, was recorded in coal-tar workers (Giri et al., 2012). Gene polymorphisms in another CYP isozyme CYP1B1 and the antioxidant enzyme, catalase, were linked to BaP-DNA adduct levels in human lymphocytes (Schults et al., 2013). A strong association between PAH exposure during pregnancy and CYP1B1 polymorphisms leads to deficits in cognitive development of African American, Dominican, and Caucasian children (Wang et al., 2010). Also of interest was the finding that children living in the surrounding of a petrochemical factory in Mexico showed CYP1A1 and glutathione-S-transferase M1 (GSTM1) polymorphisms, increased DNA damage, and 1-OHP concentrations

making them vulnerable to PAH exposure (Sanchez-Guerra et al., 2012).

Polymorphisms in CYP genes from 500 patients with colon cancer showed CYP1A2, CYP2E1, and microsomal epoxide hydrolase (mEH) (Kiss et al., 2007), indicating the susceptibility of individuals with CYP and mEH polymorphisms to colon cancer as these genes control PAH metabolism. Another study reported polymorphisms in CYP1A2, CYP2E1, CYP1B1, and CYP2C9 genes, which showed a strong association with red or processed meat consumption, a rich source of PAHs (Küry et al., 2007).

PAHs adsorbed onto particles in polluted air have been implicated in cardiovascular diseases and lung cancers in exposed populations. Binkova et al. (2007) found a strong association between PAH-DNA adducts levels and polymorphisms of DNA repair gene xeroderma pigmentosum group D (XPD) and the detoxification enzyme GSTM1 in population exposed to polluted air in Prague. This enzyme has also been suggested as a marker to monitor metabolic activation of PAHs in smokers (Wang et al., 2012b). Polymorphisms of another isozyme of GST family, the GSTP1, have been implicated in reduced fetal growth. These studies suggest the potential use of GSTP1 as a marker to detect risks arising from exposure to PAHs by mothers from susceptible populations (Duarte-Salles et al., 2012). Additionally, polymorphisms in genes coding for other detoxification enzymes such as GSTM1 and GSTT1 detected in smokers also showed a strong association with colorectal adenomas (Moore et al., 2005).

Another PAH detoxification enzyme, the UDP-glucuronosyltransferase (UGT) polymorphisms, has been associated with a reduced elimination of PAHs from the body. An increased risk of colon cancer was predicted in a population-based study whose subjects had UGT1A1 polymorphisms (Girard et al., 2008). Because intake of PAHs through diet has been involved in colon cancer causation (reviewed in Diggs et al., 2011), functional polymorphisms in other PAH detoxification genes hold lot of promise as markers not only for colon but also for other gastrointestinal tract cancers.

In addition to drug metabolizing enzymes, polymorphisms in aryl hydrocarbon receptor (AhR) gene is another biomarker, worthy of consideration. Gu et al. (2011) reported AhR polymorphisms in idiopathic infertile male subjects. These polymorphisms were found to be associated with reduced sperm concentration, increase in sperm DNA fragmentation, and BPDE-DNA adduct levels in spermatozoa.

Not only are polymorphisms in PAH activation and detoxification enzymes but also polymorphisms in DNA repair genes serve as useful biomarkers. In addition to DNA repair gene XPD (Binkova et al., 2007), polymorphisms exist in other DNA repair enzymes as well.

An association among polymorphisms in DNA repair gene, the DNA methyltransferase 1 and 3B and DNA strand breaks were reported by Leng et al. (2008). These findings suggest that variants in haplotypes of these genes could be used as markers to predict cancer susceptibility. Polymorphisms in ataxia telangiectasia (ATM) lead to impairment in repair of chromosomal damage and cell cycle control in people exposed to toxicants. Wang et al. (2011) found that in workers occupationally exposed to PAHs, the ATM polymorphisms were associated with susceptibility to DNA repair capacity.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

One of the caveats in using biomarkers is categorizing the exposure scenarios. Sometimes exposure misclassification cannot be avoided. This situation may lead to employing an incorrect biomarker that may not be able to capture the functional relationship between exposure and effect. In such situations, ex vivo studies are useful to control exposure settings so that gene—gene interactions could be studied well and help validating the biomarkers.

Thus far, several biomarkers that denote exposure, effect, and susceptibility have been proposed and studies involving these for most part yielded definitive information. At the same time, some studies were inconclusive because of the lack of correlation between biomarkers. In some studies, the PAH-DNA adducts concentrations failed to show either a correlation with urinary metabolites of PAHs or with DNA repair enzymes. To fully exploit the potential of biomarkers in PAH-induced disease diagnosis and intervention strategies, correlation among biomarkers of exposure and effect and effect and susceptibility needs to be investigated. This approach could be integrated into the exposome concept to address environmental and human health issues arising from PAH exposures.

Additionally, bioinformatics and systems biology resources could be exploited to advance the field further. Proteomic and genomic approaches could be used to identify additional biomarkers of PAH exposure, effect, or susceptibility. Data from these studies could facilitate the discovery and validation of new biomarkers for PAH-induced cardiovascular, neurological, reproductive, and developmental disorders and cancer.

Metals

Swaran J.S. Flora, Abha Sharma

National Institute of Pharmaceutical Education and Research, Raebareli, U.P., India

INTRODUCTION

The term biomarker is used to measure the interaction between a biological system and an environmental agent, which may be chemical, physical, or biological. They form the essential end points of cascade of events involved in metal exposure and progression of related disease, analysis of which may contribute significantly to the successful risk management against heavy metal toxicities. This chapter provides some recent updates of biomarkers and their role in determining exposure to some of the specific metals. It will also provide a comprehensive account of molecular- and cellular-based biomarkers of toxicity.

CLASSIFICATION OF BIOMARKERS

Broadly biomarkers could be categorized into three categories:

1. **Biomarkers of exposure**. These are directly related to the measurement of dose and function of a metal exposure. They can be further subdivided into the following:
   - *Molecular lesions* include formation of DNA and protein adducts, glycosylated hemoglobin, and amino acid conjugates through induction of electrophilic chemicals, chromosomal aberrations, and micronuclei following exposure to metals.
   - *Endogenously produced biomolecules* include production of various chemicals and enzymes in response to metal intoxication.
   - *Cellular/tissue changes* include alterations in sperm motility, sperm count, macrophage activity, red blood cell counts, and lymphocyte ratios.
   - *Unchanged exogenous agents* include heavy metals.
2. **Biomarkers of effects**. These biomarkers are also known as "response biomarkers" include

measurements of biochemical, physiological, or behavioral alterations as end results of metal exposure.
3. **Biomarkers of susceptibility**. These biomarkers are strong indicators of the natural characteristics of an organism, which possibly contribute toward making them more susceptible to the effects of an exposure to a particular toxicant. These biomarkers can be genetic such as chromosomal aberrations, polymorphisms, etc.

SELECTION OF AN IDEAL BIOMARKER: BENEFITS AND DRAWBACKS

Choice or selection of biomarkers needs to be appropriate to attain accurate results. An ideal biomarker should possess certain specified characteristics such as:

1. Sample collection and analysis should be reliable and easy.
2. Use of biomarker is ethically proven.
3. Biomarker should be disease and organ specific and relevant intervention can be considered.
4. It should reflect a subclinical and reversible change.

BIOMONITORING OF EXPOSURE TO HEAVY METALS

Heavy metals are known to cause oxidative deterioration of biomolecules by initiating free radical mediated chain reaction resulting in lipid peroxidation, protein oxidation, and oxidation of nucleic acids such as DNA and RNA. Exposures to metals must be recognized promptly, and affected individuals should be evaluated and managed without delay.

LEAD

Inorganic Pb is considered to be one of the oldest occupational toxicants and is widely used in industries and life because of its favorable properties such as malleability, resistance to corrosion, and low melting point. Paints are the primary source of Pb exposure and the major source of Pb toxicity. Formation of reactive oxygen species (ROS) and changes in glutathione (GSH) as well as other antioxidant enzyme activities contribute equally to oxidative stress in lead intoxication.

Biomarkers of Exposure

1. *Blood lead levels:* Blood Pb (BPb) level (mainly erythrocyte lead) is the one of the primary and most verifiable biomarker used for the assessment of Pb exposure and toxicity. Up to 50% of inhaled Pb is transferred to bloodstream in adult humans, measurement of which reflects both recent and past exposures. Mobilization of Pb from bone into the blood contributes significantly (45%–55%) in enhancing the blood Pb levels, even in persons without excessive exposure to Pb. Evaluation of blood zinc protoporphyrin (ZPP) level can be used for determining Pb exposure (Yang et al., 2015).

2. *Plasma lead levels:* Plasma Pb levels (PPb) have also been associated with toxic effects of Pb as plasma fraction is rapidly exchangeable in the blood. Easy exchange of lead from bone to plasma occurs via exchangeable pool, whereas lead can move from nonexchangeable pool to the surface only when bone is actively being resorbed. Pb exposure affects plasma viscosity and also disturbs the agreeability and deformability of erythrocyte (Kasperczyk et al., 2015).

3. *Urine lead levels:* Spot urine specimen is subjected to large biological variations rendering it unreliable along with precipitation of urate salts in urine, which serves as another complicating factor in the analysis. Inorganic Pb remains unmetabolized and is excreted unchanged, primarily in the urine. Urine analysis is a noninvasive method and is favored for long-term biomonitoring and is acceptable in Pb workers as biomarker (Sommar et al., 2014).

4. *Lead levels in hair and nails:* Hair as biomarker of exposure has several advantages over other substrates, such as easy and noninvasive collection, minimal cost, inert, and easy storage and transportation for analysis. However, the ability to distinguish between endogenous and exogenous Pb is a major problem, and various geographical and ecological factors affect Pb distribution in hair. Techniques such as atomic absorption spectrometry can be used for the quantitative determination of Pb in fingernail, which indicates its environmental exposure. Another study showed that nail is not a reliable biomarker of exposure for women using surma (Ikegami et al., 2016). Toenails are preferred because they are comparatively less affected by various environmental contaminants, reliable, and noninvasive (Bakri et al., 2017).

5. *Bone and teeth lead levels:* Studies suggest the cumulative measurement of bone Pb levels as the most important determinant of some forms of toxicity. There is a strong association between bone Pb levels and blood Pb levels of adults exposed to lead (Behinaein et al., 2017). However, an appropriate selection of the bone type for analysis of Pb levels is necessary as different types of bones have different characteristics that potentially contribute toward their efficacy to absorb Pb. Though analysis of bone Pb levels has been recommended as one of the effective biomarker, still further research is warranted. X-ray fluoroscopy is considered among the most consistent and sensitive tools for assessing this. Compared to bones, teeth have been shown to be a superior indicator of Pb exposure as they also provide information about prenatal exposure and hence could be valuable in the understanding of various embryonic anomalies. The estimation of Pb in dental surface enamel by graphite furnace atomic absorption spectrometry may be used as a suitable biomarker of environmental exposure to Pb (De Oliveira et al., 2017).

Biomarkers of Effects

General signs and symptoms of Pb poisoning may include abdominal pain, anorexia, nausea and constipation, headache, joint and muscle pain, difficulties with concentration and memory, sleep disturbances, anemia with basophilic stippling, peripheral neuropathy and nephropathy. Some of the major biomarkers of effect or response biomarkers associated with Pb intoxication are discussed below:

1. *Systemic manifestations:* Lead poisoning has been associated with various hematological, gastrointestinal, and neurological dysfunctions, resulting in progression of diverse adverse effects and diseases.

   a. *Hematological manifestations:* Lead-induced hematological effects are mainly due to reduced life span of erythrocytes and inhibition of hemoglobin synthesis. These effects result in anemia, which may be mild, hyper, chronic, or microcytic. The adverse effects of lead appear even with blood concentration as low as 10 μg/dL. Basophilic stippling and premature erythrocyte hemolysis are the two common and promising biomarkers exhibiting hematological

manifestations on Pb exposure. Impairment of the activity of pyrimidine 5′-nucleotidase takes place, which increases the concentration of pyrimidine nucleotides in red blood cells, preventing maturation of erythroid elements and eventually leading to anemia presented in two case reports (Warang et al., 2017).

b. *Gastrointestinal manifestations:* Case reports indicate severe gastrointestinal dysfunction such as abdominal cramps, constipation, dilated stomach descending into the pelvis, small bowel distension, nausea, abdominal pain, belching, heart burn, loss of appetite hunger pain, liver damage as shown by liver biopsy (Verheij et al., 2009).

c. *Neurological manifestations:* Lead mimics calcium ions, which grants it the potential to cross blood—brain barrier and interferes with the normal development of a child's brain and nervous system. High levels of lead are associated with impaired cognitive function and various neuropsychiatric symptoms such as short-term memory and attention deficit disorders. Lead level in blood and urine in pediatric patients with attention deficit hyperactivity disorder was determined with the outcome that it is correlated inversely to neurological development in the early 7 years of life (Sánchez-Villegas et al., 2014).

d. *Renal manifestations:* Chronic exposure results in renal ganglioside alterations with urinary microalbumin excretion; however, these symptoms are variable and lack specificity. Chronic exposure is associated with tubule interstitial nephritis and progressive deterioration of renal function. The effect of low environmental exposure of Pb on kidney can be identified by monitoring the activity of lactate dehydrogenase. Proteinuria was also found in higher levels in Pb-exposed people (Cabral et al., 2012).

e. *Cardiovascular manifestations:* Association between Pb exposure and coronary heart disease, heart rate variability, and death from stroke has also been indicated; however, there are limited reports and scientific evidence to support this finding. High levels of serum asymmetric dimethylarginine, adipocyte fatty acid—binding protein, adiponectin, and chemerin have been reported recently in women living in Pb-contaminated area of Mexico (Ochoa-Martinez et al., 2017).

f. *Reproductive manifestations:* Lead affects both male and female reproductive systems and has been associated with decreased sperm count and motility in men and miscarriage, prematurity, low birth weight, and problems with development during childhood in women. *In utero* exposure of fetus to Pb might be due to the mobilization of Pb from mother's bones. Moreover, increased calcium intake may further mitigate this phenomenon (Pant et al., 2014).

g. *Toxic manifestations on bones and teeth:* Tooth decay, missed and filled teeth, dental abrasions, and significant increase in the prevalence of periodontal diseases such as gingivitis and periodontitis have been linked to Pb exposure. Use of combined laser ablation lead isotope and histological analysis method for the determination of Pb level in children's dentine and enamel of deciduous teeth furnish information about timing, duration, and source of Pb exposure during fetal development and early childhood (Shepherd et al., 2016). Presence of "Lead lines" along metaphyses of long bones and the margin of flat bones is also an important biomarker. The effect of Pb on bones of female rats suggests that it can damage bone biomechanics. Therefore, this finding would relate with the increases in the risk of bone fracture in elderly women exposed to Pb (Lee et al., 2016).

h. *Respiratory manifestations:* Inflammatory biomarkers in blood (WBC counts, PLA2 activity, and total protein levels) of Pb-exposed guinea pigs were examined and signified that inhalation exposure to lead acetate may lead to asthma-like disease (Farkhondeh et al., 2013).

i. *DNA manifestations:* Techniques such as comet, micronucleus, and chromosomal aberration tests are applied to identify the genetic damage occurred in heavy metal—exposed population. Elevated mean percent tail DNA, frequency of chromosomal aberration, and micronucleus in peripheral blood lymphocytes as well as in buccal epithelial cells were found in occupationally Pb-exposed worker (Chinde et al., 2014).

2. *Biomarkers of oxidative damage*
a. *ALAD-δ-aminolevulinic acid dehydratase:* Several enzymes/enzymatic processes responsible for heme synthesis can be used as potential biomarkers for the lead toxicity, primarily being δ-aminolevulinic acid dehydratase (δ-ALAD), involved in catalyzing the condensation of two molecules of ALA to porphobilinogen. Blood Pb levels >20 μg/dL strongly inhibit the activity of ALAD, which makes it the most sensitive measurable biological index of lead toxicity. However, there are two limitations in the determination of ALAD activity: (1) wide range of normal activity, and (2) unstable nature of the activity during storage (La-Llave-León et al., 2017). 8-Hydroxy-2′-deoxyguanosine as a sensitive and

noninvasive biomarker of Pb induced oxidative DNA damage (Pawlas et al., 2017).

b. **ALA-U, ALA-B, ALA-P:** ALA is synthesized in mitochondria from glycine and succinyl-CoA by ALA synthetase (ALAS). Inhibition of ALAD results in activation of ALAS, which further results in ALA accumulation in blood, plasma, and urine, thereby making ALA a critical biomarker of early biological effect of Pb also (Saxena and Flora, 2004). Effect of lead on bone marrow is more precisely depicted by increased ALA in plasma or blood than urine, although ALA-U has been a recommended biomarker of Pb exposure. Lead interrupts erythrocytes energy homeostasis, resulted with decreased glucose metabolism, which lead to cell dysfunction in Pb-exposed people (Feksa et al., 2012).

c. **Zinc Protoporphyrin:** ZPP concentrations are widely used as biomarkers for lead toxicity. Ferrochelatase is another crucial enzyme that catalyzes the insertion of iron into protoporphyrin IX. However, in the cases of Pb toxicity, this enzyme is inhibited and the pathway is interrupted. Also, if sufficient iron is not available, Zn is substituted for Fe, resulting in increased ZPP levels. This alteration is an important diagnostic feature coexisting with a limitation that these elevations do not appear in the blood until Pb levels reach 35 μg/dL. The three enzymes of heme biosynthesis, i.e., ALAD, coproporphyrin oxidase, and ferrochelatase, are affected by Pb exposure resulting in decreased level of erythropoietin, consequently reducing hemoglobin synthesis (Mazumdar et al., 2017).

d. **Pyrimidine nucleotidase and nicotinamide adenine dinucleotide synthetase:** Decreased activities of pyrimidine nucleotidase and nicotinamide adenine dinucleotide synthetase in blood also serve as useful biomarkers in humans for diagnosing lead intoxications (Kim et al., 2002).

Biomarkers of Susceptibility

1. **Cytogenetic markers:** Sister chromatic exchanges (SCEs), high-SCE frequency cells (HFCs), and DNA−protein cross-links (DPCs) have also been shown to be reliable markers for biomonitoring lead exposure. Genotoxicity of Pb was measured using SCE, erythrocyte ALAD, urinary delta-aminolevulinic acid (U-ALA), and BPb in workers occupationally exposed to Pb (Sanders et al., 2009).

2. **Biomarkers of gene expression**
   a. **ALAD, VDR, and HFE polymorphism:** Several biomarkers at the molecular level also exist, which help in estimation of Pb in exposed individuals.

ALAD G177C polymorphism yields two alleles, ALAD1 and ALAD2. Higher blood Pb levels are observed in individuals carrying two copies of ALAD2 allele; however, hemopoiesis and severe effects of intoxication in brain and bone are observed in ALAD 1−1 homozygotic individuals. The role of ALAD genotype polymorphism in Pb toxicity has been studied in Pb-exposed and -unexposed workers. They found higher level of B-Pb and U-Pb in ALAD2 carriers than in ALAD1 homozygotes. P-Pb values were found to be comparable in both ALAD genotypes, but ALAD1 homozygotes are more prone to kidney toxicity (Tian et al., 2013).

b. **Apoptotic gene expression:** Mitochondrion plays an extremely crucial role in Pb-induced apoptosis and is dependent on mitochondrial permeability transition pore opening as studied in rat proximal tubular cells (Liu et al., 2016). Apoptotic signals triggered by Pb are stimulated by caspase cascade and extracellular signal−regulated kinase dephosphorylation pathway in hepatic stem cells of adult rat (Agarwal et al., 2009).

ARSENIC

Arsenic (As) is a highly toxic metalloid, which poses severe effects, and its use as a deadly poison has been known and reported for many years. Arsenic in its free form generates free radicals resulting in lipid peroxidation, depletion of antioxidant enzymes, and DNA damage, thereby establishing oxidative stress as the major mechanism of As-induced toxicity and carcinogenicity (Flora, 2011).

Biomarkers of Exposure

Assessment and quantification of As exposure usually involves the measurement of As levels in environmental media (water and soil) and/or the use of biomarkers of exposure (blood, urine, and nails). Analysis of total As in blood, hair, or nails, and total or speciated metabolites of As in urine is the most common biomarker of As exposure.

1. **Blood arsenic levels:** Blood As levels better indicate recent and relatively high-dose exposures. Arsenic is cleared from blood within a few hours after it is absorbed. Blood As levels, however, may not be very reliable and promising biomarker of exposure because of its rapid clearance, particularly in cases of intoxication with very low levels of inorganic As. Examination of porphyrin profile provides an indication of As exposure. Thus it can be a useful biomarker of As exposure (Hall et al., 2006).

2. *Urine arsenic levels:* Clouded urine is frequently seen in most severely As-intoxicated patients as absorbed As if primarily excreted through urine. Generally, urinary As is analyzed as total or speciated; however, during inorganic As exposure determination of both speciation and total urinary As contents plays a critical role. Although estimation of urinary As is a consistent biomarker of exposure, it poses few drawbacks, such as accurate sample collection time, volume of urine to be voided, etc. Arsenic can be determined by measuring it and its metabolite (monomethylated and dimethylated metabolites) concentrations in urine of exposed people as a biomarker of exposure (Laine et al., 2015).

3. *Arsenic levels in hairs and nails:* Hair and nails are also preferable samples to detect and quantify exposure to As, as absorbed arsenic accumulates in both hair and nails and its elevated levels are noted within few weeks after acute poisoning. This elevation may account to binding of As to sulfhydryl groups in keratin, and because hair and nails grow slowly, their analysis may give an indication of past As exposure. Arsenic content in both toenail and fingernail has been significantly elevated among individuals consuming contaminated well water and was reported to be significantly correlated with hair As content.

Biomarkers of Effects

General symptoms of As poisoning that develop gradually include headaches, confusion, severe diarrhea, drowsiness, blood in the urine, cramping muscles, hair loss, and stomach pain. Lungs, skin, kidney, and liver are the major target organs of arsenic toxicity, and coma leading to death is the ultimate consequence. Moreover, As poisoning has also been associated with increased risk of heart disease, cancer, stroke, chronic lower respiratory diseases, and diabetes. Such clinical manifestations form some of the important biomarkers of effect.

1. *Systemic manifestations*:
   a. *Skin manifestations:* Keratosis, hyperkeratosis, leukomelanosis, depigmentation, and melanosis are the characteristic skin lesions associated with As toxicity. They are typically exhibited by diffuse thickening of palms and soles, alone or in combination with nodules, and presence of numerous rounded hyperpigmented macules in the form of raindrops in the body. In severe cases, cracks and fissures may be seen in the soles. Leucomelanosis is another common skin lesion, consisting of hypopigmented macules with a spotty white appearance (Zhang et al., 2014).

   b. *Respiratory manifestations:* Scientific evidence from various studies/reports suggests the possible role of As poisoning in the occurrence of lung disease. Chronic respiratory disease in the form of chronic cough or chronic bronchitis because of prolonged drinking of As-contaminated water has been observed. In addition, reduced pulmonary function and features of restrictive lung disease and combined obstructive and restrictive lung disease were noted in individuals exposed to As (Steinmaus et al., 2016).

   c. *Gastrointestinal manifestations:* Chronic As toxicity has been reported to cause symptoms such as dyspepsia, abdominal pain, gastroenteritis, nausea, diarrhea, and anorexia indicating dysfunctioning of gastrointestinal system (Ahmad et al., 1997).

   d. *Hepatic manifestations:* Liver damage such as portal hypertension, liver fibrosis, hepatomegaly, and intrahepatic portal vein obstruction is associated with arsenic exposure. Liver cirrhosis was observed as one of the major outcome following medication with inorganic As compounds. Various studies show that As toxicity is predominantly associated with hepatomegaly, in which hepatic fibrosis is the predominant lesion. Dysregulated lipid metabolism, oxidative stress, altered cytokine profiles, and enhanced inflammation may be involved in arsenic-induced liver injury (Arteel, 2015).

   e. *Cardiovascular manifestations:* Exposure to As has been related to an increased incidence of cardiovascular diseases, especially Black Foot Disease, ischemic heart disease, and hypertension. Soluble thrombomodulin could be a specific and stable biomarker associated with chronic As exposure (Hasibuzzaman et al., 2017). Arsenic exposure was also found to be associated with increased blood pressure in pregnant women, which could lead to risk of cardiovascular disease (Farzan et al., 2015).

   f. *Neurological manifestations:* Peripheral neuropathy, paresthesia, increased incidence of cerebrovascular disease, sleep disturbances, weakness, cognitive and memory impairment, mood disorders, headache, and vertigo are some of the major outcomes of chronic arsenicosis as observed in adults and children exposed to As from air and water as evident by epidemiological studies (Tsuji et al., 2015).

   g. *Hematological manifestations and induction of diabetes mellitus:* Various hematological abnormalities have been reported in cases of acute and chronic As poisoning. A characteristic pattern of anemia and its accumulation in erythrocytes,

leucopoenia, neutrophil depletion, and thrombocytopenia were observed (Heck et al., 2008). Also, significantly increased prevalence of diabetes mellitus was reported due to drinking As-contaminated water.

h. *Carcinogenesis and other effects:* Skin cancers are one among the most prevalent cancers due to chronic As exposure and might arise in the hyperkeratotic areas or nonkeratotic areas of the trunk, extremities, or hand. Apart from skin carcinomas, urinary bladder, liver, and lung cancers are also reported due to chronic exposure to As. Increased level of serum vascular endothelial growth factor may cause angiogenesis in As-induced cancers (Rahman et al., 2015a,b).

2. *Biomarkers of DNA damage:* Excessive free radical generation has been linked to enhanced carcinogenesis/mutagenesis (Flora et al., 2008). Arsenic-generated free radicals have been shown to induce degradation of DNA resulting in malfunctioning of DNA repair enzymes.

a. *8-Hydroxyguanine, 8-hydroxyguanosine, and 8-hydroxy-2-deoxyguanosine formation:* For free radical attack, guanine is the most sensitive base present in DNA, which gets converted to various markers such as 8-hydroxyguanine, 8-hydroxyguanosine, and 8-hydroxy-2-deoxyguanosine (8-OHdG) after oxidation. Among all other markers, 8-OHdG adduct is one of the most abundant base modifications excreted in urine, and it is regarded as a suitable oxidative DNA damage biomarker because of its easy collection. 8-Oxoadenine, the oxidized form of adenine, has also been detected in urine of As-exposed animals. All these markers are difficult to detect through existing analytical methods as they transform into stable end products. Still techniques such as single cell gel electrophoresis or comet assay has been extensively used for this purpose (Azqueta et al., 2015). Another recent technique employing immunospin trapping as in the ODD test detects As-induced DNA damage more efficiently. Maternal exposure to As leads to DNA damage that could be identified by measuring 8-oxo-7, 8-dihydro-2′-deoxyguanosine and N7-methylguanosine, which serve as biomarkers. The latter biomarker could be used for monitoring fetal health linked to As exposure (Chou et al., 2014).

3. *Biomarkers of oxidative damage:* At the biochemical level, increase in ROS levels and unsaturated reactive aldehydes, such as malondialdehyde (MDA), 4-Hydroxynonenal (HNE), and 2-propenal (acrolein) and isoprostanes are one among the first response to As-induced oxidative stress, levels of which can be measured as indirect indicators of oxidative injury to blood and soft tissues (Chouhan and Flora, 2010). Arsenic also alters antioxidative enzymes such as malondialdehyde, catalase, GSH, and glutathione peroxidase and elevation in hydroxyl radical (Guo et al., 2015).

a. *δ-Aminolevulinic acid dehydratase (ALAD):* Arsenic has strong affinity for nucleophilic ligands, which results in direct inhibition of heme biosynthesis pathway through metal—mercaptide bond formation with the functional sulfhydryl groups. δ-Aminolevulinic acid dehydratase is found to be highly sensitive to the presence of As by virtue of its sulfhydryl moiety. Dose-dependent increase in urinary excretion of uroporphyrin and coproporphyrin was observed following As exposure. Heme oxygenase too has been proposed as a biomarker of response to environmental As exposure (Flora et al., 2007). The role of ALAD genotype in determining Pb toxicity in children has been studied, which suggests that ALAD1-2/2-2 genotype may have lower level of U-ALA in environmentally Pb-exposed children (Tasmin et al., 2015).

b. *Antioxidant enzymes:* Antioxidant activity of enzymes such as SOD, CAT, glutathione-6-phosphate dehydrogenase, glutathione S-transferase (GST), GSH reductase, and GPx is directly or inversely proportional to As toxicity depending on the dose and time of exposure (Dobrakowski et al., 2016). After evaluating all pulmonary biomarker-based alterations, GST has also been proposed as a potential biomarker for As toxicity. However, the techniques introduced to measure the oxidative stress have not yet been fully exploited to monitor the status of exposed populations.

Biomarkers of Susceptibility

1. *Cytogenetic markers:* Sister Chromatic Exchange (SCE) is considered to be one of the early biomarker of As-induced genotoxicity. Along with SCE, presence of micronuclei (MN) in isolated bladder and buccal cells has been considered as possible target tissues for direct exposure to As from drinking water. Reports indicate an increase in MN in lymphocytes in individuals chronically exposed to As via drinking water or occupational exposure (Guzman et al., 2017).

2. *Biomarkers of gene expression:* Growing evidence indicates the association of As with alterations in the repair of oxidative damage, measurement of which holds great promise as a susceptibility biomarker

of oxidative DNA damage in populations exposed to As.

a. *OGG1 polymorphism:* At the gene level, chronic arsenicosis is linked with reduced expression of 8-oxoguanine DNA glycosylase (OGG1) gene encoding 8-oxoguanine DNA glycosylase, primary enzyme responsible for the removal of 8-oxoguanine from DNA (Fig. 30.1). Microbiomes present in human gut, skin, and respiratory tract have genes that are induced by As ppb level exposure and precede detoxification process. Therefore, microbiomes gene expression could be taken as biomarker of exposure (Rosen, 2015).

b. *Polymorphism in genes involved in DNA repair pathways:* A strong correlation was observed between the urinary levels of 8-oxo-dGuo and monomethylarsonic acid. The ability of As to interfere with various DNA-repairing enzymes can be attributed to the fact that As reacts with thiol groups of zinc binding structures present in Nucleotide excision repair (NER) enzymes, such as the Zn finger proteins XPA and XPD. It has been observed that chronic As exposure leads to *Ogg1* deficiency, which aggravates the normal cellular repair function process (Bach et al., 2015).

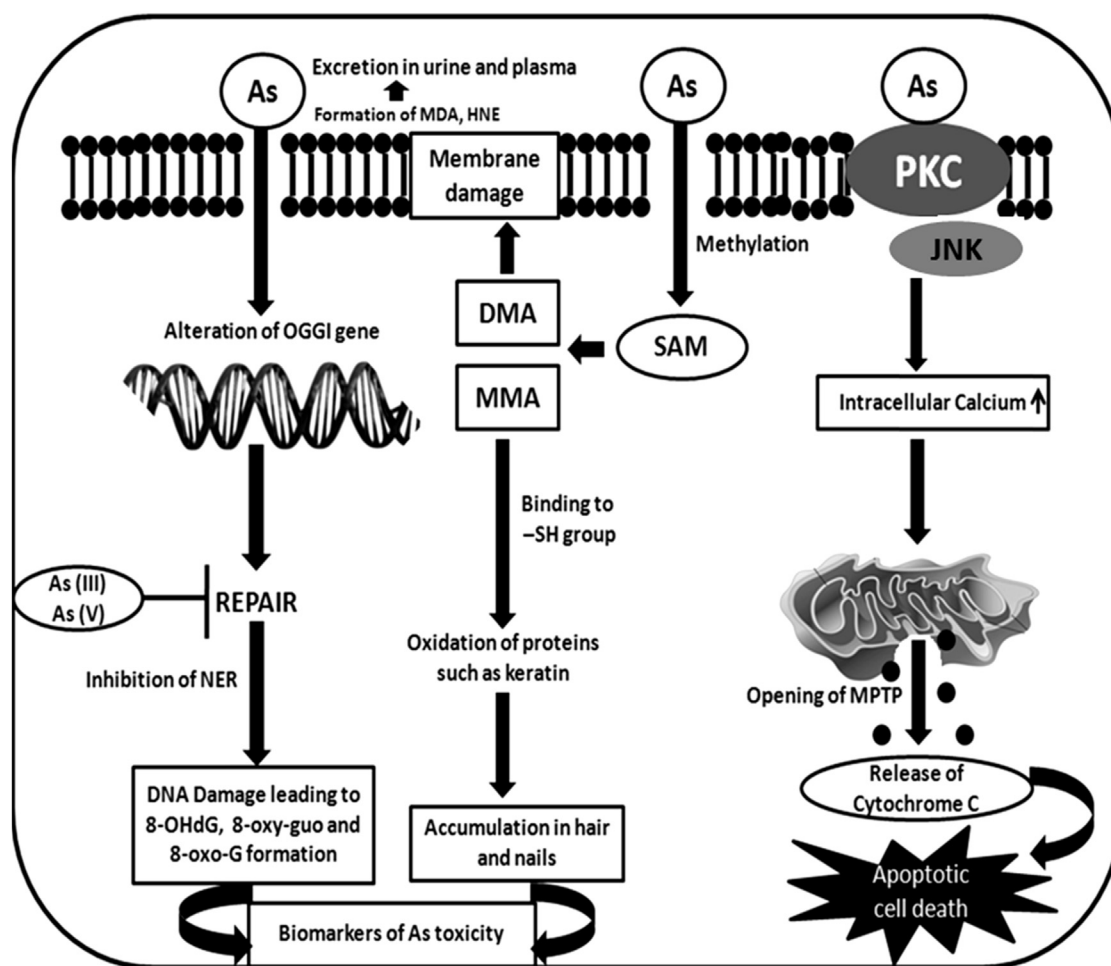
c. *Genes involved in apoptosis:* Generation of ROS, accumulation of calcium, deficiency of p53 and intracellular GSH, Akt/mTOR signaling pathway inhibition, and ROS/JNK activation are the events that collectively lead to apoptosis during As toxicity; and all these genotoxic and cytotoxic effects, both in vivo and in vitro, can be determined through single cell electrophoresis (comet assay) (Wang et al., 2017). Thus, various biomarkers exist for the rapid and efficient diagnosis of As toxicity, employing of which will definitely yield some positive results. However, in spite of enough scientific awareness, As toxicity continues at an alarming level, thereby proving to be a menace, which could be possibly reduced by increasing awareness, decreasing exposure to the toxicant, and better utilization of these biomarkers.


FIGURE 30.1 Major cellular interactions of arsenic, indicating plausible biomarkers of arsenic toxicity.

MERCURY

Mercury (Hg) is involved in causing serious public health disaster in Minamata Bay, Japan (Flora et al., 2008). Its toxic manifestations are also elicited in response to its binding with primary and secondary amine, amide, carboxyl, and phosphoryl groups.

Biomarkers of Exposure

Hg exposure could be complicated by the enhanced latency period of several weeks to months between the exposure and the development of clinical symptoms. Moreover, early symptoms are also hard to recognize. There exist several biomarkers of exposure for Hg poisoning, determining of which helps in early diagnosis and treatment. Analysis of Hg levels in blood, hair, and urine reflects recent exposure to the toxicant but do not correlate with total body burden. The presence of micronuclei has been detected in lymphocytes of exposed individuals and serves as an extremely important biomarker of exposure.

1. *Blood mercury levels:* Blood mercury level is determined using whole blood analysis and provides accurate information only about recent exposure, which renders it unsuitable for indicating prenatal exposure during early periods of pregnancy. Specifically alimental organic Hg and short-term exposure to mercury vapor are exhibited by the whole blood analysis, with organic Hg localized in erythrocytes. Thus, separate analysis of whole blood, erythrocytes, and plasma is recommended to analyze the presence of various species of Hg. Normally, the quotient of Hg content in erythrocytes and plasma is 2:1. A new method is developed and validated to measure MeHg exposure in newborns using dried blood spots (Basu et al., 2017).
2. *Urine mercury levels:* Analysis of urine samples for both mercury and creatinine determination also provides a much more valid index of recent exposure than the blood Hg level. A new method is developed for the determination of urine Hg. Samples were prepared using techniques such as vortex-assisted ionic liquid dispersive liquid—liquid microextraction and microvolume back-extraction, and for detection voltammetric analysis was performed using screen-printed electrodes modified with gold nanoparticles. The Hg threshold level in urine is $10-20\ \mu g/L$ set by World Health Organization. The detection limit of this method was from 1.1 to 1.3 $\mu g/L$ statistically (Fernández et al., 2016).
3. *Mercury levels in hair, nails, breast milk, and umbilical cord blood:* Mercury levels can be determined in hair, and total amount of this toxicant in both hair and blood correlates well with the total methyl mercuric content in the exposed individuals. Hair measurement provides an indirect noninvasive method of measuring Hg levels in the brain. Prenatal Hg exposure can also be assessed by analysis of umbilical cord tissue or umbilical cord blood, and maternal blood and maternal hair segments (Sakamoto et al., 2016). However, in case of exposure to mercuric vapors, hair is not a reliable biomarker. Along with all these, toenail and breast milk are also considered to be important biomarkers of MeHg toxicity. Hair samples of dentists were analyzed to determine the index of mercury exposure as they use dental amalgam. The hair sample showed 10-ppb mercury level, which is considered normal, so it is not taken into account of an occupational hazard to dentists (Wijesekara et al., 2017).

Limitations of Biomarkers of Exposure

All of the abovementioned biomarkers may surely help in rapid and accurate detection of Hg intoxications, but their selection poses certain difficulties influenced by number of factors that include (1) difficulty in obtaining blood samples post exposure; (2) variation in toxicokinetic, retention, and deposition; (3) extrapolation of low-level exposure data from animals to humans; (4) human exposure to other metal intoxicants, such as As, Pb, etc., in conjunction with Hg; and (5) difficulty in speciation, and it is essential to use certified reference material for quality control and assessment.

Biomarkers of Effects

In humans, Hg toxicity has been implicated in the development of various diseases and pathological conditions, resulting in dysfunctioning of vital organ systems of the body such as nervous system. There exist various biomarkers of effect or response biomarkers to detect systemic manifestations associated with mercury intoxication.

1. *Systemic manifestations:*
   a. *Neurological manifestations:* Mercury poisoning has been reported to cause various neurodegenerative diseases such as amyotrophic lateral sclerosis, Alzheimer's diseases, and Parkinson's disease, exhibiting its strong neurotoxic potential. Its neurotoxic properties received labels such as "hatter's shakes" in which the individual experiences excessive tremors and psychological disorders such as being hyperirritable, blushing easily, having a labile temperament, being depressed or despondent, suffering from insomnia, and suffering from

fatigue. Moreover, mercuric chloride was found to increase free radical production in synaptosomal fractions suggesting oxidative damage and contributing significantly to neurotoxicity and neurodegeneration. Brain stem auditory evoked responses were measured as biomarkers of subtle Hg-induced neurological impairments. The people consuming methyl mercury via fish are at risk to suffer with amyotrophic lateral sclerosis (Andrew et al., 2018).

b. *Reproductive manifestations:* Mercury intoxication has been involved in causing various reproductive dysfunctions such as reduced number of sperms, testicular atrophy, reduced size of infants in one birth, reduced survival rate of fetuses, and fetal deformity. Inorganic Hg exposure impaired gonads of zebrafish, and the mechanism involved is an alternation of sex hormone levels that leads to disrupt transcription of hypothalamic-pituitary-gonadal (HPG) axis—related genes (Zhang et al., 2016).

c. *Cardiovascular manifestations:* Mercury exposure increases blood pressure as it accumulates in heart, following which are abnormal heartbeats and myocarditis. It has been reported to promote platelet aggregation and blood coagulation, myocardial infarction, altering heart rhythm and function, reduced sympathetic and parasympathetic nerve functions of the heart, and sclerosis of the arteries (Gribble et al., 2015).

d. *Immunological manifestations:* Occupational mercury exposures among miners are more at risk of autoimmune disorder. A report suggests that low level of organic Hg exposure is associated to subclinical autoimmunity among reproductive age females (Somers et al., 2015). Animal studies indicate adverse effect of Hg on immune system. However, fewer studies represented the immunotoxicity on human health. The difference may be due to dose variations, exposure route, and dissimilarity between the immune system of animal and human (Gardner and Nyland, 2016).

e. *Nephrotoxic manifestations:* Glomerular deposits of IgG1 and IgG4 are considered an important marker of mercury-induced nephropathy; however, their distribution and deposition varies according to Th1 and Th2 immune responses. An experimental study was conducted to determine the effect of Hg on rat kidney. Aldo-keto reductase and glutathione S-transferase pi (GSTP1) are identified as new biomarkers that could be utilized for evaluating nephrotoxicity (Shin et al., 2017).

2. *Biomarkers of oxidative damage*
  a. *Urinary markers:* Exposure to mercury elicits a specific change in the pattern of porphyrin excretion, characterized by increased urinary concentrations of coproporphyrin and pentacarboxyl porphyrin. Elevation in urinary NAG concentration is also associated with the direct poisoning of Hg compounds. Urinary porphyrins (coproporphyrin and precoproporhyrin) may also be developed as possible biomarkers of Hg toxicity in children with autism spectrum disorder (Khaled et al., 2016).
  b. *Metallothionein:* Metallothionein, a low molecular weight (6−7 KDa) protein, is one of the major molecules playing critical role in scavenging and reducing the toxic effects of Hg. Metallothionein and genetic polymorphisms may affect urine and hair mercury concentrations. Glutathione-S-transferase (*GSTT1* and the *GSTM1*) genes deletion may be the risk factor for enhanced susceptibility to mercury exposure (Wang et al., 2012).

Biomarkers of Susceptibility

1. *Cytogenetic markers:* Determining alterations at molecular level due to metal intoxication forms another important category of biomarkers, helping in precise identification and diagnosis. Metal-specific lymphocytes act as biomarkers of sensitivity among patients suffering from health problems due to dental amalgams. Respiratory burst and chemotaxis in polymorphonuclear leukocytes have also been used to assess the extent of Hg exposure.

2. *Biomarkers of apoptotic gene expression:* Mercury significantly alters the expression of various genes involved in cell survival and apoptosis, proving it to be a potent genotoxin. It inhibits the activity of NF-Kβ, thereby enhancing the sensitivity of renal cells to apoptotic stimuli. Mercury-induced ROS generation leads to p38, caspase, and TNF-α activation; alteration of calcium homeostasis; and inflammatory cytokine gene expression that has a possible role in regulating both apoptosis and necrosis. Thioredoxin, an antioxidant system, oxidized by Hg compounds leads to increased ASK-1 phosphorylation and number of apoptotic cells along with activation of caspase-3 (Branco et al., 2017). Disorders of apoptosis and cell accumulation may play critical role in enhancing Hg-induced afflictions; however, their rapid diagnosis and measurement through biomonitoring may help in overcoming lethal consequences. Development of potent and novel biomarkers and proper utilization of

existing techniques will surely lead to reduction in cases of Hg intoxication.

CADMIUM

Cadmium (Cd) is recognized as a potential occupational health hazard because of its widespread and extensive dissemination in the environment. The famous itai-itai ("ouch-ouch") disease of Japan characterized by multiple fracture, distortion of the long bones in skeleton, and severe pain in the joints and spine was a result of consuming Cd-polluted rice.

Biomarkers of Exposure

1. *Blood cadmium levels:* Estimation of blood Cd levels is one of the major and promising biomarker to detect Cd toxicity and has also been shown to be an excellent indicator of Cd body burden. However, levels of Cd in blood mainly reflect recent exposure (Friedman et al., 2006).

2. *Urine cadmium levels:* Urinary excretion of Cd itself also serves for a good purpose and is regarded as a marker of both Cd exposure and proximal tubule injury. During exposure the concentration of Cd in the epithelial cells rise until the all the cells die and slough off into the urine. At this point urinary excretion of Cd increases markedly. Cd level in urine is an indicator of a long-term exposure because of its good to excellent temporal stability in urine. The urinary Cd is being affected by factors such as changes in smoking habits and increased excretion of proteins in some diseases (Vacchi-Suzzi et al., 2016) (Fig. 30.2).

Biomarkers of Effects

1. *Systemic manifestations:* "The Cd blues," often collectively referred to in this way, show flu-like symptoms such as chills, fever, and muscle ache and are induced on acute exposure to Cd. Further symptoms may lead to inflammation, cough, dryness, irritation of the nose and throat, headache, dizziness, weakness, fever, chills, and chest pain.
FIGURE 30.2 Induction of metallothionein by cadmium in liver and kidney, followed by excretion in urine, a major biomarker of Cd toxicity.

2. *Renal manifestations:* Kidney is reported to be the critical target organ as it is the main storage organ for Cd. However, Cd exerts its toxicity only when critical threshold is reached, which is estimated to be 150−200 ppm. Measuring urinary cystatin C concentration is being evaluated as biomarker of various types of ischemic and nephrotoxic renal injury (Prozialeck et al., 2016).

3. *Bone manifestations:* Increased risk of bone fractures, osteomalacia, pain in the back and in the extremities, difficulties in walking, and pain on bone pressure are some of the common response biomarkers associated with Cd toxicity. Effect of Cd on subchondral and interradicular bone of experimental rats was studied, and it resulted in decrease in bone volume and increase in tibial yellow bone marrow (Rodríguez and Mandalunis, 2016).

4. *Carcinogenesis:* Increased risk of prostrate, renal, breast, and lung cancers has been associated with occupational exposure to Cd. Cd exposure increases the risk of breast cancer (Larsson et al., 2015).

5. *Other manifestations:* Cadmium has been reported to cause impairment of pulmonary function suggestive of obstructive syndrome, and no adverse effects on hepatic, nervous, and reproductive systems has been documented so far. However, at the same time, enhanced Cd levels in blood were associated with a modest elevation in blood pressure levels. The effect of Cd exposure on pregnant women was found to be associated with decreased gestational age and increased preterm birth (Yang et al., 2016).

1. *Urinary markers:*

a. *Metallothionein:* Urinary levels of metallothionein have been used both as a marker of Cd exposure and renal injury. For example, identifying critical level of urinary metallothionein indicates the onset of toxic manifestations. It plays a key role in transporting Cd to the epithelial cells of the proximal tubule and is a specific metal-binding protein that makes it a superior biomarker. It was also found that genetic variation in the metallothionein gene region and metal-regulatory transcription factor 1 affects urinary Cd level (Adams et al., 2015). Urinary Cd showed good to excellent temporal stability in both sampling methods, i.e., spot urine or first morning void sampling. However, some factors such as increase of protein excretion and change in smoking habits may bring short-term changes in urinary Cd levels (Vacchi-Suzzi et al., 2016).

b. *β-2 microglobulin and Clara cell protein-16 (CC-16):* Urinary biomarkers are considered to be the best and most promising in the diagnosis of Cd-induced nephrotoxicity. Some of the urinary biomarkers that have been used for this purpose include Cd-binding protein metallothionein and low molecular weight proteins such as β-2 microglobulin, Clara cell protein-16 (CC-16), and Cd itself. These are some of the effective biomarkers for renal dysfunction. $β_2$-Microglobulin and CC-16 are low−molecular weight proteins, filtered at the glomerulus and reabsorbed by the proximal tubule. In addition, Cd-induced renal injury can be identified by these existing markers only its late stages and by the time they are detected injury to the kidney becomes irreversible and untreatable. This evokes the need for better and early biomarkers of Cd-induced kidney injury. A study suggests that Cd-exposed rats showed increase level of urinary cystatin C because of disruption of megalin-mediated uptake of cystatin C by epithelial cells of the proximal tubule that could be an early biomarker for renal damage (Prozialeck et al., 2016).

c. *Kidney injury molecule-1:* Another sensitive marker of cadmium-induced proximal tubular injury includes kidney injury molecule-1 (Kim-1). Elevated levels of Kim-1 appears in urine only after 6 weeks of Cd intoxication, whereas classic signs of Cd-induced proximal injury, which include overt polyuria and proteinuria, become evident only after 9−10 weeks. The ecto domain of Kim-1 is shed into the urine as a result of renal injury induced by a variety of agents including cisplatin, Hg, and chromium. It offers several advantages over the existing urinary biomarkers: (1) it is a more specific marker of Cd-induced proximal tubular injury because of specific production by injured renal cells and then shed into urine, (2) it is highly conserved and upregulated after renal injury in variety of species including mice, rats, nonhuman primates, and humans, (3) almost nil expression is observed in noninjured kidney, making it relatively easy to detect in cases of Cd-induced renal injury, and (4) it is highly stable in urine, without any requirement of special preservatives, even at the temperature of $-80°C$ for months. Recent study suggests that Kim-1 might serve as a sensitive biomarker to assess kidney injury in children due to Cd exposure (Cárdenas-González et al., 2016).

d. *NAG, alanine aminopeptidase, and α-GST:* Proximal tubule−derived enzymes NAG, alanine aminopeptidase (AAP), and α-GST are the other biomarkers, which have been studied. Reports

indicate that NAG and α-GST outperformed traditional markers of Cd toxicity such as β2-microglobulin.

2. *Biomarkers of DNA damage:* Apart from all these urinary metallothionein mRNA, 8-OH-dG, albumin, and creatinine were also found to be sensitive markers of acute Cd-induced testicular damage and dysfunction. Measurement of 8-OHdG adduct in urine samples of exposed individuals has been used as an early marker of oxidative DNA damage, evaluated by the comet assay, immunoperoxidase staining coupled with a monoclonal antibody, and cytogenetic tests (Filipič and Hei, 2004).

Biomarkers of Susceptibility

1. *Biomarkers of gene expression:* In Cd-related carcinogenicity, various regulatory genes are activated, such as immediate early response genes (IEGs). Overexpressions of IEGs constitutively stimulate cell proliferation and induction of carcinogenesis. Cadmium-induced carcinogenicity is also found to be induced by expression of several stress response genes such as metallothionein (MT), genes for encoding heat-shock proteins (HSPs), oxidative stress response, and synthesis of GSH. Identification of these biomarkers is involved in detection of both early and late stages of Cd poisoning.

2. *Biomarkers of apoptotic genes:* Cadmium-induced cellular responses include variety of molecular markers that can be identified for the better and rapid identification of Cd-induced toxic manifestations. Some of them include, identifying release of cytochrome C from mitochondria, caspase-3 activation, intracellular GSH oxidation, inhibition in the expression of Bcl2 and p53, and involvement of Fas-FADD caspase 8 pathways and MT-3 in inducing apoptosis in renal tubular cells. cDNA microarray and quantitative real-time PCR results revealed decreased expression of proapoptotic and DNA repair genes, suggesting enhanced carcinogenic potential of Cd. lncRNA-MALAT1 was reported as a novel biomarker of Cd exposure. It was observed that Cd toxicity increases MALAT1 expression, which regulates apoptosis, proliferation, and cell cycle progression (Huang et al., 2017a,b).

Thus, as evident from the reports available there exists various biomarkers for the effective diagnosis of Cd intoxications; however, few limitations exists, which has to be overcome to develop better and much more efficient biomarkers. Development of molecular biomarkers is the need of the hour, with a continuous increase in the number of metal-poisoning cases.

CHROMIUM

Chromium (Cr III and Cr VI) has widespread industrial applications such as chrome plating, welding inox steel and other special steels, painting, leather tanning, and wood preserving. Cr (VI) is classified as Group I human carcinogen and transported inside the cells through anion channels as chromate.

Biomarkers of Exposure

Analysis of Cr levels in various body fluids, such as blood, serum, and urine, also significantly determines exposure to Cr along with a measurement of the internalized dose of Cr and serves as important biomarkers of exposure.

1. *Blood, serum, and urine chromium levels:* Blood and urine are prominently used for the biological monitoring of workers exposed to Cr. The levels of indicators for nasal injury, genetic damage, and micronucleus were determined in low and high Cr-exposed workers; this indicates that blood Cr could be used as a biomarker for occupationally exposed people (Li et al., 2016). Recent study suggests that measuring serum MDA level in occupationally exposed workers could be a reliable biomarker of its exposure (Mozafari et al., 2016).

2. *Exhaled breath condensate chromium levels:* Analysis of exhaled breath condensate (EBC) is a novel approach being utilized currently to quantify both internal dose of toxicant inhaled and the level of free radical production (Caglieri et al., 2006). EBC seems to be suitable biomarkers for assessing inflammation and enhanced oxidative stress and can be efficiently used to investigate lung tissue levels of Cr (VI). Also, magnetic resonance imaging (MRI) is considered a good choice for monitoring of internalized doses of Cr in lung tissues.

Biomarker of Effects

1. *Systemic manifestations:* There are various health hazards and systemic effects associated with Cr exposure, which serves as important biomarkers of effect or response biomarkers for effective diagnosis of Cr poisoning.

   a. *Respiratory manifestations:* The adverse effect of Cr depends on exact dose, duration, and the specific compound involved. Higher incidences of nasal mucosa injury; dyspnea; urticaria; angioedema; pharyngitis; rhinitis; polyps of the upper respiratory tract; cough; phlegm; wheezing and shortness of breath; nasal allergy; nasal septal perforation; throat irritation; bronchial asthma;

alteration in lung function; and nose, throat, and lung tumors; tracheobronchitis; and bronchospasm have also been observed in workers exposed occupationally to chromium (Jamal et al., 2017).

b. Skin manifestations: Dermal contact with chromium compounds is known to cause various skin manifestations such as irritant and allergic contact dermatitis, localized erythematous or vesicular lesions at points of contact or generalized eczematous dermatitis, dryness, erythema, fissuring, papules, scaling, and swelling. Penetration of the skin by chromium leads to painless erosive ulceration known as "chrome holes" (Buters and Biedermann, 2017).

c. Carcinogenesis: Increased risk of respiratory system, lung, nasal, gastrointestinal, and sinus cancers has been shown to exist in workers exposed to Cr (VI). In addition, the carcinogenicity appears to be associated more with the inhalation of Cr (VI) compounds (Welling et al., 2015).

d. Developmental manifestation: Chromium exposure to pregnant women is a threat because of its potential health effects on susceptible embryos such as premature rupture of membranes, and there may be increased risk of delivering low birth-weight infants. The adverse effect of Cr on developing embryo may differ by infant gender (Huang et al., 2017a,b).

2. Biomarkers for oxidative damage: Although the mechanism of Cr (VI)-induced toxicity is not clear, it is believed that oxidative stress plays an important role, suggesting MDA as a prominent biomarker for occupational Cr exposure.

a. Biomarkers for DNA damage: 8-hydroxydeoxyguanosine and 8-Oxo-G: Measurement of oxidative DNA base modifications such as 8-hydroxydeoxyguanosine (8-OH-dG) and 8-Oxo-G plays vital role in the identification of Cr-induced DNA damage, thus serving as a key biomarker relevant to carcinogenesis. Estimation of 8-Oxo-G may not be wholly reliable and assessment of further oxidized products of 8-Oxo-G should be considered while evaluating chromate-induced DNA damage and mutagenesis. Increase in DNA strand breaks as estimated by comet assay is also suggested to be a valid biomarker for assessing genotoxic response to Cr compounds. Male workers occupationally exposed to Cr (VI) were investigated to find out the biomarker of oxidative DNA damage and lipid peroxidation. Exposure to Cr(VI) was linked with increase in the level of urinary 8-OHdG and MDA (Pan et al., 2018).

Biomarkers of Susceptibility

1. Cytogenetic markers

a. DNA−protein cross-links: Quantifying DNA−protein cross-links (DPC) in peripheral blood mononuclear cells of human subjects has also been used as a biomonitoring tool. This technique provides a sufficiently sensitive approach to determine DNA damage in Cr-exposed populations. Unique kinetic principles involved in the formation of this adduct points toward the ability to detect low levels of Cr exposure. Few advantages including the cost effectiveness of cross-link assay and multiple analyses of samples led to establishment of DPC measurements as one of the popular method for rapid screening of DNA damage among potentially exposed populations (Macfie et al., 2009).

b. Sister chromatic exchange (SCE: Blood may be analyzed for the presence of SCEs (intrachromosomal rearrangements, SCEs) in lymphocytes. Lymphocytes play an important role in biomonitoring as they come into contact with Cr(VI) while migrating through the blood, where uptake of Cr(VI) that has leached from the lungs takes place. But at the same time they seem to be inappropriate for the monitoring of early biological effects and effective dose of exposure. However, lymphocytes may be useful in monitoring exposure to Cr at high levels (Mamyrbaev et al., 2015).

2. Biomarkers of gene expression and apoptosis: Hypoxia-induced factor HIF-1 plays an important role in Cr-induced toxic manifestations. It is known and reported to modulate the expression of several cancer-related genes such as heme oxygenase1 and vascular endothelial growth factor by regulating oxygen homeostasis (Rana, 2008). Both p53-dependent and p53-independent pathways have been shown to play major role in Cr-induced apoptosis (Fig. 30.3). Generation of ROS by Cr (VI) activates upstream kinases resulting in phosphorylation of p53 and further DNA damage (Gavin et al., 2007).

THALLIUM

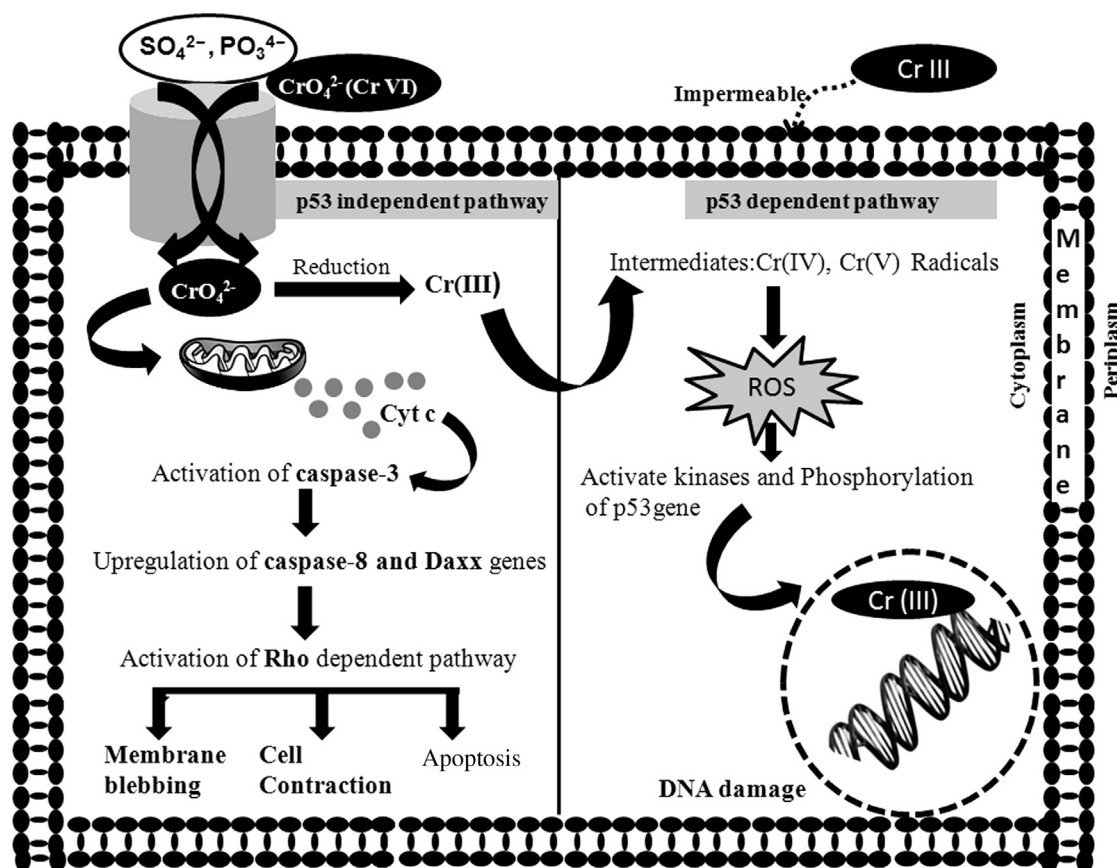
Thallium (Tl) is widely distributed in the environment in the earth's crust and is present at very low concentrations in soil and sulfide-based minerals. It is used in small amounts in pharmaceutical and electronics manufacturing, the latter being the current major industrial consumer of Tl (Karbowska, 2016). Interaction of Tl


FIGURE 30.3   Mechanism of Cr induced genotoxicity and associated biomarkers of susceptibility.

with cells at different level is considered as a major mechanism involved in eliciting toxic manifestations. Person consuming thallium-contaminated alternative medicine suffered from diffuse alopecia with gastrointestinal and neurologic symptoms (Senthilkumaran et al., 2017).

Biomarkers of Exposure

Analysis of various body fluids, such as blood, serum, urine, and breast milk is a common biomarker employed for detection of exposure to Tl.

1. *Blood thallium levels:* Disappearance of Tl from the blood is observed within several days, but it is not considered to be a reliable biomarker as it reflects only recent exposures. It can readily cross the placental barrier and also excreted into the breast milk; however, elimination from the body tissues occur slowly through urine and feces (Blanchardon et al., 2005).
2. *Urinary thallium levels:* Urinary Tl levels reflect recent exposure. Appropriate methodology for analysis of urine or blood TI includes atomic absorption spectroscopy and inductively coupled

plasma emission spectroscopy. Measurement of Tl from 24-h urine collection is the method of choice for diagnosis. A study demonstrated that qualitative Tl urinary assay is as important as quantitative assay in determining Tl poisoning that could be used in determination of Tl exposure in persons using drugs such as heroin and cocaine (Ghaderi et al., 2017).
3. *Presence of thallium in hair samples:* A good correlation was found between urinary and hair Tl concentrations, when both the samples were collected simultaneously. Elevated Tl levels in hair can be observed as early as 2–3 weeks after intoxication (Misra et al., 2003). Besides blood and urine, thallium also concentrates in hair, making it an efficient biomarker of Tl toxicity.

Biomarkers of Effects

Clinical manifestations of Tl poisoning can be characterized as acute, subchronic, and chronic, depending on the dose of Tl, route, and duration of exposure.

1. *Systemic manifestations:* Tl exhibits adverse effects on various organ systems, which serve as useful response biomarkers for the diagnosis of Tl intoxication.

a. *Dermal and ocular effects:* Complete hair loss along with hair discoloration usually occurs after a month of exposure, and characteristic pattern of black pigmentation at the roots of scalp hair may also be observed. Thallium interferes with normal process of cutaneous keratinization, parakeratosis, dilated hair follicles filled with keratin and necrotic sebaceous materials, mild epidermal atrophy, and vacuolar degeneration of the basal layer. Exposure to Tl for about 1 month leads to formation of transverse white lines in the nail called as Aldrich-Mees' lines or leukonychia striata (Zhao et al., 2008). In early stages of poisoning, the optic disk reveals the typical picture of neuritis with ill-defined and red papillae, followed by the development of pale or white papillae as a result of atrophy of the optic nerve.

b. *Respiratory manifestations:* Acute ingestion of Tl was reported to cause severe lung damage resulting in diffuse alveolar damage with hyaline membrane formation and pulmonary edema. Bronchopneumonia was also observed.

c. *Gastrointestinal manifestations:* Gastrointestinal symptoms were reported to occur immediately within one to few hours after acute exposure and comprised of inflammatory reaction in the first exposed tissues or organs causing glossitis, pharyngoesophagitis, gastritis, enteritis, and colitis. After 3—4 days of intoxication nausea and vomiting occurs, followed by abdominal pain, severe constipation, and stomach and duodenal ulcers.

d. *Cardiovascular manifestations:* Thallium toxicity induces various cardiac complications, such as myocardial damage, electrocardiographic changes, decrease in mean arterial pressure and heart rate, sinus tachycardia, irregular pulse, hypertension, and angina-like pain. It is quite common for paralyzed patients, often short of breath already, to develop severe dyspnea and cyanosis, followed by death (Cvjetko et al., 2010).

e. *Hepatic manifestations:* Tl compounds could induce reactive oxygen species formation, membrane lipid peroxidation, and reduced GSH oxidation and collapse mitochondrial membrane potential. As liver mitochondria are a target of Tl toxicity, its mechanism of toxicity was investigated. It was found that Tl has disruptive effect on the mitochondrial respiratory complexes, which lead to the ATP depletion and reactive oxygen species formation (Eskandari et al., 2015).

f. *Renal manifestations:* Renal excretion of Tl sulfate is slow and may be detected as late as 2 months after ingestion. During the initial stage of exposure there is albuminuria, with erythrocytes, leucocytes, and cylindrical casts in the urinary sediment; however, in the later phase of serious illness, there is a fall in the concentrating ability of the kidneys, often with recovery afterward.

g. *Neurological manifestations:* In very serious or even fatal cases, true "pseudobulbar paralysis," with paralysis of the ocular muscles, facial paralysis, amblyopia, and paralysis of the recurrent nerve was observed. However, paralysis of the vagal nerve may possibly be the direct cause of death. Acute oral exposure to Tl causes disturbances of the peripheral and central nervous systems leading to symptoms such as ataxia, tremor, multiple cranial palsies, numbness of toes and fingers, "burning feet" phenomenon, muscle cramps, convulsions, and death. In chronic poisoning, ataxia and paresthesia may be the outstanding symptoms, which may eventually progress to peripheral neuropathy with weakness and atrophy of the associated musculature (Osorio-Rico et al., 2017).

h. *Reproductive manifestations:* Reproductive system is highly susceptible to Tl and leads to various adverse effects, such as decreased sperm motility, inhibition of β-glucuronidase activity, histopathological alterations of the testes, increased embryolethality, decreased libido and impotence in humans, and lower sexual activity in laboratory animals. Thallium has the ability to cross placental barrier as evident by skin and nail dystrophy, alopecia, and low body weights in newborns of intoxicated mothers (Xia et al., 2016).

i. *Developmental manifestations:* Tl exposure may result in achondroplasia, leg bone curvature, parrot beak deformity, microcephaly, and decreased fetal size. High-level exposure to Tl at the end of pregnancy leads to the death of fetuses (Mulkey and Oehme, 1993).

Biomarkers of Susceptibility

1. *Cytogenetic markers:* Chromosomal aberrations are considered to be sensitive biomarkers of genotoxic damage, such as DNA breakage. Thallium has been shown to induce chromosomal aberrations and SCEs following exposure. Thallium showed weak mutagenic effect both in vitro and in vivo. However, no effect of the induction of primary DNA and chromosomal damage was observed. Cellular and genotoxic effects of Tl were investigated in human peripheral lymphocytes by chromosome aberration assays, and it was discovered that Tl induced clastogenic and aneuploidogenic effects (Rodríguez-Mercado et al., 2017).

2. *Biomarkers of gene expression and apoptosis:*
   Exposure to Tl leads to opening of mitochondrial membrane pores and release of cytochrome C, caspase-3, and caspase-9, resulting in cell death. Estimation of these proteins proves to be of immense value and serves as potential biomarkers of toxicity. p53, p21, and Bcl$_2$ estimation also play an important role in detecting Tl-induced apoptosis as Tl inhibits cell cycle progression at G2/M phase by suppressing CDK activity through the p53-mediated induction of the CDK inhibitor p21(Cip1), which in turn triggers the activation of a mitochondrial pathway and Bcl-2 family, promoting the formation of the apoptosome and, consequently, apoptosis (Cvjetko et al., 2010).

MANGANESE

Chronic exposure to manganese (Mn) leads to neurodegenerative changes resembling Parkinson's disease such as movement disorder, referred to as "manganism." A meta-analysis study revealed that elevated Mn level in plasma, whole blood and low level in serum in people are at higher risk for neurological disorder (Du et al., 2018).

Biomarkers of Exposure

The measurement of Mn in biological media (blood, serum, plasma, urine; and less frequently in hair, nails, cerebrospinal fluid, feces, and saliva) have been suggested as biomarkers of exposure. Blood and urinary Mn are the most widely investigated biomarkers of exposure. Half-life of Mn in blood has been reported to be 10–42 days, whereas it is less than 30 h in urine.

1. *Blood Mn levels:* Elevated blood Mn concentration accompanied by a progressive, symmetric Parkinsonism (characterized by prolonged L-dopa responsiveness) and a reduced [^{18}F]FDOPA uptake by Positron emission tomography has been reported in few cases (Racette et al., 2005). Report suggests a link between Mn exposures with serum prolactin level that could be a diagnostic marker of its exposure (Tutkun et al., 2014). Investigation of Mn in blood cell and plasma revealed that the former could serve as a potential internal biomarker. However, further validation studies need to be performed for its establishment as biomarker (Ge et al., 2018).
2. *Urinary Mn levels:* Studies suggest urine Mn as a potential noninvasive marker of Mn intoxication. As Mn gets mainly excreted in feces and only a very small proportion in urine, measuring urinary Mn is of little interest as biomarker of current exposure (Hoet et al., 2012).

3. *Manganese levels in hair, nails, and saliva:*
   Manganese concentration in saliva is a noninvasive biomarker of exposure. However, reports suggest that Mn in saliva is not a more sensitive measure or better indication of Mn exposure. Hairs and nails Mn level on the other hand may reflect low-level exposure of Mn (Ntihabose et al., 2017). Estimation of Mn in teeth and hair indicate long-term low-level Mn exposure, which could be a reliable biomarker of exposure. Several studies suggested that hair Mn is a more reliable and applicable biomarker of Mn exposure in school-aged children (Liang et al., 2016). A recent study suggests that the human toenails and tooth dentin Mn levels could be sensitive, specific, and easy-to-acquire biomarker of Mn exposure (Ward et al., 2017).

Biomarkers of Effects

Manganism due to an increased Mn concentration in brain regions is a neurological syndrome similar to Parkinson's disease (Rivera-Mancía et al., 2011). General symptoms associated with Mn exposure include behavioral changes such as increased anxiety or nervousness, apathy, loss of memory, decreases in concentration, bradykinesia, less-frequent resting tremor, rigidity, frequent dystonia of the trunk and extremities, extrapyramidal movement disorder with characteristic "cock-walk," and difficulty in walking backward are observed (Olanow, 2004).

1. *Nervous system:* Manganese can readily cross the blood–brain barrier by facilitating diffusion, active transport, divalent metal transport 1 (DMT-1)–mediated transport, and transferrin-dependent transport mechanisms leading to accumulation of Mn in various brain regions (Au et al., 2008). Use of excessive amounts of Mn-containing herbals and supplement products by the people could lead to neurotoxicity (Schuh, 2016). MnB could be diagnosed by a sensitive, feasible, effective, and semiquantitative index known as Pallidal index (Li et al., 2014). A study was performed to evaluate the low-level exposure of Mn on central nervous system function. It was found that T1 signal intensity in various parts of the basal ganglia significantly increased with Mn exposure, suggesting T1-weighted MRI a possible biomarker of exposure to Mn (Baker et al., 2015). An effect on the levels of serum prolactin, luteinizing hormone, follicle-stimulating hormone, testosterone, and thyroid-stimulating hormone that consequently influence the metabolism of neuroendocrine hormones has been reported (Kim et al., 2007).

2. *Cardiovascular effects:* An epidemiological study conducted among ferroalloy workers reported decreased systolic blood pressure. Similar studies have also been reported where potential cardiotoxicity in 656 workers (547 males and 109 females) engaged in Mn milling, smelting, and sintering to Mn dioxide exposure has been reported (Jiang and Zheng, 2005).

3. *Hematological effects:* Chronic Mn poisoning caused alterations in erythropoiesis and granulocyte formation. An increased level of erythrocyte superdioxide dismutase and plasma malondialdehyde in men working in Mn smelters has been reported, whereas an elevated level of serum prolactin and the increased activity of lymphocytes Mn-dependent superoxide dismutase have been suggested as useful peripheral biomarkers of Mn exposure. Children with iron deficiency were linked with increase whole blood Mn concentrations (Smith et al., 2013).

4. *Reproductive effects:* Impotence and loss of libido are the two common problems among male workers exposed to Mn. Another study suggested that Mn affects pituitary gland function, which is reversible when exposure stops. Welders with lower inhibin B level indicate impairment of the testicular sertoli cells (Ellingsen et al., 2007). Consumption of Mn-contaminated drinking water by the pregnant women may impair fetal growth (Rahman et al., 2015a,b).

5. *Immunological effects:* Suppression of T and B lymphocytes, primarily CD4+ and CD8+ T-lymphocytes leading to the reductions in serum immunoglobulin G (IgG) and alterations in immune cell number have been reported following pulmonary exposure to welding fumes containing Mn particles (Antonini et al., 2012).

Biomarkers of Susceptibility

Altered RNA expression and cytotoxic markers: An increased expression of GS mRNA has been observed because of Mn-potentiated cellular overload of iron. Overexpression of GS mRNA reflects a change in intracellular levels of Mn(II). An increase in proinflammatory genes (tumor necrosis factor-α, iNOS) and activated inflammatory proteins (P-p38, P-ERK, and P-JNK) in primary rat glial cells has been reported after Mn exposure (Chen et al., 2006). Polymorphism has also been suggested as a genetic marker with no direct physiological relevance to Mn neurotoxicity.

Concurrent Exposure of Heavy Metals

Human exposure occurring simultaneously to more than one heavy metals such as Pb, Cd, As, Mn and MeHg, may produce additive or synergistic toxic effects due to their binding affinity towards same biological pathway such as NMDA receptor, Na^+-K^+ ATPase pump, biological Ca^{+2}, Glu neurotransmitter (Flora, 2016). They have common mechanism of toxicity such as oxidative stress, variation in hematopoietic system, and disturbance in neurotransmitter function. The toxicity of heavy metals and their correlation with disease in humans have been studied by gene expression profiling. Heavy metals exposure may express genes that are responsible for detoxifying toxic metals, enzymes metabolizing xenobiotics, and repair DNA. Heavy metal−exposed people are more prone to renal and urological diseases. These genes could be validated to establish them as early biomarkers for renal damage. The mode of action of concurrent metal exposure and its mechanisms to induce cognitive dysfunction have been reported (Karri et al., 2016). Study showed that urine excretion of ALA can be established as biomarker of exposure and may also assist in evaluating onset of neurological diseases linked with exposure to heavy metals (Andrade et al., 2015).

CURRENT CONCERNS AND BIOLOGICAL RELEVANCE

Biomarkers are one of the keys to quantify the interaction of metals and its potential impact on living organisms, including human beings. Previous reports suggest long history of use of urine and blood as established matrices for biomarkers, but the advent of molecular biology has opened up new vistas. Introduction of novel analytical techniques and instrumentation led to recognition of specific compounds of metals in biological samples such as fluids and tissues. Detection of speciation of metallic ions and complexes marks an important step because only specific species of a metal has the ability to be transported into cells and across the blood−brain and placental barriers. Data obtained from biomonitoring can be utilized for a variety of applications eventually leading to enhanced assessment of exposure mitigation strategies. As a common surveillance tool, biomonitoring helps in identifying baseline exposure levels, trends in exposure levels over time, and unique subpopulations with higher exposure levels. Various exposure and kinetic models have been developed to estimate the dose of exposure to the toxicant; however, results get greatly influenced by many sources of variability and uncertainty. Biomonitoring helps in eliminating those errors and has been recognized as a valuable quantitative tool to improve dose estimates, thus helping in improvement of the human health through early risk assessment of metals. In conjunction with the existing biomarkers and technology, the advent of "omic" molecular technologies

(genomic, proteomic, and metabolomic) has led to enormous augmentation in the speed and precision of biomarker (endpoint) measurements. The better and in-depth understanding of these early molecular markers in relation to other toxicological endpoint responses hold great promise in the future for the formation of more effective health surveillance strategies.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Biological survey forms a close association with environmental survey in environmental epidemiologies. Biomonitoring is useful for the assessment of exposure, but few limitations exist, which interfere with their ability to completely exhibit their potential. There is an immense spur to implement more biomonitoring tools into the field of exposure science, for which traditional methods should be improved and supplemented with newer, noninvasive technologies resulting in more informed risk assessment and decision-making. Moreover, advanced techniques are required to elucidate the mechanisms underlying interactive effects of metal mixtures and developing a gene—environment link. At the same time, expanding the repertoire of available biomarkers of metal exposure, investigating and employing the same in well-designed models will prove to be of immense benefit in the evaluation of metal intoxication along with designing of suitable measures to minimize hazardous exposures.

Melamine

Karyn Bischoff

**Cornell University, Diagnostic Toxicologist, New York State Animal Health Diagnostic Center,
Ithaca NY, United States**

INTRODUCTION AND HISTORICAL BACKGROUND

Melamine (1,3,5-triazine-2,4,6-triamine) has numerous uses in manufacturing. It has been used in yellow pigments, dyes, and inks and can be polymerized with formaldehyde to produce a variety of durable resins, adhesives, cleansers, and flame retardants. Cyanuric acid is used to stabilize chlorine in swimming pools. Protein in foods is estimated based on the nitrogen content; because melamine is 67% nitrogen by molecular weight, it has been added to foodstuffs (both human and animal) to increase the apparent protein content. Structural formulas of melamine and cyanuric acid are shown in Fig. 31.1.

Early in 2007, there were reports of inappetence, vomiting, polyuria, polydipsia, and lethargy in cats and dogs, including laboratory cats on a feeding trial for a commercial pet food (Cianciolo et al., 2008). The

FIGURE 31.1   Structural formulas of melamine and cyanuric acid.

pet food was recalled on March 15 and analyzed for possible contaminants. Melamine was found, as were low concentrations of cyanuric acid, ammelide, and ammeline, which are intermediates in the production and degradation of melamine. The United States Food and Drug Administration (FDA) investigation determined that two common pet food ingredients, sold to manufacturers as wheat gluten and rice protein concentrate, were mislabeled by Chinese exporters to avoid inspection (Osborne et al., 2008). Samples of the imported wheat gluten contained 8.4% melamine, 5.3% cyanuric acid, and 2.3% and 1.7% ammelide and ammeline, respectively (Rumbeiha et al., 2010). Eventually, more than 150 pet food products were identified as containing contaminated ingredients and were recalled. Analysis revealed that these products contained up to ~3200 ppm melamine and 600 ppm cyanuric acid (Cianciolo et al., 2008; Skinner et al., 2010).

Cats and dogs ingesting the contaminated food had evidence of renal failure. Cats had urine-specific gravities <1.035 and elevated serum urea nitrogen and creatinine concentrations. Urinalysis revealed the presence of circular green—brown crystals in urine sediment. Postmortem examination of animals that died typically noted bilateral renomegaly and evidence of uremia. Microscopic lesions were found primarily in the kidneys. Renal tubular necrosis was present, with evidence of rupture and regeneration. Distal convoluted tubules contained large golden-brown birefringent crystals (15—80 μm in diameter) with centrally radiating striations and smaller amorphous crystals (Cianciolo et al., 2008; Thompson et al., 2008). Crystals from kidneys and urine contained 70% cyanuric acid and 30% melamine based on infrared spectra (Osborne et al., 2008; Thompson et al., 2008).

Previous outbreaks of renal failure associated with pet foods and other animal feeds, including feeds for
poultry, swine, and raccoon dogs in the Republic of Korea, Japan, Thailand, Malaysia, Singapore, Taiwan, the Philippines, South Africa, Spain, China, and the United States were investigated and determined to be associated with melamine contamination (Acheson, 2007; Osborne et al., 2008; Reimschuessel et al., 2008, 2009; Bhalla et al., 2009; Gonzalez et al., 2009; Yhee et al., 2009; US FDA, 2010).

The 2007 pet food recall is considered a sentinel event by some (Osborne et al., 2008; Lewin-Smith et al., 2009). Indeed, 1 year later, melamine contamination of milk-based baby formula was found in China. Chinese authorities detected melamine concentrations between 2.5 and 2563 ppm in 13 commercial brands of milk powder and trace contamination in 9 others (Bhalla et al., 2009). Approximately 300,000 children may have been affected, more than 52,000 were hospitalized, and 6 died. Melamine-contaminated products were found in almost 70 countries, including the United States, and some children in Taiwan, Hong Kong, and Macau could have been clinically affected (Hau et al., 2009; Reimschuessel et al., 2009; Skinner et al., 2010).

Renal damage occurred in 0.61%–8.5% of exposed children, according to various estimates (Liu et al., 2010). Clinical signs of renal failure in children who consumed contaminated milk products included unexplained crying, anuria or polyuria, stranguria, hematuria, and the presence of stones in the urine, but many children were asymptomatic (Hau et al., 2009; Hu et al., 2010; Wen et al., 2010). The outbreak of melamine-induced nephropathy in children was different from the outbreak in companion animals and livestock in that cyanuric acid was not an important contaminant and was not required for crystal formation. Crystals in the infants contained melamine and uric acid at a molar ratio of 1:1 to 1:2 (Skinner et al., 2010; Wen et al., 2010).

Most affected children were between 6 and 18 months of age (Skinner et al., 2010; Wen et al., 2010). Clinical pathology findings in affected infants included elevated serum potassium, urea nitrogen, and creatinine concentrations (Sun et al., 2010). Hematuria and the presence of fan-shaped crystals were reported in urine samples and urine pH ranged from 5.0 to 7.5 (Hau et al., 2009). Renal calculi ranged in size from 2 to 18 mm in diameter, and approximately half were <5 mm in diameter. Diameter was dependent on the concentration of melamine in the diet but not on the duration of exposure (Hu et al., 2010). Renal calculi were usually bilateral; uroliths were also found in the ureter, unilaterally or bilaterally, and in the urinary bladder (Hau et al., 2009; Gao et al., 2010; Wen et al., 2010). A renal biopsy from an affected child showed glomerular sclerosis, swelling and necrosis of renal tubular epithelium, tubular dilation with the presence of material consistent with a stone, and an interstitial lymphoplasmacytic infiltrate. Tubular changes resolved after treatment (Sun et al., 2010).

TOXICOLOGY OF MELAMINE

Toxicity

As mentioned previously, until 2007 melamine was believed to have a relatively low toxicity based on animal studies. The oral LD_{50} of melamine is 3200 mg/kg in male rats, 3800 mg/kg in female rats, 3300 mg/kg in male mice, and 7000 mg/kg in female mice. Long-term administration of melamine to laboratory rodents at concentrations ranging from 0.225% to 0.9% of the diet produces urolithiasis (Melnick et al., 1984). A study involving dogs fed 125 mg/kg melamine reported crystalluria but no other adverse effects (Lipschitz and Stokey, 1945). Cyanuric acid has similarly low toxicity when given alone but is known to produce degenerative changes in the kidneys of guinea pigs when given at doses of 30 mg/kg body weight for 6 months, and in dogs and rats fed a diet containing 8% monosodium cyanurate (Canelli, 1974).

The combination of melamine and cyanuric acid is markedly more toxic to most animals than either compound when given alone. Cats fed diets containing 0.2% each of melamine, and cyanuric acid had evidence of acute renal failure within 48 h (Puschner et al., 2007). A pig fed 400 mg/kg each of melamine and cyanuric acid daily had transient bloody diarrhea within 24 h. Necropsy revealed perirenal edema and round golden-brown crystals with radiating striations in the kidneys. Similar lesions were present in tilapia, rainbow trout, and catfish dosed with 400 mg/kg each of melamine and cyanuric acid daily for 3 days (Reimschuessel et al., 2008).

Pharmacokinetics/Toxicokinetics

Melamine undergoes rapid renal elimination and is almost completely excreted within 1 day in monogastric mammals, though excretion is prolonged in ruminants (Dorne et al., 2012). Detectable melamine concentrations have been reported in edible tissues from animals, particularly the kidneys, for up to 4 days in lambs and up to 20 days in poultry (Lv et al., 2010; Bai et al., 2010). Melamine can be detected in cow's milk for up to 4 days post dosing (Shen et al., 2010).

Mechanism of Action

Cats and dogs ingesting contaminated food had evidence of renal failure. Although previous animal

studies found that both melamine and cyanuric acid were relatively nontoxic when given individually, they caused crystal formation in renal tubules when given together. Melamine and cyanuric acid crystallize, forming a molecular lattice structure at pH = 5.8 (Osborne et al., 2008; Bhalla et al., 2009). Crystals form in the distal convoluted tubules of the kidneys and contain 70% cyanuric acid and 30% melamine based on infrared spectra results (Osborne et al., 2008; Thompson et al., 2008). Intratubular obstruction causing increased intrarenal pressure most likely contributes to the pathology.

After consuming contaminated formula for 3–6 months, children developed urolithiasis, which can result in obstruction and secondary renal changes. Tubular changes resolved after treatment (Sun et al., 2010). Although cyanuric acid did not contribute to the formation of urinary calculi in children during this incident, uroliths in children were produced by a similar interaction between melamine and uric acid (Gao et al., 2010). This interaction has also been reported in poultry (Bai et al., 2010). Humans and most other primates lack the enzyme uricase, which converts uric acid to allantoin (Reimschuessel et al., 2008). Compared to adults, human infants excrete between 5 and 8 times as much uric acid, possibly increasing their susceptibility to melamine toxicosis (Skinner et al., 2010). Urinary pH < 5.5 is associated with the formation of urate crystals and low pH and could contribute to melamine/urate stone formation (Gao et al., 2010).

Treatment

The basic treatment regimens for crystalluria and urolithiasis related to melamine ingestion include fluid therapy and supportive care in both veterinary and pediatric patients (Anon., 2007; Wen et al., 2010). Because low urinary pH is associated with crystal formation in infants, alkalization of the urine was used to maintain urine pH between 6.0 and 7.8 in affected children (Gao et al., 2010; Wen et al., 2010). Antispasmodic drugs such as anisodamine or atropine were given to facilitate excretion of uroliths and pain management was instituted (Bhalla et al., 2009; Wen et al., 2010). Most children recovered fully, but 12% were found to have renal abnormalities 6 months after treatment (Liu et al., 2010).

BIOMARKERS

There are relatively few published papers on biomarkers associated with exposure to melamine and related compounds. There have been studies in affected children, but most of those studies used biomarkers to explore the pathophysiology of kidney injury.

Nonetheless, findings from these and other studies could be useful in diagnostics as specific, sensitive, early, noninvasive indicators of kidney damage associated with melamine exposure (Camacho et al., 2011; Gao et al., 2011; Zhang et al., 2012; Bandele et al., 2013).

Melamine + Cyanuric Acid Biomarkers

Serum chemistry findings in companion animals that were exposed to melamine and cyanuric acid in contaminated feed included indicators of renal failure such as increased blood urea nitrogen (BUN), creatinine, and phosphorus. Serum sodium and chloride concentrations were decreased. Other serum chemistry changes included increased cholesterol, triglycerides, and the liver enzyme γ-glutamyl transpeptidase (GGT) (Dobson et al., 2008; Chen et al., 2010). The presence of characteristic crystals was often noted on urinalysis.

Several rodent studies have looked for other markers associated with exposure to melamine + cyanuric acid. Zhang et al. (2012) fed diets containing 0–240 ppm melamine and equal concentrations of cyanuric acid to Fischer 344 (F344) rats. A low dose (120 ppm) resulted in increased urine concentrations of replication protein A-1 (RPA-1), though there was minimal evidence of renal injury on histopathology. RPA-1 indicates injury to renal distal convoluted tubules and collecting ducts. Bandele et al. (2013) did a similar study with F344 rats gavage fed 5 mg/kg/day melamine and an equal amount of cyanuric acid and found that the urine concentration of kidney injury molecule-1 (KIM-1) increased approximately 9- to 49-fold and clusterin increased about 8- to 24-fold. However, in rats given approximately equivalent daily doses, using dietary concentrations of 60 ppm of each contaminant, there was no elevation of RPA-1 or KIM-1. Increases in KIM-1 and clusterin were observed in gavage-fed rats on day 4, and peak concentrations were detected on day 14 of melamine + cyanuric acid exposure. Urine concentrations of both KIM-1 and clusterin declined somewhat by day 21. KIM-1 and clusterin are both indicators of renal response to injury. There was no change in serum BUN or creatinine concentrations in any of the rats. Silva et al. (2016) also looked at F344 rats and did find that BUN and creatinine were elevated in rats fed diets containing at least 240 ppm each of melamine and cyanuric acid for 28 days, but not in the lower dietary concentration groups. However, serum concentrations of some microRNAs, specifically microRNA-128-3p and microRNA-210-3p, were decreased at dietary concentrations of 180 ppm each of melamine and cyanuric acid, which were associated with histologic renal lesions.

Melamine appears to have effects on amino acid metabolism (Zhao and Lin, 2014). Schnackenberg et al. (2012)

looked specifically at hydroxyproline concentrations in the urine of F344 rats fed diets containing 0–240 ppm each of melamine and cyanuric acid. Hydroxyproline is a breakdown product of collagen; it is released during tissue injury and was used as an indicator for renal tubular damage. The increase in hydroxyproline was dose-dependent and correlated with histologic lesions of renal fibrosis. Urine hydroxyproline concentrations increased by day 4 in rats fed diets containing 240 ppm melamine + cyanuric acid, by day 14 in rats fed 180 ppm of each contaminant, and by day 28 in the group fed diets containing 120 ppm of each.

Xie et al. (2010) dosed Wistar rats for 15 days with gavage doses of 100–600 mg/kg/day melamine alone, or with 50 ppm melamine + 50 ppm cyanuric acid, and analyzed the urine using a variety of methods. An incomplete list of their findings is present in Table 31.1. These biomarkers were used to determine what metabolic pathways were affected by melamine and melamine + cyanuric acid. Again, amino acid metabolism was affected. Some metabolites were involved in tryptophan metabolism. These include 5-hydroxy-3-acetaldehyde, indolacetaldehyde, N-acetyl-5-hydroxytryptamine, and nicotinamide. Metabolites involved in tyrosine metabolism include tyramine, tyrosine, and dopa. Metabolites involved in arginine metabolism include L-arginine, urea, and guanidinoacetate. Cis-aconitate is involved in the citric acid cycle.

Kim et al. (2012) dosed male Sprague–Dawley rats with 63 mg/kg melamine and 6.3 mg/kg cyanuric acid for 30 days, then analyzed the kidneys for the biomarkers listed in Table 31.2. Decreased concentrations of asparagine, aspartate, glutathione, and alanine were associated with decreased resorptive ability of the renal proximal convoluted tubules. Medullary tissues had increased asparagine, choline, creatinine, cysteine, ethanolamine, isoleucine, glutamine, and myoinositol, but decreased phenylalanine and tyrosine. Renal cortex had increased isoleucine and decreased threonine and myoinositol. Increased concentrations of ethanol and lactic acid were attributed to inhibition of the citric acid cycle. High-mobility group protein B1 (HMGB1) is released as a proinflammatory mediator by necrotic cells. Increases in HMGB1 correlated with increases in BUN and serum creatinine. Increased netrin-1 is associated with toxic renal injury. Increases in netrin-1 were seen before changes in BUN and creatinine.

Camacho et al. (2011) and Bandele et al. (2013) looked at expression of genes involved in the regenerative response to injury in the kidney (Table 31.3). They fed diets containing 7–694 ppm each of melamine + cyanuric acid for 7 days or 60 ppm of each for 28 days to F344 rats. Results of these studies are listed in Table 31.3. The KIM-1 gene had the most dramatic upregulation, which

TABLE 31.1 Biomarkers in the Urine of Wistar Rats Dosed With Melamine + Cyanuric Acid at Doses of 50 ppm Each or Melamine at Doses of 100, 300, and 600 mg/kg by Gavage for 15 days (Xie et al., 2010)

Biomarker	Concentration in Melamine + Cyanuric Acid Group	Concentration in Melamine Only Groups

correlated with dose and was not evident at subclinical doses. CLU, Spp1/osteopontin, and Lcn2 upregulation did not increase at subclinical doses either but increases were associated with a threshold dose of melamine + cyanuric acid and were not dose-dependent.

Pacini et al. (2014) looked at the effects of dietary melamine and cyanuric acid in trout. Crystals in the urinary tract were persistent at high dietary doses of melamine and cyanuric acid. Activity of catalase and glutathione S-transferase was elevated in kidneys of fish exposed to melamine and cyanuric acid or melamine alone, but not in fish fed a diet containing cyanuric acid alone.

TABLE 31.2 Biomarkers in the Kidneys of F344 Rats Given Subclinical Doses of Melamine + Cyanuric Acid (5 mg/kg/day) in the Diet or via Gavage for 28 days (Kim et al., 2012)

Biomarker	Change in Concentration	Location
HMGB1	Increased	Kidney
Netrin-1	Increased	Kidney
Asparagine	Decreased	Renal cortex
Aspartate	Decreased	Renal cortex
Glutathione	Decreased	Renal cortex
Alanine	Decreased	Renal cortex

Lcn2	Up	Up 60−90X	No
Timp-1	Up	Up 12 X	
Gapdh	Up		No

Melamine Only Biomarkers

Stones from the upper urinary tracts of children exposed to melamine were composed of melamine and uric acid at molar ratios between 1:1 and 1:2 (Chang et al., 2012; Liu et al., 2012). Uric acid was in the form of uric acid dihydrate and ammonium urate. No cyanuric acid or other melamine analog were detected. Uric acid is produced as the final step in the oxidation of purines in humans and other primates because in these species uric acid is produced as a final step in the oxidation of purines, whereas other mammals further oxidized uric acid to allantoin via uricase (Liu et al., 2012). Thus, serum uric acid concentrations in humans and related primates tend to be higher than those in other mammals. Serum uric acid was decreased in children with melamine-associated nephrolithiasis (Xie et al., 2010).

Persistent serum creatinine concentrations >7.1 µg/dL were associated with increased risk of stones. Some affected children had elevated total, direct, and indirect bilirubin and elevated alanine aminotransferase and aspartate aminotransaminase, both hepatic enzymes, in the serum (Hu et al., 2012). Urine was turbid and contained sediment, blood, and protein (Wang et al., 2009; Gao et al., 2011), but melamine was not always detectable in the urine of children with nephroliths (Wang et al., 2009). However, when Lin et al. (2013) analyzed urine in school-aged children for melamine with a spot test, it was present at small concentrations (mean 2.48 µg/mmol creatinine). They concluded that a spot test could be used to predict total excretion over the previous 24 h. The study also looked for β2-microglobulin, a biomarker for proximal tubular dysfunction, but it was not detected. Microalbumin and N-acetyl-β-glucosaminidase, other biomarkers for renal tubular injury, were present but did not correlate with melamine exposure.

Protein has a role in stone formation and was also present in small amounts in the melamine/uric acid stones from children. Protein can form the nucleus of the stone and help bind the crystals together. It has been proposed that cell membrane proteins can anchor the stone in place within the urinary tract. Examples of cell membrane proteins associated with uric acid/melamine stones include phosphatidylserine, CD44, osteopontin, and hyaluronan. Some metabolic and structural proteins, associated with leakage of cells during apoptosis or necrosis, were also found in the stones, as were inflammatory proteins such as α2-macroglobin, complement component 3, attractin, and fibronectin 1. Table 31.4 compares the proteins found in stones from children exposed to melamine to those found in stones from rats fed diets containing 2% melamine for 13 weeks.

Metabolites present in the urine of children exposed to melamine indicated an effect on the citric acid cycle (Zhao and Lin, 2014). Duan et al. (2011) analyzed urine from children with documented nephrolithiasis associated with either melamine exposure or other causes. The biomarkers they detected are listed in Table 31.5. Increased L-β-aspartyl-L-glycine, L-homocysteine sulfonic acid, hypoxanthine, and vanylglycol and decreased 5C-aglycone, proline, and 3-hydroxysebacic

TABLE 31.5 Biomarkers Found in Urine From Two Groups of Children With Nephrolithiasis: Those Exposed to Melamine and Those Not Exposed to Melamine (Duan et al., 2011)

Biomarker	Change in Concentration	Melamine or Other Causes
L-beta-aspartyl-L-glycine	Increased	Melamine group only
5C-aglycone	Decreased	Melamine group only
Proline	Decreased	Melamine group only
3-hydroxysebacic acid	Decreased	Melamine group only
L-homocysteine sulfonic acid	Increased	Melamine group only
Hypoxanthine	Increased	Melamine group only
Vinylglycol	Increased	Melamine group only
Creatinine	Increased	Both groups
Uric acid	Increased	Both groups
7-methylguanine	Increased	Both groups

acid were associated with melamine exposure but not with other causes of nephrolithiasis. L-homocysteine sulfonic acid is a metabolite of homocysteine and a general indicator of renal disease. Hypoxanthine is a progenitor of uric acid and indicates uric acid accumulation in the tubules. Proline is an amino acid involved in glutamate metabolism and is suppressed by elevated uric acid. Uric acid accumulation in the renal tubules is also associated with decreased glycogen storage, for which 3-hydroxysebacic acid is a marker. 5C-aglycone is an indicator of decreased renal resorption of vitamin K. Wang et al. (2009) and Gao et al. (2011) also analyzed urine from children exposed to melamine, both before and after medical treatment. They determined that urine α1-microglobulin and β2-microglobulin, markers for

resorptive function of the proximal convoluted tubules, were elevated at presentation. This elevation persisted for at least 3 months. Urine microalbumin, which indicates increased glomerular permeability, was mildly elevated and remained high for at least 3 months (Wang et al., 2009). Urine IgG concentrations are also indicative of glomerular damage. IgG elevations were associated with the presence of stones and remained elevated for more than 6 months. An indicator of damage to tubular epithelium, N-acetyl-β-D-glycosidase elevation correlated with younger patients and increasing stone diameter (Gao et al., 2011).

Hsieh et al. (2012) experimented with the effects of melamine on cultured human renal proximal tubular epithelium (HK-2 cells) at concentrations ranging from 100 to 1000 μg/mL to determine the effect on proteins, mRNA, and protein phosphorylation (Tables 31.6 and 31.8). Hsieh's group discovered downregulation of the antiapoptotic proteins Bcl-2 at moderate (500 μg/mL) and Bcl-x1 at high melamine concentrations (1000 μg/mL), as well as upregulation of proapoptotic proteins Bad and Bax at low (250 μg/mL) concentrations, resulting in increased apoptosis in the cells. Increased mRNA expression for vascular cell adhesion molecule-1 (VCAM-1) and transforming growth factor β1 (TGF-β1) was evident within 3 h of exposure to low (250 μg/mL) melamine concentrations. VCAM-1 is a chemoattractant for macrophages/monocytes, and TGF-β1 is a proapoptotic cytokine. Increased expression monocyte chemoattractant protein 1 (MCP-1) and the proinflammatory cytokine interleukin

mRNA	Regulation	Time Postexposure (h)	Concentration of Melamine (μg/mL)
IL-6	Up 200%	6—26	≥250
MCP-1	Up 150—300+%	6—24	≥125
VCAM-1	Up 130+%	3—24	≥250
TGF-β1	Up 200%	3—24	≥250
Fibronectin	>200%		≥250

TABLE 31.8 Phosphorylation of Inflammatory Mediators in Cultured Human Renal Proximal Tubular Cells (HK-2 Cells) Exposed to Concentrations of Melamine Ranging From 100 to 1000 μg/mL (Hsieh et al., 2012)

Inflammatory Mediator	Time Postexposure (min)	Dose-Dependent
44/42 MAPK	15—30	Yes
P38 MAPK	15—30	Yes
NF-κB	30	No

6 (IL-6) were evident a few hours later. Phosphorylation is another cell regulatory mechanism, and early phosphorylation of 44/42 mitogen-activated protein kinase (44/42 MAPK), P38 MAPK, and nuclear factor-κB (NF-κB), all of which regulate expression of proinflammatory genes, was noted.

Melamine was detected in the urine of 76% of the US population (Panuwet et al. 2012). Wu et al. (2015) looked at blood and urine from adults working in melamine manufacture. Melamine concentrations in urine were higher post- than preshift and decreased over the weekend. Creatinine, BUN, and uric acid were neither significantly elevated in melamine workers versus control workers from other fields, nor were the estimated glomerular filtration rate or estimated creatinine clearance rates significantly different. Microalbumin, N-acetyl β-D-glucosaminidase, and β2-microglobulin were measured in urine and compared to controls. N-Acetyl β-D-glucosaminidase concentrations increased with urinary melamine concentrations, and β2-microglobulin was more likely to be detectable in melamine workers. N-Acetyl β-D-glucosaminidase and β2-microglobulin are both biomarkers for early renal tubular damage. Microalbumin, a marker of glomerular damage, was not increased in melamine workers compared to controls.

Sun et al. (2012) did extensive work on biomarkers in urine, serum, and tissues of Wistar rats exposed to melamine at doses ranging from 250 to 1000 mg/kg/day (Tables 31.9 and 31.10). Succinate and citrate, involved in energy production via the citric acid cycle, were increased in the urine. Increased urinary taurine and creatinine were interpreted as general indicators of liver damage. BUN and creatinine are products of amino acid metabolism, and elevations in their concentrations are considered general indicators of renal insufficiency due to decreased glomerular filtration. Increases in dimethylglycine, N-acetylglycoprotein, taurine, very low—density lipoprotein (VLDL), low-density lipoprotein (LDL), and glucose were noted at the lowest melamine dose (250 mg/kg/day). Changes in VLDL, LDL, and glucose are possible indicators of alterations in carbohydrate metabolism. Increased serum choline, 3-hydroxybutyrate, and lactate were evident in the highest melamine dose (1000 mg/kg/day) group. All were considered indicative of a shift in metabolic pathways from glycolysis to lipolysis. Liver and kidney concentrations of choline were also increased. Concentrations of lactate, glutamate, and glucose were decreased in the liver of rats in the low-dose group, but increased in the kidneys, most likely due to a defect in tubular resorption.

Early et al. (2013) gave low (350 mg/kg/day) and high (1050 mg/kg/day) doses of melamine to Sprague—Dawley rats for 5 days and looked for changes in gene expression in renal tissue. They found upregulation of KIM-1, Clu, Spp1, A2m, Lcn2, Tnfr12a, Gpnmb, and CD44 from 5- to 3000-fold, and downregulation of Tff3 two to 10-fold. Dysregulation correlated with histologic lesions in the kidneys.

Bandele et al. (2014) noted that the increased BUN and creatinine seen in rats given high doses

TABLE 31.9 Biomarkers Found in the Urine or Serum of Wistar Rats Exposed to Melamine at Doses of 250–1000 mg/kg/day (Sun et al., 2012)

Biomarker in Urine	Change	Biomarker in Serum	Change
Succinate	Increased	BUN	Increased
Citrate	Increased	Creatinine	Increased
Taurine	Increased (1000 ppm group)	Dimethylglycine	Increased
Creatine	Decreased (1000 ppm group)	VLDL	Increased
		LDL	Increased
		Taurine	Decreased
		Glucose	Decreased
		Choline	Increased (1000 ppm group)
		3-Hydroxybutyrate	Increased (1000 ppm group)
		Lactate	Decreased (1000 ppm group)

BUN, blood urea nitrogen; *LDL*, low-density lipoprotein; *VLDL*, very low–density lipoprotein.

TABLE 31.10 Biomarkers of Melamine Found in Liver or Kidney of Wistar Rats Exposed to Melamine at Doses of 250–1000 mg/kg/day (Sun et al., 2012)

Biomarker	Change in Liver	Change in Kidney
Choline	Increased (250–500 ppm groups)	Increased
Lactate	Decreased	Increased
Glutamate	Decreased (250–500 ppm groups)	Increased
Glucose	Decreased (250–500 ppm groups)	Increased
N-Acetylglycoprotein	Increased (1000 ppm group)	
Trimethylamine-N-oxide	Decreased (1000 ppm group)	
Creatinine	Increased (250–500 ppm groups)	
Amino acids		Increased
3-hydroxybutyrate		Decreased
Pyruvate		Decreased

(1000 mg/kg) of melamine were higher in pregnant versus nonpregnant females. (Increases were milder for cyanuric acid alone.) Serum uric acids were not altered. KIM-1, clusterin, and osteopontin increased in both pregnant and nonpregnant rats given melamine, but more rapidly in the pregnant rats.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Poor quality melamine containing cyanuric acid was fraudulently added to pet food ingredients by Chinese distributors and produced morbidity and death in dogs and cats in different areas of the world. This type of fraud had likely been ongoing for several years, but was first documented in 2007. The following year, it was discovered that a purer grade of melamine had been added to milk products, including baby formula, causing uroliths in infants and young children.

Melamine and cyanuric acid interact in the renal tubules forming crystals and producing renal failure, as was evident in dogs and cats during the 2007 pet food recalls in the United States. Although many cats and dogs died, many also responded to supportive care, which mostly consisted of fluid therapy. Melamine can also interact with uric acid, and this caused urolithiasis in young children in 2008. Fluid therapy and urine alkalization were the mainstay of therapy for these children and most survived.

There have been a few studies looking for biomarkers of melamine + cyanuric acid or melamine alone in vitro or in laboratory animals, and fewer studies of biomarkers for melamine in affected children. Most of the laboratory research thus far has been directed at clarifying the pathophysiology of melamine toxicosis. These studies suggest that the physiological disruptions caused by melamine and melamine + cyanuric acid affect amino acid and energy metabolism through multiple pathways. Furthermore, melamine is able to induce

apoptosis in renal tubular epithelium in vitro. Some of the findings have potential uses in diagnostic testing for exposure to melamine or in differentiating melamine exposure from other causes of urolithiasis in children (Table 31.5). N-Acetyl-β-D glycosidase is of particular interest as an indicator of persistent urolithiasis. Upregulation of mRNA for TGF-β1, VCAM-1, MCP-1, and IL-6 was found to be an early indicator of melamine exposure in vitro, but it remains to be determined if the cytokines will be useful indicators in vivo.

Biomarkers of Petroleum Products Toxicity

Robert W. Coppock[1], *Margitta M. Dziwenka*[2]

[1]Toxicologist and Associates, Ltd, Vegreville, AB, Canada; [2]Faculty of Medicine & Dentistry, Division of Health Sciences Laboratory Animal Services, Edmonton, AB, Canada

INTRODUCTION

Petroleum releases into the environment can occur as the crude product comes from the wellhead or as the refined products that are processed to meet chemical, engineering, automotive and other specifications. Crude petroleum exists as sweet crude petroleum with minimal sulfur content or as sour crude petroleum with low to high sulfur content (Coppock and Christian, 2018). It can exist as light to heavy crude petroleum and as bitumen. Because of a large number of causes, petroleum in its various crude and refined forms and production by-products such as fracturing flowback and produced waters can be released into the environment (He et al., 2017a). Although much focus is placed on maritime incidents, spills from pipelines and other equipment used to transport petroleum have multiple environmental and social impacts (Anon, 2012; Genereux et al., 2014). Crude petroleum is a complex mixture of compounds and even more complex when the possible congeners of the individual constituents are considered. Crude oil is estimated to contain 17,000 to 20,000 different chemicals with a large component of chemically unidentified mass. Abiotic chemical markers can be used to profile and trace petroleum in the environment and assess the exposure of biota to various forms of petroleum. For petroleum, biomarkers can be used to determine internal dose with biochemical and physiological and morphological responses and assess movement of petroleum hydrocarbons in the food web (Kroon et al., 2017; Sanni et al., 2017a). Biomarkers that are robust across different species are desirable for biomonitoring of undesirable effects (Sanni et al., 2017a,b). Interpreting biomarkers to assess the impacts of petroleum pollution on the life history of organisms is important for understanding and minimizing long-term impacts on biota.

CHEMICAL MARKERS

Recent advances in analytical chemistry are reducing the mass of unidentified compounds found in crude petroleum. Matching the profile of compounds, and identification of marker chemicals and isotopes are the backbone of forensic petroleum chemistry (Adhikari et al., 2017; Wang et al., 2018). Petroleum, once it is released into the environment, undergoes weathering processes. During weathering, petroleum dynamically changes in chemistry and toxicity (Coppock and Christian, 2018). These processes include evaporation, dissolution, photochemical reactions, biological degradation, emulsification, adsorption on suspended particles, and other physical–chemical activities that change its chemical composition and density, and generally concentrates polyaromatic molecules. There is evidence that the lower molecular weight and less substituted hydrocarbons are lost by first-order kinetics. The addition of dispersant can alter the weathering processes and enhance formation of microdroplets in the aquatic system and thereby alter toxicity. The fate and transport of spilled hydrocarbons can be traced using intrinsic marker chemicals that are resistant to weathering or unique profiles that are relatively unaffected by chemical changes that occur during weathering. Commonly used marker chemicals are the branched isoprenoid alkanes pristane and phytane, and the hopanes and steranes. Fingerprinting hydrocarbon groups and other indigenous compounds can identify the source of the crude oil. Biochemical versus petroleum sources of η-alkanes can be estimated using the carbon preference index (odd number of carbons/even number of hydrocarbons) and isotopic profiles. Similar methods can be applied for identification of biofuels. At the wellhead, petroleum is generally separated from water (production water), whereas flowback water is water returned

to surface during drilling and hydraulic fracturing. Flowback and production waters consist of a complex mixture of water, water-soluble hydrocarbons, oil minuscules, mineral salts, and chemicals used in fracking or well-maintenance chemicals including biocides. Produced and flowback waters from some formations may contain naturally occurring radioactive materials (NORMs), for example radium. With depletion, a petroleum formation generally increases in water production (water/oil ratio). The ion and chemical profile in flowback and produced waters can be unique, and they can be used as forensic markers in terrestrial spills and to provide evidence of groundwater contamination (DiGiulio and Jackson, 2016). Production water from offshore wells can be released directly into the marine environment. Production water contains hydrocarbons, alkylphenols, polycyclic aromatic hydrocarbons (PAHs, also known as polyaromatic hydrocarbons), and many other chemicals and these can be used as biomarkers.

Polycyclic Aromatic Hydrocarbons

Chemically, the PAHs consist of two or more fused aromatic rings. The PAHs can be used in fingerprinting for estimating the most likely source of petroleum. Environmental PAHs are from three primary sources: combustion of organic matter, waste materials, and fossil fuels, by biogenesis, and from crude and refined petroleum. Crude oil can contain 0.2 to 7% polyaromatic hydrocarbons. The PAHs in petroleum generally contain two or three aromatic rings, and refined petroleum can, depending on the distillation temperature, contain similar polyaromatic hydrocarbons plus other polyaromatics formed by the catalytic-cracking processes. Refined petroleum generally contains more alkyl PAHs. The PAHs formed during incomplete combustion of organic matter generally contain three or more aromatic rings. Generally there is an inverse relationship between combustion temperature and the formation of alkyl polycyclic aromatics in incomplete pyrolysis assemblages. The PAHs usually become concentrated as petroleum weathers.

Tissue and Body Fluid Levels of Petroleum Hydrocarbons

Bioavailability is the transfer of the petroleum hydrocarbons from the environment into the organism. Fauna can take up environmental petroleum hydrocarbons through a variety of mechanisms, and differences can occur across genera, species, and stages in life history. Differing sensitivities of aquatic organisms can be due to unique absorptive mechanisms. Water solubility and micronization of oil in water by turbulence and chemical

dispersants are important factors in the internal dose acquired by aquatic organisms. Oil fouling by microdroplets of oil adhering to the chorion (acellular coat) of Atlantic haddock (*Melanogrammus aeglefinus*) eggs increases absorption of hydrocarbons that have low solubility in water (Sorensen et al., 2017). Oil droplets also reduce the absorption of lipids including cholesterol from the yolk sac, and there is also a positive relationship between oil fouling and cardiac defects. Copepods transfer PAHs from body fat to eggs (Hansen et al., 2017). For aquatic exposures, the time for equilibrium between the levels of petroleum hydrocarbons in body fluids and tissues and the levels in the environment is generally determined by route of exposure, time, and exposure concentration. Fish uptake of the C_4-C_7 alkylphenols with K_{ow} values less than 5 is generally directly from water and low uptake from feed (Sundt et al., 2009). The hydrocarbons that accumulate in tissues of a particular species generally are more resistant to metabolism. Organisms that occupy different ecological niches can be used to monitor the contamination of fauna by petroleum hydrocarbons. Dispersants may alter the uptake of petroleum hydrocarbons by altering bioavailability in a particular habitat. For liver metabolism, the first pass effect for clearance can occur following oral ingestion. In fish species studied, the alkylphenols are rapidly cleared from the body by the liver and excreted in the bile as conjugated and unconjugated metabolites. Bile is the body fluid of choice for estimating bioavailability of these hydrocarbons, and identification of alkylphenol metabolites in bile is considered a biomarker of exposure. Bivalve mollusks are a species that filter feeds and often concentrate both organic and inorganic chemicals in their tissues, which is a food safety issue in edible species. The location and feeding habits of fauna are a factor in their use as biomonitors. Caged blue mussels (*Mytilus edulis*) and semipermeable membrane devices can be used to concentrate polycyclic aromatics from seawater, and mussels generally are more efficient bioconcentrators than passive monitoring devices (Utvik et al., 1999). Mussels have been used as biomonitors of ecosystem health (Sundt et al., 2011; Marigomez et al., 2013). The PAHs found in tissues of aquatic organisms are generally proportioned to their abundance in the petroleum causing the incident. The polycyclic aromatic hydrocarbon level in tissues can be used as an indicator of pollution from petroleum or deposition from other sources. PAHs from spilled petroleum can bioaccumulate in fish, mussels, and copepods and follow the food chain to birds (Carls et al., 2015; Fernie et al., 2017; Sanni et al., 2017a; Willie et al., 2017; Agersted et al., 2018). Carps (*Cyprinus carpio*) accumulate two to three aromatic ring PAHs when fed a diet containing bunker A heavy oil. Nestling tree swallows (*Tachycineta bicolor*),

from nests in the oil sands mining area of Alberta, have been shown to accumulate methylated dibenzothiophenes, parent PAHs, and alkyl PAHs (Fernie et al., 2017).

BIOCHEMICAL BIOMARKERS

CYP Biomarkers

The CYP (P450) family of enzymes has a broad spectrum of substrates and are important in Phase I oxidation, hydrolysis, and reduction biotransformation reactions (Burkina et al., 2017). The transcriptional upregulation of the CYP enzymes, especially CYP1 isoforms, occurs following exposure to polyaromatic hydrocarbons (PAHs) and other structurally related planar compounds, for example, polyhalogenated aromatic hydrocarbons. The CYP1 family is upregulated after the ligand attaches to the cytoplasmic aryl hydrocarbon receptor (AhR), and the ligand—AhR complex is translocated into the nucleus. The transcriptional changes by the activated AhR are ligand specific and generally are highly cell-type specific. In addition to upregulation of CYPs, the AhR activation can also disturb cell functions inclusive of embryologic molecular chemistry. In species exposed to petroleum, upregulation of the CYPs is generally considered to be a robust biomarker of exposure to PAHs (Martinez-Gomez et al., 2009; Alexander et al., 2017; Esler et al., 2017; Sanni et al., 2017a; b). There are genetic differences between animals for synthesis of CYP enzymes families. The CYPs can be measured by gene expression methods, measurement of the CYP proteins with monoclonal antibodies, other specific protein assay methods, and measuring enzyme activity using specific substrates. The microsomal CYP1 isoforms activity, using two different substrate methods, to measure the turnover for 7-ethoxyresorufin-O-deethylase (EROD) or benzo(a)pyrene by arylhydrocarbon hydroxylase (CYP1A) in liver and other tissues is generally accepted as a biomarker of response to xenobiotic exposure (Burkina et al., 2017). In copepods exposed to water-accommodated crude oil, the *Tk-CYP3024A3* and *Tj-CYP3024A2* genes were observed to be upregulated (Han et al., 2017). Swallow nestlings in the bitumen mining area of Alberta had increased activity (EROD substrate) of hepatic CYP1 (Li et al., 2017). In Japanese medaka, exposure to Cold Lake bitumen caused a monotonic increase in CYP1A mRNA (Madison et al., 2017). The CYP1 gene expression can be upregulated following exposure to petroleum without a corresponding increase in EROD biotransformation. There is limited evidence that upregulation of the AhR as measured by CYP1A induction increases the toxicity of crude oil to fish. Juvenile sockeye salmon were exposed to water-soluble fractions of natural gas condensate—diluted bitumen, and hepatic EROD biotransformation was increased (Alderman et al., 2017). In heart muscle, the transcription of aryl hydrocarbon hydroxylase had transient upregulation and transcript abundance of CYP1A mRNA is increased. The hepatic CYP1 biomarker has also been shown to be upregulated in fish exposed to produced water, fish and cormorants exposed to oil from the Deepwater Horizon blowout (MC252), swallows (EROD activity) nesting on reclaimed oil sands, and in cattle (EROD and AHH activities) experimentally administered crude oil (Khan et al., 1996; Smits et al., 2000; Alexander et al., 2017; Dubansky et al., 2017; He et al., 2017a; Li et al., 2017). Gill EROD biotransformation in Atlantic cod (*Gadus morhua*) was upregulated after 24 h of exposure to crude oil (0.025 w/w). The evaluation of CYP1 family as a biomonitor is not a specific response to petroleum-source PAHs, can be influenced by season and other factors, and requires careful data interpretation. Increased EROD biotransformation is an indicator of the environmental exposure to an AhR receptor agonist, and other parameters of intoxication may not significantly change. Other environmental contaminants with planar configuration, such as polyhalogenated aromatic hydrocarbons, can also upregulate CYP1A. Background levels of pollutants and species response variations can occur and must be accounted for in the design of the experimental or monitoring protocols that use upregulated CYPs as biomarkers. The EROD biotransformation can be used to monitor the exposure to PAHs, and the parent PAH may or may not be bioconcentrated in tissues because of biotransformation and elimination (Martinez-Gomez et al., 2009). The products of enzymatic activity of CYP1A can be both detoxication and toxication. In detoxication, the net effect includes formation of compounds that decrease toxicity, and generally these products are rapidly excreted. For toxication reactions, the end effect generally is the formation of highly reactive compounds reacting with DNA, proteins and other macromolecules, lipid peroxidation, and upregulated metabolic rates of endogenous compounds that can disrupt homeostasis including endocrine functions. The xenobiotic exposure—linked upregulation of CYP expression may change with species, sex, reproductive status, diet, starvation, and exposure conditions. A study in Atlantic cod larvae has shown that starvation increases CYP1A gene expressions by 6.4 times, and it is considered a magnitude less than gene expression after exposure to crude oil (Hansen et al., 2016). Exposure to multiple chemicals can result in complex interactions that may alter the expected values for CYP1 (He et al., 2017a,b). Spatial biomarker patterns can be used across species for biomonitoring oil spill impacts (Martinez-Gomez et al., 2009).

Biomarkers of Responses to Oxidate Stress

Oxidative stress can occur after exposure to petroleum. Parameters generally are enzymes and substrates in Phase II biotransformation, antioxidant enzymes, and oxidized indigenous substances (e.g., lipid peroxides). The activities of superoxide dismutase and glutathione-S-transferase activities (GST) in the digestive gland were elevated in the *Anomalocardia flexuosa* clam 48 h after pulse exposed in situ to low levels of diesel oil—contaminated sea water (Sardi et al., 2017). Responses can be conflicting between tissues. For example, in clams, the GST activity decreases in gills and increases in the digestive glands. Laughing gulls (*Leucophaeus atricilla*), in a laboratory study, were orally exposed to weathered MC252 in fish (Horak et al., 2017). Hepatic total glutathione, oxidized glutathione (GSSG), and reduced glutathione (rGSH) significantly increased as mean dose of oil increased, and a nonsignificant negative trend occurred in the rGSH:GSSG ratio. Sandpipers (*Calidris mauri*) orally exposed to MC252 had increased total antioxidant capacity (Bursian et al., 2017a). In gull and sandpiper studies, the birds did not have flight exercise and the associated oxidative stress. Rainbow trout (*Oncorhynchus mykiss*) embryos, exposed to hydraulic fracking and produced water, showed increased lipid peroxidation. They also showed increased mRNA abundance for UDP-glucoronosyl transferase, glutathione transferase, glutathione peroxidase, and superoxide dismutase (He et al., 2017b). Similar effects were observed in zebrafish (He et al., 2018). Lipid peroxidation was increased in earthworms (*Eudrilus eugeniae*) exposed to benzene, toluene, and xylene used as surrogate chemicals for spilled petroleum (Eseigbe et al., 2013). GST did not show a clear dose response in juvenile halibut (*Hippoglossus hippoglossus*), Atlantic salmon (*Salmo salar*), turbot (*Scophthalmus maximus*), and sprat (*Sprattus sprattus*) following exposure to dispersed crude oil (Sanni et al., 2017a). Across species, increased activity of GST may correlate with PAH levels or GST may decrease with exposures to PAHs. Exposure of zebrafish to flowback and produced waters altered the expression of genes related to oxidative stress (He et al., 2018). Cellular pathology can be used to evaluate the effects of oxidative stress. Studies using weathered crude oil in double-breasted cormorants (*Phalacrocorax auritus*) provided pathological evidence of oxidative damage in red blood cells (Harr et al., 2017a).

Genetic Biomarkers of Petroleum Exposure

The toxic effects of petroleum hydrocarbons and their metabolites on adverse outcomes from aberrant gene expression are being explored. Studies in embryos and larval forms are identifying petroleum hydrocarbon—linked changes in gene expression that lead to developmental defects. Analyses of gene molecular chemistry are showing that exposure to crude oil modifies gene expression in a manner that is predictive of adverse outcomes resulting in abnormal phenotypes and compromised chances for survival (Cherr et al., 2017; Incardona, 2017; Sorhus et al., 2017; Xu et al., 2017). Recent studies have shown that altered regulation of differentially expressed genes during embryogenesis and larval stages are linked to physiological and morphological defects in red drum (*Sciaenops ocellatus*), haddock, and zebrafish. Fertilized zebrafish eggs/larvae were exposed to organic extracts of hydraulic fracturing flowback and produced waters (He et al., 2018). There was a significant increase in the abundance of transcripts of genes related to biotransformation including nuclei receptors (AhR, and pregnane-x-receptor), Phase I enzymes (*cyp1a*, CYP1B, CYP1C1, CYP1C2, CYP2AA12, and CYP3A65), and Phase II enzyme (uridine 5′-diphospho-glucuronosyltransferase). A significant increased abundance was also observed in the genes that respond to oxidative stress and in endocrine-mediated genes. Other genes whose exposure to petroleum may uniquely change in developing fish embryos are the *ccbe1* of edema formation, cholesterol synthesis genes, and the hepatic expression of the *fgf7* fibroblast growth factor gene. DNA itself is a target for certain petroleum hydrocarbons and is damaged by multiple mechanisms. Briefly, DNA can be damaged by toxication reactions (generally Phase I) that form reactive chemicals that subsequently cause strand breaks, base modifications, intercalation of substances between double-stranded DNA strands, and the formation of DNA adducts. DNA strand breaks can be quantified by single-cell electrophoresis, adducts identified by ^{32}P post labeling, and chromosomal damage indexed on micronucleus formation. The comet assay can detect DNA damage in a few cells from most germinal and somatic tissues (Frenzilli et al., 2017). In aquatic organisms, the most sensitive tissues for DNA damage vary between species with gill and liver cells generally being considered the most sensitive. Rapid repair of DNA damage can make application of the comet time sensitive. The comet assay has been used in a large number of species including mollusks, toads, and a large number of fish species. Biomarkers have been developed to measure the potential for DNA damage to occur in vivo. Cultures of rainbow trout hepatocytes exposed to water from oil sands tailing pond water showed single and double DNA strand breaks, and this test is a sensitive in vivo biomarker of genetic toxicity. The PAHs in the tailing pond water or their metabolites in the hepatocytes likely caused the DNA damage. Laboratory studies in Atlantic cod using crude oil from the North Sea geologic

formations have shown that 0.3 ppb total polycyclic aromatic hydrocarbons (measured value corresponding to 0.06 ppm crude oil) in sea water cause the formation of DNA adducts. A dose response increase in DNA adducts was observed in juvenile turbot, halibut, salmon (smoltified), and sprat exposed to sublethal levels of dispersed Arctic crude oil (Sanni et al., 2017a). The formation of DNA adducts can be correlated with the metabolites of polycyclic aromatic hydrocarbons identified in bile. Haddock is a fish species considered sensitive to genotoxic contaminants. DNA strand breaks, determined by comet assay of erythrocytes, have been observed in eelpout (Zoarces viviparus) following a harbor spill of bunker oil. Micronucleus formation in erythrocytes and liver of fish and in gill cells in oysters and mussels can be used as a parameter estimating chromosomal damage (Bolognesi et al., 2006). The micronucleus test is a biomarker of accumulated genetic damage that occurred in a cell. It is a common test used in a number of species including aquatic organisms and requires cell staining and light microscopy. Increased occurrences of micronuclei were observed in the gills of mussels (Mytilus edulis) collected before and after a spill of petroleum products that spread along the Lithuanian coast (Barsiene et al., 2012). The lymphocyte cytokinesis-block micronucleus assay, although not toxicant specific, is a sensitive biomarker for human exposure to petroleum, especially petroleum high in benzene (Angelini et al., 2016).

MORPHOLOGIC BIOMARKERS

Pathological changes in tissues and organs are used as biomarkers of petroleum toxicity. The tissues commonly examined by histopathology in most species are gills, heart, liver, intestines, kidney, and spleen. When coupled with enzymatic and other biomarkers, histopathology documents anatomical changes that can lead to pathophysiological dysfunctions and impaired health. The histopathology of the gill shows that the respiration, osmoregulation, and electrolyte balance may be compromised by petroleum hydrocarbons in water. Changes in the gill include edema and dilation of the secondary lamella. Proliferation of gill epithelium can occur with fusion of the secondary lamella. Increased severity of gill lesions can be observed with increasing concentrations of PAHs in sediment. Epithelial hyperplasia and fusing of lamella were reported in fish exposed to an environmental release of fracking flowback water. Necrosis and other lesions in the kidney can be linked with biliary levels of PAHs and their metabolites. An increase in the number of rodlet cells in the kidneys of bream (Abramis brama) can be observed after the fish were environmentally exposed to fuel oils. Hyperplasia of the intestinal mucous cells can also occur. Liver histopathology was used to assess the toxicity of Arabian crude oil and dispersed crude oil in juvenile rabbit fish (Siganus canaliculatus) (Agamy, 2012). Hepatic lesions evaluated were cytoplasmic vacuolization, megalocytosis, dispersed coagulative necrosis, lymphocytic infiltration, melanomacrophage aggregates, spongiosis hepatis, pericholangitis, and bile stenosis. In wild bream (Abramis brama) exposed to refined petroleum, hyperplasia of mucous cells in the skin was observed. The gills had lamellar capillary aneurysms, epithelial proliferation, and proliferation associated with fusion of the secondary lamella and mucous cell, which was hypertrophic. In a laboratory study, pre-spawning Atlantic cod were exposed in the laboratory to production water from North Sea oil wells (Sundt and Bjorkblom, 2011). In fish exposed to 0.2% production water (diluted with sea water), there was decreased ovarian ova development accompanied by atresia and inflammation in the ovary. Male fish exposed to production water were observed to have decreased mature sperm and increased spermatogonia and spermatocytes. In a study using mesocosms, fiddler crabs (Uca longisignalis and U. panacea) were exposed to Louisiana crude oil mixed in sediment (Franco et al., 2018). Microscopic examination of the hepatopancreas showed a threefold increase in the numbers of blister cells. This cellular change has also been reported in other species of crustaceans. Blister cells secrete digestive enzymes. Immunohistochemistry of killifish exposed in the wild to weathered crude oil (MC252) showed increased staining for CYP1A in gill pillar cells, head kidney distal and proximal tubular cells, and the vascular endothelial cells (Dubansky et al., 2017). Ingestion of fresh crude oil targets the lungs in cattle. This risk is exacerbated by the effects of volatile hydrocarbons on the nervous system and occurrence of emesis. Vacuolated pulmonary macrophages and hepatocytes generally occur. Double-breasted cormorants exposed to weathered crude oil had increased relative liver and kidney weights (Harr et al., 2017b). Orally exposed birds had renal histopathology consisting of squamous metaplasia and increased epithelial hypertrophy of the collecting ducts and renal tubules, and increased occurrences of mineralization. Orally dosed birds also had cytoplasmic vacuolization of exocrine pancreatic cells. Thyroid follicular hyperplasia was observed in birds dermally exposed to oil. The cardiac walls were thin with flabby musculature in all birds exposed to oil. Echocardiography showed likely oil-treatment linked dilative cardiomyopathy supporting pathophysiologic cardiac dysfunction (Harr et al., 2017c). Elevated thyroid hormones also have been observed in tree swallows nesting in active oil sands areas (Li et al., 2017).

Teratology

Abnormal organogenesis and early development can be a biomarker of eggs, embryos, and larvae being exposed to crude oil (Incardona et al., 2014; Cherr et al., 2017; Incardona, 2017; Alsaadi et al., 2018). The general syndrome observed in fish is fluid accumulation in the yolk sac and around the heart, abnormal myocardial development, craniofacial and other defects, and increased tissue staining for CYP1A (Hodson, 2017; Incardona, 2017; Sorhus et al., 2017). The currently identified teratogenic components in the crude oil hydrocarbon mixture are the planar PAHs and the dibenzothiophenes. The heart is a target at low PAHs concentrations in the developing fish embryo. Embryonic cardiotoxicity can occur with and without induction of the AhR, but induction of the AhR may contribute to cardiotoxicity. Crude petroleum and tricyclic PAHs cause abnormal cardiac rhythm. This effect is likely due to changes in ion gating, changes in membrane potentials, and subsequent alterations of the cardiac action potential. Abnormal heart contractility likely leads to abnormal cardiac development (proliferation and failed looping). There are interactions between physiological functions and the cascade of genetic events for normal development in proteins that regulate gating of calcium ions. The genes that control bone morphogenic proteins (BMPs) and genes regulating calcium ion homeostasis may be involved. In zebrafish, the mutant silent heart (*sih*) has decreased expression of troponin T and is a teratogenic syndrome very similar to that observed with PAH exposure. Atlantic haddocks have a greater sensitivity to crude petroleum than zebrafish and also have craniofacial terata following PAH exposure. Teratogenic effects were observed in red drum larvae exposed to ocean-weathered crude oil (Xu et al., 2017). Developmental abnormalities observed are decreased brain area and lens diameter, pericardial edema, and decreased body length. Diluted or pipeline bitumen is embryotoxic to fish and causes a condition in fish embryos that resembles blue sac disease (craniofacial malformations, pericardial and yolk sac edema, spinal curvatures, fin erosion, hemorrhaging, and induction of CYP1) (Alsaadi et al., 2018). A study in Japanese medaka showed that malformations increase with increasing total bitumen-linked PAHs levels in water (Madison et al., 2017). The malformations included craniofacial and yolk sac edema. The fish also had impairment of swim bladder inflation. Developmental toxicity of the organic chemical fraction of hydraulic fracturing flowback and produced waters was tested in zebrafish (He et al., 2018). Compounds in the organic extract included PAHs, alkyl PAHs, and other major substances including polyethylene glycols, alkyl ethoxylates, octylphenol ethoxylates, and high molecular weight (C_{49-79}) ethylene oxide polymeric material. A significant increase in spinal malformations and pericardial edema were observed. Exposure of fish to low transient levels of PAHs, which do not produce morphological changes, decreased swimming performance. Decreased physical performance likely compromises abilities to migrate, forage, and evade predators. The cardiac biomarker is linked to the collapse of the herring population in Prince William Sound after Exon Valdez oil spill (Cherr et al., 2017).

BIOMARKERS IN BIRDS

The toxicity of weathered MC252 sweet crude oil from the Deepwater Horizon blowout was studied in aquatic birds (Alexander et al., 2017; Bursian et al., 2017a,b; Cunningham et al., 2017; Harr et al., 2017a,b). Double-breasted cormorants were exposed, under laboratory conditions, to weathered MC252 crude oil by the oral and oiled feathers routes of exposure. Fish that had previously received a measured amount of oil were live fed to foraging birds to give a daily dose of 5 mL or 10 mL of oil/day. For feather–dermal exposure, 13 g of MC252 was applied to the breast and back feathers of the birds. Biochemical, hematological, histopathological, and clinical parameters were used as biomarkers. For hematology, anemia was observed in all of the cormorants exposed to MC252. The packed cell volume decreased in a dose-related manner, and Heinz bodies were observed in the red blood cells and reticulocytes were observed. Blood clotting times were prolonged. In cormorants orally exposed to oil in fish, there were significant decreases in plasma activities of aspartate amino transferase and gamma glutamyl transferase; decreases in the plasma levels of calcium, chloride, cholesterol, glucose, and total protein; and increases in plasma urea, uric acid, and phosphorus concentrations. Cormorants exposed by the oral and feather routes had an increase in the hepatic CYPs identified by an increase in biotransformation of EROD, benzyloxyresorufin O-debenzylase, methoxyresorufin O-demethylase, and pentoxyresorufin O-depentylase and an increase in CYP1A protein expression. Laughing gulls (*Leucophaeus atricilla*) were orally exposed to MC252 using the same methods as cormorants except the gulls were fed thawed frozen fish. The total hepatic glutathione/oxidized glutathione and reduced glutathione significantly increased with increasing mean oil dose. Plasma levels of 3-methyl histidine, an indicator of muscular wastage, were positively correlated with oil exposure. Exposure to crude oil can cause decreased red blood cell numbers and decreased hematocrit and is often accompanied by Heinz bodies being observed in the red blood cells. Plasma haptoglobin can decrease with

increasing PAH exposure suggesting intravascular hemolysis. Plasma ferritin is increased with increasing PAH levels. Behavior of birds can be used as biomarkers. For example, birds that have oiled feathers can exhibit decreased wing performance and increased takeoff distances (Maggini et al., 2017a; b).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Diagnosis of petroleum intoxication is dependent on the use of chemical markers and biomarkers. Few biomarkers are specific for petroleum intoxication. Complicating factors in the diagnosis of petroleum intoxication from petroleum spills are natural systems that generally contain multiple anthropogenic pollutants. The measured response of in situ fauna to the parameters studied generally is not limited to the specific substances of interest but is the net response of the organism to all pollutants in its ecological niche. The logical and knowable use of chemical markers and biomarkers of petroleum intoxication can provide a diagnosis of exposure to petroleum hydrocarbons and a diagnosis of systemic harm. The biomarkers that are linked to understanding cause and effect with pathophysiology at the phenotypic and molecular levels can be directly linked to adverse outcomes that have negative effects on life history and population dynamics. A battery of selected biomarkers can be used to assess adverse effects of petroleum hydrocarbons across multiple genera and species of fauna and provide input for determining multiple species effects and relative risks. In the future, it is likely that real-time monitoring tools for identification of anomalies and changes in gene expression will enhance the current biomarker tools for understanding mechanisms and adverse effects from long-term exposures to petroleum hydrocarbons.

Biomarkers of Chemical Mixture Toxicity

Antonio F. Hernández[1], Fernando Gil[1], Aristidis M. Tsatsakis[2]

[1]Department of Legal Medicine and Toxicology, University of Granada School of Medicine, Granada, Spain; [2]Center of Toxicology Science & Research, Medical School, University of Crete, Heraklion, Greece

INTRODUCTION

Humans are continuously and increasingly exposed to low doses of a large number of chemicals through different sources and routes, such as food, drinking water, drugs, breathing air, and uptake through the skin. Many of these chemicals are persistent and may accumulate in animal tissues, may biomagnify in food webs, and can contribute to many chronic diseases, thus increasing the general population's concerns about the potential toxic effects of exposure to combined chemicals. Chemical mixtures may contain both known and unknown components, depending on whether they are intentionally or unintentionally formed; however, real-world mixtures tend to involve low doses of individual mixture components. The exposure scenario is characterized by exposure to all components of the mixture at the same time, either simultaneously or sequentially, and by a similar route as they occur together. Prediction of health risk from chemical mixture exposure is a complex issue that cannot be based only on the knowledge of individual chemicals because in such a case it would likely lead to wrong conclusions. The degree of exposure and the hazards associated with such combined exposures can be determined by risk assessment (Alexander et al., 2008; Crofton, 2009).

POTENTIAL CHEMICAL MIXTURES

Pesticides

Pesticides comprise of many different categories of chemicals and almost always occur in mixtures with each other in the environment or in foodstuffs. Multiple exposures to pesticides occur in occupational settings and from environmental and nutritional sources, with intensive agriculture workers being more heavily exposed to mixtures of pesticides. The type and severity of their adverse health effects are determined by the individual chemical category, the dose and the duration of exposure, and the exposure route. Because pesticides are often applied in mixtures to crops, their residues can be found in foods and drinking water. However, based on national and Europe-wide monitoring programs of pesticide residues in plant products, levels are infrequently above maximum residue limits and thus considerably below thresholds of concern (Alexander et al., 2008). Accordingly, the probability of experiencing adverse effects from combined exposures is considered to be rare, unless pesticides interact and produce synergism or potentiation (Hernández et al., 2013a, 2017), circumstances that could occur at doses above thresholds of concern. Moreover, finding a measurable amount of a pesticide (or metabolites) in a biological fluid or tissue does not mean that the levels of parent compounds or metabolites will have an adverse health effect (CDC, 2009).

Organophosphate (OP) and *N*-methylcarbamate insecticides are two of the most widely used pesticides that act by a similar mechanism of action, inhibition of acetylcholinesterase (AChE). Thus, it is important to evaluate the cumulative risk in the case of simultaneous exposure to mixtures of these compounds (Lowitt, 2006; Padilla, 2006). The nonspecific metabolites of OP pesticides, dialkylphosphates (DAPs), are the most commonly used indicators for the assessment of cumulative exposure to OPs in humans (Barr and Buckley, 2011; Kavvalakis and Tsatsakis, 2012) and may be useful for studies looking at epidemiological associations with adverse health outcomes. However, important limitations include a lack of specificity with respect to the OP from which they were derived, the occurrence of preformed DAPs in the environment, and the fact that DAP levels commonly encountered in

food and the environment are toxicologically irrelevant. For *N*-methylcarbamates, only acute exposure may need to be considered because of their reversible mode of action on AChE.

Organochlorinated Compounds

Various formerly used chlorinated pesticides (e.g., dichlorodiphenyltrichloroethane (DDT) and its major metabolite dichlorodiphenyldichloroethylene (DDE)), as well as the industrial chemicals polychlorinated biphenyls (PCBs) and the industrial waste polychlorinated dibenzodioxins (PCDDs), are ubiquitous environmental contaminants. As a result of their high chemical stability and environmental persistence, they may reach the trophic chain and bioaccumulate in fatty foods (González-Alzaga et al., 2018). However, the chlorinated pesticides and PCBs are no longer produced and the emissions of PCDDs into the environment have been significantly reduced over time. Thus, the levels of these persistent organochlorinated compounds in the environment and foods are generally decreasing (Alexander et al., 2008).

The general population is primarily exposed to dioxins and PCBs from diet (>90%), with foods from animal origin being the most important sources, particularly fatty fish (González-Alzaga et al., 2018). The toxic and biological effects of these compounds are mediated through the aryl hydrocarbon receptor (AhR). There is some evidence that subtle developmental effects caused by these organochlorinated compounds, alone or in combination, may occur at maternal body burdens that are only slightly higher than those expected from average daily intakes in Europe (EFSA, 2005).

Halogenated Flame Retardants

Brominated flame retardants, such as polybrominated diphenyl ethers (PBDEs), are known to leach from treated materials during their lifetime. These chemicals are also ubiquitous, persistent in the environment, bioaccumulative, and toxic to both humans and the environment. In contrast to the chlorinated organic compounds, the levels of PBDEs increased in the environment and in humans until 2004, when some technical mixtures were strictly banned in the United States and Europe, resulting in decreased levels in animals and humans. Despite the chemical structure of PBDEs resembling that of PCBs, they do not activate the cytosolic AhR, indicating a different mechanism of action from that of dioxin-like PCBs (Alexander et al., 2008). PBDEs may impair circulating hormone levels, decrease fertility, and interfere with neurodevelopment, presumably by inducing oxidative stress—related damage and interference with signal transduction (Costa et al., 2014).

Organophosphate flame retardants (OPFRs) were marketed as a less toxic and less bioaccumulative alternative than PBDEs. However, there are indications that OPFRs affect endocrine systems, producing sex-dependent effects on the hypothalamic—pituitary—gonad axis, and dysregulation of the thyroid hormone system. These chemicals can also affect several neurodevelopmental processes such as apoptosis, synaptogenesis, and neurite outgrowth (Dishaw et al., 2014).

Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) consist of a large group of several hundred chemically related organic compounds of varied toxicities that may contaminate food. PAH sources include domestic heating source systems, gasoline fuel exhaust, coal tar, asphalt, and cigarette smoke. These chemicals are usually found as a mixture containing two or more of them, some of which are persistent in the environment and resistant to biodegradation. They have been shown to cause carcinogenic and mutagenic effects and are potent immunosuppressants. Metabolites of pyrene and DNA adducts have been used as biomarkers of exposure to PAHs. Potential adverse birth outcomes have been described after PAH exposure during pregnancy (Ramesh and Archibong, 2011; Hood et al., 2011). In addition, the combined exposure of pregnant women to PAH and other common environmental pollutants, such as environmental tobacco smoke, might adversely affect fetal development (Polanska et al., 2014). As different PAHs probably have different mechanisms of action, a toxic equivalent factor principle is not suitable for cumulative risk assessment. The combined effect of PAHs is thus not always additive and, in some instances, synergistic and antagonistic effects have been observed. Benzo[*a*]pyrene (BaP) is the most potent carcinogenic substance among the PAHs, and as long as its relative contribution to total PAH is relatively constant in foods, BaP concentration is a good indicator of the total carcinogenic potency of a PAH mixture (Alexander et al., 2008).

Metals

Metals are potentially hazardous chemicals that occur in the environment as a result of natural geological conditions, industrial emissions, and mining activity. They show different chemical forms and bound states that play a major role in their toxicity and partially account for potential interactions with other chemicals. Besides, specific interactions between metals may account for by the differences between the observed effects of metal

mixtures and additive predictions; however, significant deviations from additivity are not necessarily biologically relevant (Liu et al., 2017). Interactions can occur because of competition between divalent toxic and nontoxic metal cations for intestinal divalent metal transporters (DMT1) that mediate their absorption, leading to a reduced toxicity of heavy metals ingested. After absorption, metallothionein plays a crucial role in the homeostasis of metal elements because of the binding of its free thiol group to divalent ions such as Cd^{++}, Hg^{++}, Cu^{++}, Zn^{++}, and Pb^{++}. Metallothionein is also highly inducible, so previous exposure to toxic metals can reduce the adverse effect of a subsequent exposure (Alexander et al., 2008). The interaction of metal mixtures may differ across organs because of the varied ability to produce metallothionein, reduced glutathione, and heat shock proteins. More than an additive response may be observed under combined exposure to Pb, Cd, and As in experimental systems and human studies (Wang and Fowler, 2008).

BIOMONITORING FOR ASSESSING HUMAN EXPOSURE TO CHEMICAL MIXTURES

Human biomonitoring data and biomonitoring equivalents can be used to estimate absorbed doses of chemical compounds from all routes (Fig. 33.1). Biomonitoring is the direct measurement of a chemical or its metabolites in body fluids (e.g., urine, blood, or saliva), tissues (e.g., hair), or exhaled air that enables the assessment of people's exposure to toxic substances. These analytes are known as biological markers or biomarkers of exposure. Biomonitoring represents an actual measure of integrated exposure regardless of the route of exposure and allows for multiple chemical exposure assessments (Wang et al., 2010). Another important function of biomonitoring is the development of "reference ranges" that describe general population exposures to contaminants; however, health-based guidelines for their interpretation have not yet been established for many chemicals. Biomonitoring, as a measure of internal dose, is influenced by alterations of toxicokinetic processes resulting from interactions of the components of mixtures (CDC, 2009; SCHER, 2011). In contrast, biomonitoring equivalents are quantitative benchmarks of safe, or acceptable, concentrations of a chemical or its metabolite in biological specimens that are consistent with selected reference values, such as human threshold limits (Reference dose (RfD), tolerable daily intake (TDI) etc.), by taking into account the available toxicokinetic data of the chemical (Boogaard et al., 2011).

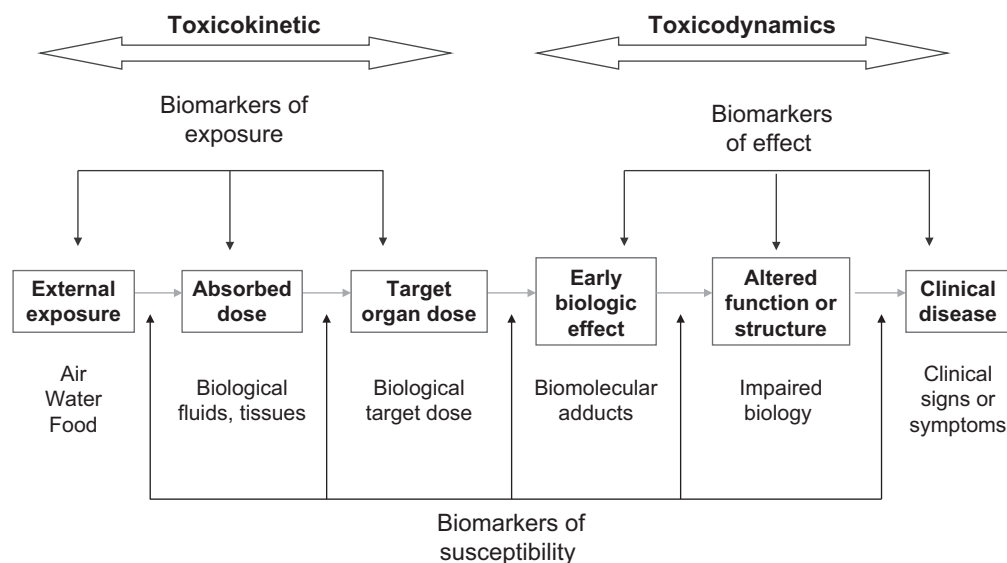
The chemical composition of a mixture is often unknown and the concentration of the individual components may vary with time and environmental conditions. Assessments of the exposure to a mixture generally use relevant available data, such as emissions data, measurement of the components (or a lead component) in the sample of interest, and biomarker information (SCHER, 2011). Biomarker identification and characterization is therefore critical for risk assessment. A framework for the assessment of combined exposures to multiple chemicals has been recommended by the WHO/IPCS using a tiered approach that involves stepwise considerations of both exposure and hazard with increasingly data-informed analyses (Gomes and Meek, 2009).


FIGURE 33.1 Paradigm of toxicity: continuum of events leading from external exposure to clinical disease. Role of biomonitoring to predict health consequences from the exposure.

Biological Specimens

Because of the relatively short biological half-life of nonpersistent chemicals in the body, the sampling period for the biological specimen to be analyzed can be important for the accuracy of representing the exposure to these chemicals. Physiological variations can affect the concentrations of certain chemicals and thus modify the sampling period. Blood and urine samples are the most widely used and accepted matrices for biomonitoring xenobiotic levels in the human body after occupational and environmental exposure. However, these biological fluids only reflect recent exposure (Gil and Hernández, 2009).

Blood

Blood is a complex matrix containing several components, such as proteins, lipids, and different types of cells. Biomonitoring of exposures to OP and N-methylcarbamate pesticides can easily be performed by using plasma and red blood cell cholinesterase activities (butyrylcholinesterase [BuChE] and AChE, respectively), which have become practical and useful tools for testing pesticide applicators to prevent overexposure to these compounds (Lessenger, 2005). Measurement of cholinesterase activity is a practical example of an integrated measure of a likely additive effect when there have been combined exposures to anticholinesterase compounds and would reflect any joint effects of these exposures (Alexander et al., 2008). Plasma BuChE activity is more sensitive to inhibition by some OPs than erythrocyte AChE activity and also recovers more rapidly following exposure. However, inter- and intraindividual variations in cholinesterase activities over time make this enzyme assay inaccurate at exposures causing up to 20% enzyme inhibition. In addition, it is not possible to elucidate which class of OP caused the inhibition, and certain OPs can induce adverse health effects without significant cholinesterase inhibition (Marsillach et al., 2013).

Persistent organic chemicals, such as the PCBs, PCDDs, polychlorinated dibenzofurans (PCDFs), organochlorine insecticides (DDT and its metabolite DDE), and brominated flame retardants, are chemicals readily measured in blood because of their partition into this matrix. The serum concentrations of these lipophilic chemicals can be affected by increased levels of serum triglyceride concentrations, as occurs transiently after a meal, because of the redistribution of these chemicals from adipose tissue. This variation can be corrected for by using lipid-adjusted units for these chemicals. The particular case of cord blood is of interest because it is indicative of fetal exposure, but a more sensitive analytical method is needed to measure these chemicals because cord blood has lower lipid concentration than maternal blood (Wang et al., 2010).

Heavy metals such as Pb, Cd, and Hg are typically measured in erythrocytes because of their affinity for thiol groups. They are found at increasing concentrations with advanced age as a result of their slow elimination from the body (Wang et al., 2010).

Urine

Chemicals metabolized to polar products are eliminated into the urine because of their increased hydrophilicity. Urine has the advantages of an easy collection and of higher concentrations of nonpersistent chemicals than has blood. Unlike blood, chemicals in the urine may not be at steady state because urine is an elimination pathway and its water content can vary throughout the day (Wang et al., 2010).

OP exposure can be assessed by analysis of the DAPs and leaving group metabolites in urine. DAP metabolites are produced during the hepatic and serum metabolism of many OPs and are eliminated in the urine. A leaving group, specific for each OP, is also generated during this metabolic process and excreted by the kidney. Urine DAP measurements do not provide specific information regarding the particular OP of exposure, as the metabolism of a given OP can release different DAPs, and the same DAPs can be released by different OPs. Moreover, detection of urinary DAPs or leaving groups cannot discriminate between OP exposure and environmental exposure to nontoxic OP degradation products ("preformed" DAPs in the environment), resulting in possible overestimation of the exposure. Furthermore, due to their short half-lives, they can be detected between 24 and 48 h following exposure and their levels can vary throughout the day. Thus, exposure assessment from a single urine sample may lead to conflicting results because of the variability of DAP excretion in humans. Regardless of these limitations, factors associated with greater DAP levels might be helpful for risk assessment, and measurement of DAPs in hair provides valuable information about chronic OP exposures (Barr and Angerer, 2006; Margariti and Tsatsakis (2009); Sudakin and Stone, 2011).

The presence of pyrethroid insecticide metabolites in the urine of the US population indicates widespread exposure to these widely used insecticides; 3-phenoxybenzoic acid (3-PBA), a common metabolite for many pyrethroids, has been detected in more than 70% of the samples of the 1999–2002 National Health and Nutrition Examination Survey, with children showing higher levels than adolescents and adults. Moreover, cis- and trans-(2,2-dichlorovinyl)-2,2-dimethylcyclopropane-1-carboxylic acids were highly correlated with 3-PBA, indicating that urinary 3-PBA was derived primarily from exposure to permethrin, cypermethrin, or their degradation products (Barr et al., 2010).

PAHs are converted by cytochrome P450 enzymes to hydroxylated metabolites, such as phenanthrols and 1-hydroxypyrene, which can be measured in urine. Although pyrene is commonly found in PAH mixtures, the extent of its contribution to the mixture can vary by time and setting. Thus, the measurement of 1-hydroxypyrene alone, despite the fact that it has been used widely as an indicator of recent exposure to PAH, may not accurately reflect the composition of the other PAHs in the mixture, particularly those with carcinogenic effects (Wang et al., 2010).

New Matrices for Assessing Cumulative Exposure

Alternative or complementary biological matrices are available for the detection of chemicals, such as human milk, saliva, adipose tissue, hair, meconium, and nail. The use of these matrices requires not only standardized collection, storage, processing, and analytical protocols but also understanding the absorption and metabolism of the chemicals of interest. The validation of analytical procedures is absolutely necessary for a proper implementation of nonconventional samples in biomonitoring programs (Gil and Hernández, 2015). Some matrices, such as hair and nails, are easily contaminated and difficult to collect in a standardized way. Others are difficult to obtain and available only in small amounts. Moreover, environmental chemicals are normally present in the biological matrix at trace levels, and thus, highly sensitive, specific, and selective multianalyte methods are required for the extraction, separation, and quantification of these chemicals (Calafat and Needham, 2009). The presence of a chemical compound in these matrices reflects an exposure, but given that many of them lack safe reference ranges, correlations with blood levels must be established to ensure that they are related to the total body burden (Esteban and Castaño, 2009).

Milk

Human milk is contaminated by lipophilic compounds as a result of long-term pollution by chemicals with long half-lives that tend to degrade slowly in the environment and to bioaccumulate in the food chain. Diet, particularly fatty fish, is a major factor that influences breast milk levels of persistent organohalogenated compounds. While organochlorine pesticide, PCB, and dioxin levels in breast milk have declined in countries where these chemicals have been banned or otherwise regulated, PBDE levels raised (Solomon and Weiss, 2002) until they experienced a modest decline after their ban (Bramwell et al., 2014). Human milk can be used to assess an infant's exposure to these chemicals from breastfeeding; however, the sampling of this matrix needs to be considered because the lipid content varies by the maturity of the milk. Although organic pollutants are the major chemicals measured in breast milk, heavy metals can also be determined in this matrix although they tend to accumulate more in blood (Esteban and Castaño, 2009).

Saliva

Saliva is a readily collectable material with potential diagnostic usefulness as a result of the presence of toxic compounds. However, saliva has several limitations as a suitable sample for analytical purposes, such as variation in flow rates, potential blood contamination during saliva collection, and the absence of reliable reference values for human populations (Gil and Hernández, 2015). In spite of these limitations, saliva has been accepted as a useful tool for biological monitoring of chemicals and may represent a complementary matrix to blood and urine for heavy metal analysis (Olmedo et al., 2010; Gil et al., 2011). Saliva sampling has also been shown to be suitable for measuring some pesticides rather than their metabolites in occupationally exposed adults and in children (Rodríguez et al., 2006).

Hair

Hair is a vehicle of excretion of substances from the human body and as such can indicate cumulative exposure to xenobiotics. Hair has been used to monitor occupational exposure to heavy metals, pesticides, PCDDs, PCBs, and, to a lesser extent, PAHs (Esteban and Castaño, 2009). Hair has also been proposed as an attractive choice for environmental health surveys of these and other environment chemicals. Human hair is a stable matrix, easily accessible for noninvasive sampling, and does not show storage changes for the period between sampling and analysis. Furthermore, it allows for repeated determinations over time. Although blood and urine concentrations clearly reflect recent exposure, hairs reflect past exposure, providing an average of their growth period. Limitations for hair include the potential for external contamination and the lack of sufficient information to define a normal range of reference typically found in the general population (Gil et al., 2011; Gil and Hernández, 2015).

Heavy metals are incorporated into the hair matrix by binding the thiol groups present in keratins. Their concentration varies significantly according to age, sex, hair color, hair care, smoking habits, and racial/ethnic factors. In the case of mercury, most of the levels measured in hair specimens represent exposure to organic mercury, particularly from fish consumption. Hence, hair is less useful for determining inorganic mercury. Nonetheless, the diverse sources of hair mercury can be individually identified by using high energy-resolution X-ray absorption spectroscopy as the different chemical forms of mercury bind in distinctive intermolecular configurations to hair proteins, as supported by molecular modeling (Manceau et al., 2016).

The detection of DAPs in human hair has been proposed as a useful tool for assessing either chronic exposure to OPs or past, acute poisoning if the appropriate hair segment is studied (Margariti and Tsatsakis, 2009; Tsatsakis et al., 2012). Recently, suitable analytical procedures have been reported for multiresidue pesticide analysis in human hair (Lehmann et al., 2018), which will allow for a better monitoring of long-term exposure to nonpersistent pesticides.

Meconium

The fetus can be exposed to different chemicals, including drugs of abuse, most of which are deposited and accumulated in the meconium, particularly during the second and third trimester of pregnancy. Meconium and placenta and cord blood are pertinent biological matrices for assessing the actual body burden of environmental contaminants in neonates. Meconium indicates cumulative exposure, whereas amniotic fluid is an indicator of fetal exposure to chemicals. Thus, meconium appears to be the best matrix for the determination of prenatal exposure to xenobiotics (Esteban and Castaño, 2009; Gil and Hernández, 2015).

For instance, measurement of DAP levels in meconium has been proposed as a potential biomarker for the assessment of OP exposure during pregnancy (Tsatsakis et al., 2009).

Biomolecular Adducts

The narrow sampling window for nonpersistent chemicals in blood can be extended by measuring biomolecular adducts whenever they are formed. The approximate duration of albumin and erythrocyte adducts is 21 days and 3 months, respectively. Because adducts last longer in blood than the parent chemical or metabolite, they can be used to assess for exposure when the sampling period is different from the time of exposure (Wang et al., 2010).

OP-modified enzymes remain longer in the blood than intact OPs, which are rapidly eliminated. Thus, they can be used as better biomarkers of exposure than the parent OPs. This is the case of OP-adducted BuChE and acylpeptide hydrolase (APH), which can be detected in plasma and red blood cells, respectively, several weeks following exposure because of their longer half-lives as compared with parent compounds or metabolites (11 days for BuChE and 33 days for APH). Moreover, both OP-adducted enzymes provide a longer window for detection than the determination of urinary metabolites or free parent OP compounds in blood (Marsillach et al., 2011).

The stable adducts formed on the active site of BuChE and APH following the aging process can be identified and characterized by liquid chromatography coupled with mass spectrometry (MS) and matrix-assisted laser desorption/ionization time-of-flight (John et al., 2008; Marsillach et al., 2013). In contrast to AChE, a baseline sample is not required with MS analyses for evaluation of OP exposures. OP agents may also bind to albumin, particularly on tyrosine-411, the most reactive residue of albumin. The OP–tyrosine bond is more stable and does not age like OPs adducted to active-site serine, allowing for a longer window of exposure detection and a more reliable identification of the OP involved in the exposure (Lockridge and Schopfer, 2010; Marsillach et al., 2013). OP-adducted albumin has been detected in serum from exposed humans even in the absence of AChE inhibition, and thus albumin has been proposed as a useful biomarker for OP exposure (Li et al., 2010).

Some PAH metabolites may also form adducts with biomolecules. Apart from the parent PAH or metabolite, the measurement of biomolecular adducts for some of these compounds in blood (e.g., binding of BaP to DNA, hemoglobin, or albumin) can extend the sampling window to assess for exposure and account for interindividual metabolic variations. Thus, determination of PAH-adduct levels is more informative than monitoring PAH exposures (Wang et al., 2010).

A comprehensive analysis of adducts (the so-called adductome) allows for the simultaneous detection of a variety of known and unknown adducts in DNA and protein samples by using MS-based methods. However, hemoglobin and serum albumin adducts are preferable over DNA adducts because of their greater abundance and half-life in blood.

DNA–protein cross-links are DNA adducts formed when proteins covalently bind to chromosomal DNA. These adducts can be induced by a variety of chemical and physical agents and have been associated with a number of pathophysiological conditions such as aging, cancer, heart disease, and neurodegenerative disorders (Groehler et al., 2017).

RISK ASSESSMENT OF COMBINED ACTIONS OF CHEMICAL MIXTURES

Because humans are often exposed to different chemical components at the same time, the possibility for combined effects of mixtures needs to be addressed in risk assessments for characterizing health risks for the particular exposure conditions. However, the complexity and variability of chemical mixtures and the paucity of data from studies using standard toxicological methods on combined actions of chemical mixtures challenge the risk assessment approach (Alexander et al., 2008). Evaluation of chemical mixture effects requires a systematic and integrated approach of in vivo, in vitro, and in silico data, together with

systematic reviews (and metaanalysis, if available) of high-quality epidemiological studies (Hernández and Tsatsakis, 2017).

The prediction of toxic effects of a mixture is only possible with full knowledge of the individual components of the mixture, their mode of action, and dose-response curves. Nevertheless, this seldom occurs in practice. When information on the mode of action of the mixture components is unknown, the independent action concept is often used as default in human toxicology mixture assessments, although this approach may underestimate the toxicity. In turn, if the dose/concentration approach is applied, it may result in overprediction of toxicity (SCHER, 2011).

There are general principles of mixture toxicology describing how individual chemicals in a mixture affect one another: the concept of additivity (or no interaction) and interaction (Fig. 33.2). Additivity expectations can be derived from the concepts of dose addition and independent action, which assume that chemicals act by the same or different modes of action, respectively (Silins and Högberg, 2011). In this situation, also termed "non-interaction," the toxicity of a mixture resembles the effects expected to occur when all mixture components act without enhancing or diminishing their effects. By contrast, the term "interaction" indicates that the combined effects of two or more chemicals are stronger or weaker than would be expected on the basis of the additive effect, leading to synergism or antagonism, respectively. Interactions are difficult to predict because they are influenced by the relative dose levels, the route(s), timing and duration of exposure (including the biological persistence of the mixture components), and the biological targets (Alexander et al., 2008; Kortenkamp et al., 2009).

The nature of the combined effects of chemical mixtures varies significantly with dose. At exposures above the thresholds of effect for the individual components of the mixture, both toxicokinetic and toxicodynamic interactions can occur, thus making it difficult to predict the occurrence of adverse effects because of antagonism, potentiation, or synergism. Interactive effects giving rise to possible health concerns may start from concentrations around the lowest observed adverse effect level. Conversely, when exposures are below the respective dose thresholds for effect for each chemical in the mixture, the risk of combined adverse effects is much less likely to occur or is toxicologically negligible. For simple dissimilar action, individual components in the mixture are not assumed to contribute to the overall effect of the mixture if they are present at subthreshold levels of toxicity (Alexander et al., 2008; Mumtaz et al., 2010; SCHER, 2011).

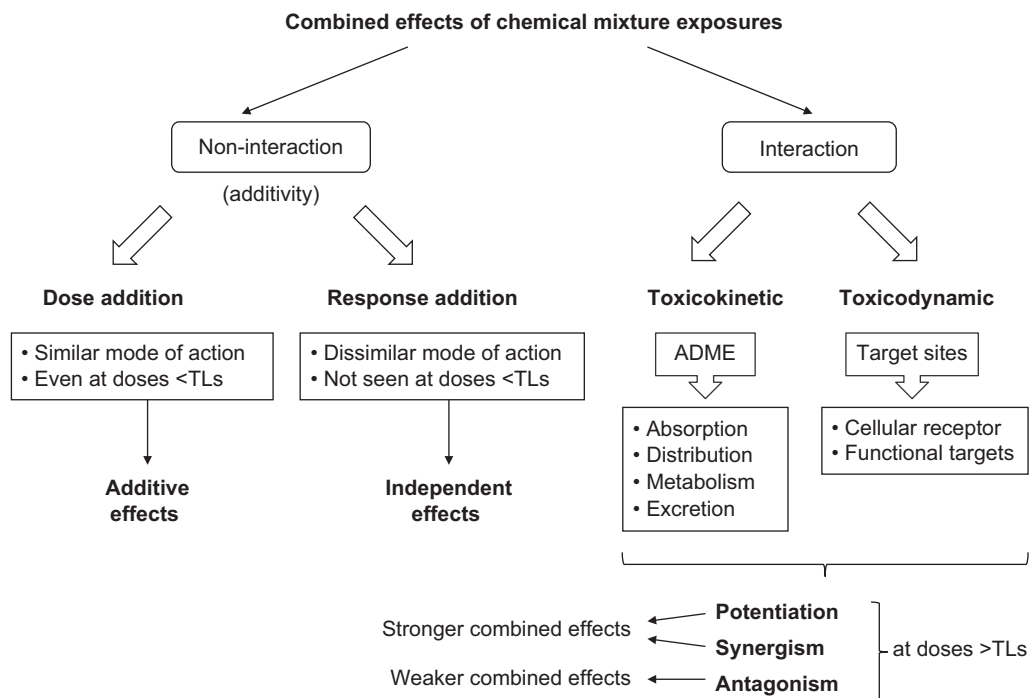
Toxicokinetic interactions are a common cause of deviations from additivity. Examples are chemicals modifying the absorption, distribution, excretion, or metabolism of others. In contrast, toxicodynamic interactions occur at the cellular receptor/functional target level (Hernández et al., 2017). Competition of two components at the same target will usually result in addition


FIGURE 33.2   Type of combined effects of chemical mixtures exposure (TLs: threshold levels for toxicity).

of effects or antagonism (effect inhibition); it is very unlikely that this will lead to synergism. Weak agonists may function as antagonists by occupying the receptor and preventing the binding of a more potent ligand (Alexander et al., 2008; Wang et al., 2010).

Co-exposure to multiple metals may cause neurotoxic effects which are absent with exposure to a single metal at similar dose (Andrade et al., 2015). The additive toxicity approach has also been considered for assessing the combined effect of pesticides that have similar chemical structures and/or modes of toxic action. This is the case of concurrent multiple OP exposure, wherein a summation of the inhibitory effects of individual compounds on AChE activity is usually observed (Hernández et al., 2013a). A physiologically based pharmacokinetic model developed by Timchalk and Poet (2008) anticipated that at low environmentally relevant doses of the OP insecticides chlorpyrifos and diazinon, the cholinesterase inhibition would be dose additive. The assessment of the effect of a mixture of parathion, demeton-S-methyl, carbaryl, carbofuran, and aldicarb indicated an additive inhibitory effect on AChE activity (Mwila et al., 2013). Controversial findings have been reported for mixtures of several N-methylcarbamates (carbaryl, carbofuran, formetanate, methomyl, methiocarb, oxamyl, and propoxur) assayed in rats at equitoxic component doses and at environmental levels (Moser et al., 2012). In adult animals, the relative potency mixture showed dose additivity for erythrocyte AChE inhibition and motor activity, whereas brain AChE inhibition showed a modest greater-than-additive (synergistic) response but only at a middle dose. In rat pups, either dose-additive effects (brain AChE inhibition and motor activity) or slightly less-than-additive effects (erythrocyte AChE inhibition) were observed. At both ages, environmental levels of the chemical mixture showed greater-than-additive responses on the two cholinesterases and motor activity, with significant deviations from predicted at most doses tested (Moser et al., 2012).

Although additive effects imply that the chemicals in a mixture are acting by the same mechanism and at the same target, synergism can result from chemicals simultaneously acting in different toxicity pathways, thus magnifying their final toxic effect. Synergistic action in the carcinogenic process can be represented by the classical initiation–promotion model. Epidemiological evidence has indicated that cigarette smoke and inhaled arsenic exposure act synergistically to increase the incidence of lung cancer in smelter workers. By contrast, potentiation occurs when the toxicity of a chemical on a certain tissue or organ system is enhanced when given together with another chemical that alone does not have toxic effects on the same tissue or organ system (e.g., liver toxicity of carbon tetrachloride is enhanced with isopropanol) (Alexander et al., 2008).

BIOMARKERS OF TARGET ORGAN TOXICITY OF CHEMICAL MIXTURES

A biomarker of effect is usually a molecular indicator of a specific biological or disease state that can be measured in peripheral body fluids. Nevertheless, a broad concept would include any measurable change in a biological system or organism, including measured alterations in the structure or function of organs or tissues. Biomarkers of effect represent a valuable tool for assessing and controlling combined exposures from different routes and different compounds (Table 33.1). Recently, the approach of grouping chemicals focusing on common adverse outcomes could allow the use of shared effect biomarkers, even unspecific, as when used in combination they may reflect specific "signatures" of biochemical changes induced by a chemical mixture (Andrade et al., 2015). Early response biomarkers have the advantage of being interpreted within the context of integrated systems models, which connect these biomarkers to adverse outcomes of regulatory concern (DeBord et al., 2015).

A variety of strategies have been used for biomarker development, including transcriptional profiling, and proteomic and metabolomic approaches (Fig. 33.3). Examples of these markers are altered enzymatic activity, changes in protein expression or posttranslational modification, and altered gene expression, or protein or lipid metabolites, or a combination of these changes (Žurek and Fedora, 2012).

Biomarkers of Liver Damage

The liver plays a key role in the maintenance of the homeostasis of the organism and is the main organ responsible for detoxification of xenobiotics. As a result of Phase I microsomal metabolism, many chemicals undergo bioactivation instead of detoxification reactions, resulting in the generation of highly reactive metabolites. These molecular species may induce hepatotoxicity that can be assessed by measuring various peripheral proteins released in response to hepatocellular damage. However, the extremely large compensatory possibilities of the liver may account for the difficulty of proving a toxic effect in its early stage (Kaloyanova and Vergieva, 1987).

Conventional tests of hepatic damage provide information about the integrity of hepatocytes, such as serum levels of alanine and aspartate aminotransferases (ALT and AST, respectively), which are predominantly found in the periportal zone of the liver; however, ALT is considered as the gold standard biomarker of liver injury. The integrity of the biliary system is commonly assessed by measuring serum levels of bilirubin,

TABLE 33.1 Biomarkers for Assessing Target Organ Toxicity

Organ	Injury Location	Biomarker
Liver	Hepatocellular	ALT and AST (alanine and aspartate aminotransferases)
		GSTα (glutathione S-transferase alpha)
		Arginase I
		Ornithine carbamoyltransferase (OCT)
	Biliary system	GGT (γ-glutamyltransferase)
		ALP (alkaline phosphatase)
		5-Nucleotidase
		Bilirubin
	Biosynthesis	Albumin
		Prothrombin time
Kidney	Glomeruli	Urea
		Creatinine
		High molecular weight proteins (e.g., albumin[a])
		Cystatin C
		Glomerular filtration rate (GFR)
	Tubule	α1-Microglobulin[a]
		β2-Microglobulin[a]
		N-Acetylglucosaminidase (NAG)[a]
		Cystatin C[a]
		Kidney injury molecule-1 (KIM-1)[a]
		Neutrophil gelatinase−associated lipocalin (NGAL)
		GSTα[a] (for proximal tubule damage)
		GSTπ[a] (for distal tubule damage)
	Scarring	Collagen fragments[a] (e.g., fibronectin, laminin)
Brain	Neurons	Neuron-specific enolase (NSE)
		Hyperphosphorylated neurofilament (pNF-H)
		Ubiquitin C-terminal hydrolase L1 (UCH-L1)
		Microtubule-associated protein 2 (MAP-2)
		Microtubule-associated protein tau (MAPT)
		Translocator protein (TSPO)
	Glial cells	Glial fibrillary acidic protein (GFAP)
		Myelin basic protein (MBP)
		S100B protein
	Peripheral[b]	Erythrocyte AChE

Continued

TABLE 33.1 Biomarkers for Assessing Target Organ Toxicity—cont'd

Organ	Injury Location	Biomarker
Lung	Lung epithelia	CC16 (Clara cell protein 16)
		Krebs von den Lungen 6 (KL-6)
		Surfactant proteins (SP)
		Mucin 5B
		Cleaved cytokeratin 18 (cCK-18)
	Extracellular matrix remodeling	Matrix metalloproteases (MMP)
		Lysyl oxidase−like (LOXL)
	Immune dysfunction	Cytokines
		Chemokines
		T-cell activation

All biomarkers are determined in serum unless otherwise indicated.
[a]Measured in urine.
[b]Surrogate biomarker for monitoring anticholinesterase pesticides exposure by measuring acetylcholinesterase activity in erythrocytes (red blood cells).

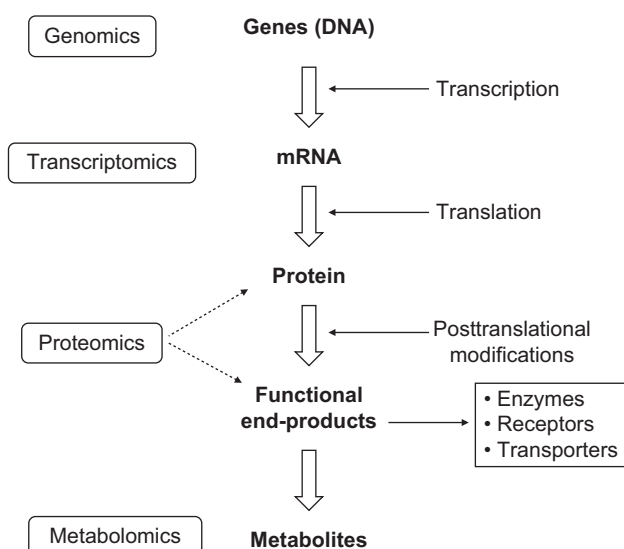
γ-glutamyltransferase (GGT), and alkaline phosphatase (ALP) (Ozer et al., 2008; Gil and Hernández, 2009). Because of the lack of specificity of ALP, which can increase as a result of abnormalities of the biliary system and in certain skeletal disorders, either GGT or 5-nucleotidase can be assayed to clarify the origin of increased serum ALP. Increased serum bilirubin levels result from cholestatic and parenchymal liver diseases where the liver-blood cycling of conjugated bilirubin through membrane transporters is impaired. In turn,


FIGURE 33.3 A functional -omics approach for biomarker development.

serum albumin and prothrombin time (which requires the presence of clotting factors produced in the liver) are the most commonly used tests to assess the biosynthetic capacity of the liver (Khalili et al., 2011).

Abnormalities in these liver function tests may be used to monitor liver damage from combined or mixed exposure. Additional information can be provided by more specific biochemical parameters not routinely used to assess drug/toxicant-induced liver injury because most of them involve ELISA measurement and a higher cost. Some examples are arginase I, ornithine carbamoyltransferase (OCT), glutathione S-transferase alpha (GSTα), and 4-hydroxyphenylpyruvate dioxygenase (Bailey et al., 2012). Arginase I catalyzes the catabolism of arginine to urea and ornithine and is highly liver specific, showing the earliest and greatest increase in serum after liver damage. OCT, like arginase I, is also involved in the urea cycle and its elevation in serum indicates damage to periportal hepatocytes (Ishikawa et al., 2003). From the eight GST classes (alpha, pi, mu, theta, kappa, sigma, omega, and zeta), the alpha GST class is more abundantly expressed in human liver and kidney. Unlike ALT and AST, GSTα is found in high concentration in centrilobular cells and is therefore more sensitive to injury in this metabolic zone of the liver. GSTα is released shortly after hepatocellular damage, leading to a greater increase in plasma levels than that found for ALT or AST (Singh et al., 2011).

Anand et al. (2005) examined the hepatotoxic outcome of secondary, tertiary, and quaternary mixtures of thioacetamide, allyl alcohol (a periportal hepatotoxicant), chloroform (a centrilobular hepatotoxicant), and trichloroethylene (that causes midzonal liver injury). These compounds are metabolized by the CYP2E1 enzyme and also exhibit nephrotoxic and carcinogenic potential in rodents. Higher ALT levels were observed without histopathological changes, similar to what has been described in chloroform alone studies, where slight plasma membrane injury was caused by its reactive metabolite phosgene. The observed subadditive toxicity was attributed to the fact that certain solvents (e.g., chloroform) enhance the elimination of others (e.g., trichloroethylene), leading to an antagonistic interaction (Anand et al., 2005). In a cross-sectional study a combined chemical exposure to lead and organic solvents under the permissive exposure level (indicating that it is not harmful to most workers) showed additive effects on the same target organ (liver), even if each single exposure occurs below the permissible exposure limit (Chang et al., 2013).

An increase in triglycerides and total cholesterol has been described as specific for toxic hepatitis (Kaloyanova and Vergieva, 1987; Provost et al., 2003) and, thus, they could also serve as markers of liver dysfunction. In fact, higher levels of triglycerides have been reported to reflect the total lifetime cumulative exposure to solvents (Silins and Högberg, 2011).

Kidney

The kidney is a target organ for many xenobiotics because of the high volume of blood flowing through it and the large capacity to concentrate toxins in the renal tubular system. Although the kidney is one of the main target organs for xenobiotic-induced toxicity, early detection of renal damage is difficult. Conventional biomarkers of kidney damage include serum creatinine and blood urea nitrogen (BUN); however, their levels increase when the kidney damage is greater than 50%, very likely indicating an irreversible progression. The increase in low molecular weight proteins in urine (such as α_1-microglobulin, β_2-microglobulin, or retinol-binding protein), assumed to be freely filtered, reflects tubular dysfunction and is an earlier and more sensitive biomarker of kidney tubular toxicity than is serum creatinine. Lysosome-derived enzymes, such as N-acetyl β-D-glucosaminidase (NAG) and β-galactosidase, are also used for monitoring proximal tubule insults because of their high activity in the kidney and its stability in urine (Gil and Hernández, 2009). Total urinary protein is a sensitive and early biomarker of changes in the glomerular filtration and the tubular reabsorption systems and has been used to assess progressive loss of kidney function (Goodsaid et al., 2009).

Several novel, sensitive, and tissue-specific biomarkers of nephrotoxicity have been proposed to improve detection of early acute kidney injury (AKI) following exposure to nephrotoxicants as compared with traditionally used biomarkers. They also enable the localization of the injury to a specific nephron site. Some examples are urinary kidney injury molecule-1 (KIM-1), neutrophil gelatinase–associated lipocalin (NGAL), interleukin-18 (IL-18), cystatin C, and GST, which are early diagnostic biomarkers of AKI; however, biomarkers such as NGAL, KIM-1, and cystatin C are also useful for chronic kidney disease (CKD). Biomarker combinations are required to increase diagnostic accuracy for either AKI or CKD detection (Wasung et al., 2015). Serum cystatin C has been considered a better endogenous marker of glomerular filtration rate (GFR) than serum creatinine in early stages of AKI and is less affected by age, gender, muscle mass, and ethnicity. Unlike creatinine, cystatin C is not secreted by the tubule, such that its appearance in urine indicates a tubular dysfunction with reabsorption failure (Charlton et al., 2014). Therefore, increased serum cystatin C is indicative of glomerular damage, while urinary levels indicate tubular damage. KIM-1 is a transmembrane

renal tubular glycoprotein involved in immune regulation and in kidney tubular regeneration that is upregulated after ischemia- or nephrotoxicant-induced injury (Simsek et al., 2013). Although NGAL is an acute-phase reactant that is found to be elevated in inflammatory conditions, it is also released from lysosomes, brush border, and cytoplasm of proximal tubular epithelial cells (Wasung et al., 2015).

The assessment of nephrotoxicant-induced abnormal renal function might include the determination of the following biomarkers in serum or urine:

- Serum creatinine, BUN, and the GFR: These should be initially determined. As they lack enough sensitivity, much more sensitive biomarkers should be studied for assessing subclinical renal damage.
- Biomarkers of glomerular damage or dysfunction: Increased urine excretion of high molecular weight protein, such as albumin or transferrin, can be helpful for an early detection of glomerular barrier defect. Serum cystatin C correlates negatively with the GFR and is a much more sensitive marker for detecting early glomerular alterations.
- Biomarkers of tubular injury: Urinary cystatin C, KIM-1, α_1-microglobulin (which is more stable at acidic pH than β_2-microglobulin) and GSTα reflect a functional impairment of the proximal tubular reabsorption due to glomerular injury or direct tubular damage. Urine GSTπ is a biomarker useful for specifically assessing distal tubular damage.
- Biomarkers of recovery/repair: Urinary elevation of clusterin, a cytoprotective chaperone, indicates recovering of renal function from the renal injury.
- Biomarkers for scarring: Collagen fragments (e.g., type I collagen, fibronectin, laminin) are useful for monitoring the progression of glomerular damage and may also reflect the degree of tubulointerstitial fibrosis.

Differences in the excretion of these biomarkers reflect different stages of severity of renal function impairment. Under conditions of chronic solvent exposure, renal damage may remain clinically silent for many years owing to the large functional reserve capacity of the kidney. The degree of reversibility depends on the severity of the disease. At a later stage, the disease can be irreversible, leading to end-stage renal failure. It is therefore important to detect kidney defects as early as possible to prevent progression of the disease (Mangelsdorf, 2009).

Adverse effects induced by chronic exposure to Pb and Cd have been monitored by measuring urinary GSTα, a hallmark of early changes in the proximal tubular integrity, which showed a positive correlation with urinary levels of these heavy metals (Garçon et al., 2004). Combined exposure to As and Cd leading to increased urinary levels was followed by considerably enhanced urinary excretion of β_2-microglobulin or NAG than each exposure alone, indicating renal tubular damage (Nordberg, 2010). In addition, individuals showing lower Cd-induced metallothionein mRNA levels displayed higher β_2-microglobulin or NAG values at comparable levels of urinary Cd (Nordberg, 2010), indicating the protecting role of this inducible metal-binding protein.

Nervous System

Exposure to some chemicals may induce persistent changes in the nervous system by affecting different neuronal targets such as membranes, intracellular signaling, axonal transport, or energy supply. Chemicals in a mixture affecting any of these targets may interact to produce neuronal damage. Mature neurons have limited capability of regeneration and are therefore at greater risk for permanent damage after a toxic injury than many other cells in the body. This limitation is partially compensated for by the large reserve capacity of the central nervous system; only when the reserve decreases below a critical level does overt neurotoxicity ensue. On the other hand, the nervous system is particularly vulnerable to toxic compounds during the early period of development (Alexander et al., 2008).

Nonneurotoxic compounds can make the blood—brain barrier (BBB) more permeable to ionic compounds and thus may potentiate their toxicity. Likewise, biomarkers originating in the brain can gain access to the blood due to disruption of the BBB. Biomarkers that are measurable with minimally invasive techniques, such as biological fluid-based molecular markers and emerging neuroimaging methodologies, could be of utility both preclinically and clinically. Potential molecular markers include glial fibrillary acidic protein (GFAP, a biomarker of astrogliosis, which consists of a cellular reaction that indicates both neuronal and glial damage), ubiquitin C-terminal hydrolase L1 (UCH-L1, a biomarker of cell body injury), myelin basic protein (MBP, a biomarker of myelin disruption), microtubule-associated protein-2 (MAP-2, characteristic of dendritic injury), neurofilaments (NF, biomarkers of axonal injury), microtubule-associated protein tau (MAPT, biomarker of neurodegeneration/axonal injury), and translocator protein (TSPO, indicative of activated glia and also may signal neuroinflammation). In turn, the main neuroimaging methodologies are magnetic resonance imaging, magnetic resonance spectroscopy, and positron emission tomography (Roberts et al., 2015).

Neuronal tissue and glial-derived proteins are easily detectable in peripheral blood and thus may serve as surrogate markers of brain damage. NF, the most

abundant protein of neurons and major components of the neuronal cytoskeleton, are released in large numbers when these cells are damaged. Because NFs are only found in neurons, their detection in blood points unambiguously to neuronal damage. NFs consist of three subunits, namely NF-light (L), NF-medium (M), and NF-heavy (H) based on their molecular weight. The function of NFs appears to be closely related to their phosphorylation status, and abnormally phosphorylated NFs in the cell bodies have been proposed as a common feature of neurodegenerative diseases. Hyperphosphorylated NFs may be a good serum biomarker for axonal injury and degeneration because of its stability within blood (Shaw, 2015).

When the central nervous system is injured in response to toxic substances or disease states, astroglial cells react to repair the damage. Astrocyte proliferation upregulates GFAP, an intermediate filament protein that provides support and strength to astroglial cells, which is partially released to blood where it can be measured (Žurek and Fedora, 2012).

Neuron-specific enolase (NSE, a glycolytic enzyme) and protein S100B (a calcium-binding protein abundant in astrocytes) have been shown to increase in serum after a number of cerebral insults, such as traumatic brain injury or stroke, resulting in structural damage. However, both NSE and S100B have limitations derived from false positive values (Žurek and Fedora, 2012).

Peripheral cells, including platelets, erythrocytes, lymphocytes, and fibroblasts, have been used to evaluate exposure to neurotoxic agents, mainly heavy metals, pesticides, and solvents (n-hexane and carbon disulfide). The best example is represented by the measurement of erythrocyte AChE following exposure to OP and *N*-methylcarbamate insecticides, as this enzyme better reflects brain AChE activity. Exposure to mixtures of these anticholinesterase pesticides has been assessed by using erythrocyte AChE inhibition as mentioned above.

Lungs

A number of molecules measured in serum, bronchoalveolar lavage fluid, or lung tissue can be used as biomarkers of lung toxicity and allow a better understanding of pathological processes. Possible biomarkers can be categorized in three groups: (1) biomarkers associated with alveolar epithelial cell dysfunction (e.g., Krebs von den Lungen 6—KL-6; surfactant proteins—SPs; mucin 5B; cleaved cytokeratin 18—cCK-18); (2) biomarkers associated with extracellular matrix remodeling and fibroproliferation (matrix metalloproteinases—MMPs; lysyl oxidase−like—LOXL; osteopontin); and

(3) biomarkers related to immune dysfunction (e.g., cytokines, chemokines, and markers of T-cell activation) (Drakopanagiotakis et al., 2018).

Inhalation of toxic compounds may result in airway irritation featured by increased permeability, edema, and cell necrosis. Cytotoxic effects in the respiratory tract are often general and nonspecific and are related to water solubility of the toxic compound. Combined exposure to ozone and NO_2 has shown an interactive effect on lung function, leading at least to an additive irritation effect. Several cell types of the bronchial epithelium are extremely vulnerable to various types of injury. This is the case for Clara cells, which contain most of the lung CYP450 activity that confers a high xenobiotic metabolizing activity. Thus, these cells are particularly sensitive to toxic injury from inhaled xenobiotics that are metabolized by CYP450 enzymes (Gil and Hernández, 2009).

Clara cell protein (CC16, also referred to as CC10) is a low molecular weight protein that is secreted along the tracheobronchial tree, particularly in the terminal bronchioles where Clara cells are localized. It can be measured in serum, bronchoalveolar lavage fluid, and sputum as a peripheral lung marker for assessing the cellular integrity or the permeability of the lung epithelium. This protein is also involved in the protection of the respiratory tract against oxidative stress and inflammation. Acute exposures to pulmonary irritants can cause a transient increase in serum CC16 levels, which is not associated with impairment of pulmonary function (Broeckaert et al., 2000; Lakind et al., 2007).

Asphalt workers have shown increased mortality from respiratory diseases because of exposure to chemical mixtures of dust, oil mist, PAHs, and nitrogen dioxide. A significant increase in CC16 concentration has been reported in asphalt pavers exposed to chemical mixtures, particularly bitumen fume and vapor, and exhaust from engines. Thus, CC16 appears to be a useful biomarker for lung epithelial injury in workers exposed to lung toxic chemical mixtures (Ulvestad et al., 2007).

Particulate matter (PM) is a complex mixture of extremely small particles and liquid droplet present in the atmosphere and considered as air pollutants. The complex mixture consists of organic carbon, ammonium, nitrates, sulfates, mineral dust, trace elements, and water. PM can develop and exacerbate diverse respiratory diseases, such as asthma and chronic obstructive pulmonary disease. Besides, PM can induce oxidative stress and inflammation on respiratory airways and eventually can lead to cancer. A number of oxidative stress and inflammatory biomarkers have been considered as potentially helpful for assessing respiratory diseases induced by PM (Kim et al., 2017).

NONSPECIFIC BIOMARKERS OF TOXIC RESPONSE

Oxidative Stress

Many chemicals, either alone or in mixtures, may produce oxidative stress as a result of increasing the generation of free radicals, affecting the mitochondrial function or decreasing levels of antioxidants and antioxidant enzymes in blood and other tissues. The initiation of oxidative damage can be reversed by intracellular antioxidants or stimulation of antioxidant enzymes or repair systems. The increase in antioxidant levels leads to the scavenging of excess free radicals and contributes to a decrease in oxidative damage, whereas a decrease in antioxidants should lead to the opposite effect (Liu et al., 2000). A brief elevation in oxidative stress rapidly induces various antioxidant defenses, particularly antioxidant enzymes, such as superoxide dismutase, catalase, and glutathione peroxidase, which quickly reduce the cellular damage and limit the ability of testing methods to detect a change (Birben et al., 2012).

Assessment of oxidative stress involves the determination of biomarkers for oxidative damage, such as decreases in antioxidant concentrations or increases in oxidative metabolites. The latter can be monitored by measuring lipid peroxidation products (malondialdehyde), protein oxidation (protein carbonyl levels and glutamine synthetase activity), or endogenous antioxidants (ascorbic acid, α-tocopherol, reduced glutathione, total antioxidant capacity of serum, and ferric reducing ability of serum) (Liu et al., 2000). Biomarkers of oxidative damage of proteins (3-nitrotyrosine) and DNA (8-hydroxy-2′-deoxyguanosine) are also used for assessing oxidative stress; 3-nitrotyrosine is formed primarily from peroxynitrite, a damaging free radical generated from superoxide and nitric oxide. Other functional indicators of oxidative stress include relative levels of 3-chlorotyrosine and aconitase activity. Aconitase is highly sensitive to oxidative inactivation by the superoxide radicals produced in the mitochondria (Rose et al., 2012). However, changes in these biomarkers may not necessarily reflect a clinically significant or pathogenic event but merely indicate that the antioxidant defense system is functioning.

Oxidative stress is a sensitive endpoint for metal mixtures, very likely because mitochondria are common targets for certain metals that bind to thiol groups or displace essential metals in antioxidant enzymes. This is the case for Pb, Cd, Hg, and As, which produce alterations of target tissue concentrations of certain essential metals (e.g., Fe and Zn) or inhibit enzymes containing thiol groups (Wang and Fowler, 2008). Alterations in essential trace elements (Cu, Se, Zn) have been reported in workers exposed to metal mixtures (Pb and Cd) showing significant decreases in the Se-dependent enzyme glutathione peroxidase in both erythrocytes and serum (Wasowicz et al., 2001). Therefore, combined exposures to metal elements can modify the antioxidant capabilities of the blood.

Prooxidant/antioxidant alterations have been observed in subjects chronically exposed to airborne particles containing coal dust, usually by inducing enhanced lipid peroxidation together with a decline in antioxidants enzymes (Ávila Júnior et al., 2009). Nonenzymatic antioxidants, such as reduced glutathione and vitamin E, were depleted in subjects more exposed to air contamination, whereas enzymatic antioxidants were either induced (e.g., GST and catalase) or inhibited (superoxide dismutase and glutathione peroxidase). Besides workers, people living in the vicinity of the polluted mining areas also face oxidative stress and risk of coal mining—related diseases (Ávila Júnior et al., 2009).

In addition to their canonical toxicity mechanisms, OP, N-methylcarbamates, and organochlorine pesticides may induce cellular oxidative stress as a result of an enhanced generation of highly reactive molecules and/or reduced capacity of the antioxidant systems of the body, thus contributing to disruption of cell function (Dettbarn et al., 2006; Karami-Mohajeri and Abdollahi, 2011). Long-term pesticide exposure in intensive agriculture workers has been associated with reduced superoxide dismutase, glutathione reductase, and delta-aminolevulinic acid dehydratase activities (Hernández et al., 2013b). If these changes are sustained over time, there is an increased risk for developing a number of chronic and degenerative diseases wherein oxidative stress plays a pathogenic role.

DNA Damage and Genotoxicity

There is much knowledge about the genotoxic effects of individual chemicals but scarce information about possible interactions or combined actions among chemicals. Some xenobiotics, including PAHs, aromatic amines, heterocyclic amines, mycotoxins, alkylating agents, and nitrosamines, have reacting groups that can interact with nucleophilic targets, such as DNA, leading to genetic damage. However, genotoxic compounds may induce DNA damage by many other different mechanisms, including oxidative stress, thus making it difficult to predict the outcome of exposure to chemical mixtures. Besides, long-lived cells with high sensitivity to chemical agents may accumulate DNA damage over time, which, if not properly repaired, leads to mutations and ultimately to an increased risk of long-term effects such as inflammatory, carcinogenic, and reproductive disorders. Interactions that affect the

bioavailability, metabolic activation or detoxification, or DNA binding or repair of DNA damage may influence the genotoxicity of a complex mixture. Initiators, promoters, and co-carcinogens all may act in concert to potentiate the final tumor outcome. However, combination effects at low and realistic human exposures, which are not possible to explore experimentally in animal studies, may be different from those obtained by experimentation at high doses (Alexander et al., 2008).

Different types of markers have been designed to assess the mutagenic (and possibly carcinogenic) response of certain chemicals. They are usually studied in peripheral cells, especially circulating lymphocytes or other cells readily accessible as the epithelial cells of the nasal or buccal mucosa. Although a positive response in these biomarkers does not always indicate increased risk of cancer, their early occurrence makes them useful for assessing toxic risks. The detection of double and single DNA strand breaks is relevant for effect monitoring of chemical mutagens and may serve as a surrogate for carcinogenesis. However, chromosomal changes are the most commonly studied biomarkers of genotoxicity. Stable chromosomal aberrations, especially long-lasting chromosomal rearrangements, have greater importance as indicators of carcinogenesis than reversible DNA strand breaks, which only reflect recent exposure. Indirect markers of chromosomal damage include sister chromatid exchange, induction of micronuclei (easily seen in enucleated cells such as circulating erythrocytes), and the comet assay, which is capable of detecting breakage of one or two strands of DNA (Greim, 2001). However, not every DNA-damaging chemical is potentially carcinogenic as it may be toxic to cells at high levels but does not pose a cancer risk in vivo. The lack of well-established dose–response relations between occupational or environmental exposures and the formation of strand breaks limits the applicability of these biomarkers (Angerer et al., 2007). Although DNA adducts have also been used to assess the genotoxic potential of chemicals (Gil and Hernández, 2009), they are considered biomarkers of exposure rather than biomarkers of effect.

PAHs may contribute to the genotoxicity and carcinogenicity of air pollution from urban environments. The exposed populations may also develop oxidative stress leading to oxidative DNA damage that results in increased levels of several markers of genotoxicity, including bulky DNA adducts, chromosomal aberrations, sister chromatid exchanges, and Ras oncogene overexpression (Farmer et al., 2003). A study conducted in children exposed to a mixture of pollutants from different sources found that the genotoxicity effects (evaluated by the comet assay) associated with exposure to low levels of benzene and Pb were enhanced by co-exposure to high levels of PAHs (Pelallo-Martínez

et al., 2014). An increase in genomic instability and cell death has been reported in the human buccal micronucleus cytome assay of workers occupationally exposed to coal residue mixtures as a consequence of oxidative damage (Rohr et al., 2013).

Occupational exposure to bitumen fumes in road paving workers has been associated with DNA damage assessed by the comet assay in blood mononuclear leukocytes (Lindberg et al., 2008). In this study, levels of DNA damage correlated with both urinary concentration of 1-hydroxypyrene and external air concentrations of bitumen fumes and vapors, thus supporting the genotoxic effects of this chemical mixture.

Combined exposures to metals have produced DNA strand breaks by a mechanism involving oxidative stress coupled with an inhibition of DNA damage reparation. Heavy metals such as Cd induce the generation of reactive oxygen species that can cause direct DNA damage. The urinary excretion of 8-hydroxyguanine is a reflection of an increased number of modified DNA bases. A synergistic effect of exposure to metals mixture on DNA oxidative stress may occur as a result of the combination of reactive oxygen species and impairment of DNA repair (Yoshioka et al., 2008).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Within mixture toxicity research, there is a need to identify the type and extent of interactions between the components of chemical mixtures and understand the underlying mechanisms. Experimental studies on whole mixtures should reflect real-life exposures, including their concentrations and component proportions, and should include several doses below the threshold level of exposure for individual compounds to assess for potential additive or supraadditive effects. The use of biomarkers of effect based on analogous endpoints of toxicity induced by individual chemicals in a mixture could be a useful tool for predicting and preventing the risk of toxicity. A better understanding mechanism underlying toxic interactions will provide a more robust basis for the development and selection of biomarkers of effect, which will be helpful for risk assessment and for the prevention of health risks in exposed populations. Advances in modern molecular biology techniques, such as genomics, proteomics, and metabolomics, as well as chip technologies, will enable the screening of effects of chemical mixtures at the molecular level and the development of more sensitive and specific methodologies for biological monitoring of combined exposures. Physiologically based toxicokinetic/toxicodynamic models will be of help for data-poor chemicals to estimate biomarker concentrations

and mechanistically relevant effects in target organs. Further well-designed studies on the interactive toxicity of mixtures would broaden the scientific database on combined exposures of chemicals and would help to elucidate their impact on the health outcomes.

Biomarkers of Toxic Solvents and Gases

Szabina A. Stice

Division of Biotechnology and GRAS Notice Review, Center for Food Safety and Applied Nutrition, US Food and Drug Administration, College Park, MD, United States

INTRODUCTION

Solvents are categorized as either organic or inorganic. Organic solvents can be further classified by their molecular structures and functional group(s) present (e.g., alcohols, ethers, ketones, aliphatic, and aromatic hydrocarbons). Solvents possess a wide range of toxicities depending on their number of carbon atoms, configuration, presence of double and triple bonds, and specific functional groups in the molecule, along with other factors. The toxicity of solvents can vary dramatically even within the same class. For example, while 2-hexanone, 3-heptanone, and 2-pentanone are all ketones with small differences in their structures, 2-hexanone is neurotoxic with a very low safe threshold value, 3-heptanone possesses only low neurotoxic potential, and 2-pentanone is not neurotoxic.

Solvents are widely used to dissolve, dilute, suspend, or extract other substances. They have various applications in the oil, gas, pharmaceutical, chemical, and other industries. These important chemicals are used as, or are used in, dry cleaning agents, nail polish removers, perfumes, detergents, spot removers, paints, varnishes, paint thinners, adhesives, drugs, and in numerous other products. Consequently, they may be commonplace in the work or home environments. The major routes of solvent exposure are the lungs (via inhalation), the gastrointestinal tract (via ingestion), and the skin. Exposure to gases may be accidental, intentional (abuse or chemical warfare agents), occupational, or environmental. During normal daily activities, nearly all of us are exposed to solvents and gases; exposure to airborne solvents is considered unavoidable (Bruckner and Warren, 2001).

As exposure may occur via multiple routes and various sources, air monitoring, a common way to estimate solvent and gas exposure, fails to provide information on the total exposure to humans and animals. On the other hand, biomarkers of toxic solvent and gas exposure enable us to assess total exposure in biological specimen(s). Furthermore, biological effects usually correlate better with biomarker levels than with air concentrations (Fiserova-Bergerova and Ogata, 1995). The specimens used most frequently for biomonitoring (measurement of a biomarker in a biological specimen) of toxic solvents and gases are blood, urine, and exhaled breath. As many solvents and gases have short residence times in the body, the sampling period for biological specimens must be carefully chosen to accurately represent exposure to these chemicals. The biomarker also must be chosen with care to ensure that it is a specific and sensitive marker of exposure to the toxic solvent or gas. Moreover, while some markers are indicators of recent exposures only, others can signal older exposures.

Early detection of biomarkers of exposure may enable us to either prevent the onset of a disease or halt its progression by avoiding further exposure to harmful chemicals and by monitoring the health of those exposed to toxic solvents and gases. Biomarkers of exposure include the measurement of the parent compound, its metabolite(s), protein adduct(s), or DNA adduct(s). Some markers may serve as biomarkers of both exposure and effects. Detection of biomarkers of effects aids us in early diagnosis and selection of effective treatment and may shed light on modes of toxic action. Biomarkers of effects include various changes at the cellular level (e.g., altered expression of metabolizing enzymes, enzyme inhibition, and altered gene expression patterns), preneoplastic changes, gene mutations, and chromosomal aberrations (Silins and Högberg, 2011).

While biomarkers of exposure are preferably, but not always, specific to the chemical of interest, biomarkers of effects are often not specific to a chemical (e.g., the

expression of the same metabolizing enzyme may be upregulated by various chemicals). Toxic effects and the mechanism of toxicity of a solvent or gas may be animal species- and/or strain-specific and depend on the route of exposure. When using residues of toxic chemicals or metabolic biomarkers to establish the extent of exposure, intra- and interspecies differences in absorption, distribution, metabolism, and/or elimination may pose significant challenges. Biomarkers that are common to test animals and humans are preferred for biomonitoring to ensure that biomarkers are predictive of effects in humans. Furthermore, as structurally related substances may have one or more common metabolites, metabolites used as biomarkers must be carefully selected; a multibiomarker approach should be employed instead of a single biomarker to detect exposure.

In reality, solvents, and chemicals in general, are often present as mixtures and not as single compounds. Some components of these mixtures may affect the toxicokinetics of other components, hence, biomarkers of exposure and effects (Hernández et al., 2014). Consequently, precautions should be taken when identifying biomarkers of mixtures or component(s) of mixtures. For a detailed discussion of biomarkers of mixtures, refer to Chapter 33. Although hundreds of solvents are in use, only a relatively small number of solvents and gases are discussed in this chapter because of space constraints and limited or unavailable biomarker data.

SOLVENTS

Solvents are used for a large number of applications. Historically, numerous chemicals or mixtures of chemicals have been used as dry cleaning solvents (e.g., benzene, chloroform, carbon tetrachloride, trichloroethylene, perchloroethylene, 1,1,1-trichloroethane, and liquid carbon dioxide) (SCRD, 2009). Acetone, ethyl acetate, and butyl acetate are utilized in nail polish removers. Ethanol is typically the solvent of choice in perfumes, but it is also employed as an excipient in medications. Many solvents, such as acetone, acetonitrile, benzene, and chloroform, are used in the pharmaceutical manufacturing process. In addition to the use of isopropyl alcohol (also known as rubbing alcohol) as a disinfectant, it is used as a solvent in cleaners along with 2-butoxyethanol, ethanol, and glycol ethers. Other common solvents include, but are not limited to, pentane, cyclopentane, hexane, cyclohexane, toluene, diethyl ether, dichloromethane, tetrahydrofuran, dimethyl sulfoxide, and methanol.

Many solvents, such as ethanol, diethyl ether, chloroform, gasoline, benzene, toluene, and acetone, are abused to achieve intoxication, often with dire health consequences. Benzene is known to be a human carcinogen based on sufficient evidence of carcinogenicity from human studies (NTP, 2016). Gasoline sniffing can cause nausea, vomiting, ataxia, dizziness, anesthesia, loss of consciousness, and even death (Poklis and Burkett, 1977). The primary target of toluene is the central nervous system (CNS). Although symptoms of CNS toxicity are reversible after acute inhalation, chronic exposure may result in irreversible damage to the CNS (Aydin et al., 2002). Acute and chronic exposures to toxic solvents are not unique to abusers; frequently they are the result of occupational exposure (Kamran and Bakshi, 1998; Filley et al., 2004). For instance, although toluene is a commonly inhaled product by solvent abusers, occupational exposure to this solvent also occurs in the dry cleaning, aviation, and chemical industries (Borne et al., 2005). Exposure to chloroform may occur due to both abuse and in occupational settings during the manufacture of this solvent. Workers at wastewater and other treatment plants can be exposed to high levels of chloroform (NTP, 2016).

If inhaled, ingested, or absorbed through the skin in large quantities, many solvents can cause CNS depression and produce symptoms of acute toxic exposure. Chronic exposures may lead to neurotoxicity, hepatotoxicity, nephrotoxicity, reproductive and developmental toxicity, cancer, or the development of other diseases. High levels of maternal solvent exposure have been reported to result in developmental disorders, fetal malformations, and even fetal death (Bowen, 2011). The physical and behavioral effects that may occur subsequent to elevated maternal solvent exposure are sometimes referred to as fetal solvent syndrome.

GASES

A number of gases, such as nitrous oxide (also known as laughing gas, used in medicine and dentistry and as an aerosol propellant), propane and butane (compressed to be used as fuels), and chlorofluorocarbons (in aerosols), are inhaled as recreational drugs. The major safety hazard of abused gases is risk of asphyxiation. Virtually every gas, excluding oxygen, can act as a simple asphyxiant by replacing oxygen from ambient air and interfering with oxygen delivery (Goldfranks, 2015). Unlike simple asphyxiants, chemical asphyxiants act by producing cellular hypoxia (interference with cellular respiration). Other gases exert toxicity by acting as irritants or as local or systemic toxins. Exposure to toxic gases (e.g., hydrogen sulfide, bromine, chlorine, and hydrogen fluoride) may also occur in occupational settings (Guidotti, 1994; Guillermo, 1994). Exposure to toxic gases may be the result of the intentional release of chemical warfare agents (e.g., chlorine and phosgene) or the consequence of accidental release (e.g., carbon monoxide [CO] [from

the incomplete burning of fuel] and chlorine [from the inappropriate mixing of cleaning agents]). The accidental release of methyl isocyanate (liquid below but a gas above 39°C) in Bhopal, India, resulted in the immediate death of at least 3800 people in 1984 (Broughton, 2005). It also caused significant morbidity and early death for many more; the combined number of injured or dead is estimated to be over 250,000.

BIOMARKERS OF TOXIC SOLVENT AND GAS EXPOSURE

The Use of the Parent Compound as a Biomarker of Exposure

The measurements of solvents from biological samples have been used to monitor solvent exposures (Imbriani and Ghittori, 2005). The most commonly used biological sample is urine. The measurement of urinary excretion of unmodified solvents has numerous advantages such as, but not limited to, having a noninvasive sample collection procedure (compared with blood and tissue sampling), being specific and sensitive (able to detect low levels of exposure), and analytical techniques for their detection are widely available and/or easily developable (Gobba et al., 1997). Moreover, the correlation between environmental timeweighted average concentration (an index of the external dose of solvents) and the levels of unchanged solvents in the urine of individuals exposed via inhalation is generally good. The correlation between the ambient air and urine levels of selected toxic solvents and gases (as indicated by their r-values) is listed in Table 34.1.

The expired air (i.e., breath) is a mixture of dead space air and alveolar air (the air in the alveoli). Dead space air is exhaled before alveolar air. The alveoli are at the end

of the respiratory tree and are the site of gas exchange with blood. The concentration of volatile compounds in the end-tidal air (the last portion of expired air) is in constant equilibrium with that in the blood (Caro and Gallego, 2009). Consequently, the end-tidal air can be used to detect and measure exposure to volatile compounds. The concentrations of volatile organic solvents (e.g., toluene, ethyl acrylate, o-, m-, and p-xylene, ethylbenzene, benzene, and naphthalene) in the alveolar air and in the ambient air of workplaces showed good correlation, i.e., r > 0.9, for all 26 compounds studied by Caro and Gallego (2009). In another study, the correlation between the levels of 10 different solvents (e.g., dimethylformamide, acetone, methyl ethyl ketone, toluene, and n-hexane) in the alveolar air and the concentration in the environmental air of exposed workers was studied (Brugnone et al., 1980). The correlation coefficient between alveolar air levels and environmental air concentrations of these solvents ranged from 0.76 (for methyl ethyl ketone) to 0.98 (for cyclohexane). When the breath of dry cleaning workers was monitored for tetrachloroethylene exposure, a solvent also known as "dry cleaning fluid" because of its wide use in dry cleaning, it was found that exposure to tetrachloroethylene can be reliably monitored from breath (Droz and Guillemin, 1986). A correlation coefficient of 0.956, indicating strong correlation, was obtained for environmental air levels of "dry cleaning fluid" and its levels in breath. Numerous other articles discuss the use of breath

for biomonitoring solvent and gas exposure (e.g., Apostoli et al., 1982; Brugnone et al., 1983, 1985; Fujino et al., 1992; Ghittori et al., 2004; Hamelin et al., 2004; Amorim and Cardeal, 2007). It is clear, based on these publications, that in addition to the use of urine for biomonitoring exposure to unmetabolized solvents and gases, breath can also be used to detect and measure exposure to these compounds. Like the collection of urine samples, the collection of breath samples is rapid and noninvasive. The correlation factors of ambient air and breath levels of selected toxic solvents are listed in Table 34.2.

In addition to urine and breath, blood may also be used for measuring biomarkers of toxic solvent exposure. Because it requires an invasive procedure to obtain and may expose those who collect it to blood-borne diseases, it is less preferred. Nonetheless, it can be as useful as urine or breath for biomonitoring. For example, in a study of toluene, the correlation coefficients for toluene levels in the air of occupational environment and concentrations of toluene in alveolar air, blood, and urine were comparable, i.e., 0.822, 0.850, and 0.846, respectively (Ghittori et al., 2004). Using blood for monitoring exposure in some cases may be superior and in other cases inferior compared with using breath or urine. In the case of acetone, monitoring exposure in blood was less useful than monitoring exposure using breath or urine. A search of the currently available literature yielded correlation coefficients of up to 0.94 for

monitoring acetone exposure in both breath and urine, while in blood the highest correlation coefficient found was 0.77 (Gobba et al., 1997; Lauwerys and Hoet, 2001).

The Use of Metabolites of Toxic Solvents or Gases as Biomarkers of Exposure

The metabolites of toxic solvents and gases can also be used to monitor exposures to these chemicals. Unfortunately, certain metabolites may form from more than one compound, rendering them nonspecific biomarkers of the parent compounds. For instance, n-hexane and 2-hexanone are both commonly used solvents that share the highly neurotoxic 2,5-hexanedione metabolite that is excreted in the urine and is used for monitoring exposure to these two solvents (Cardona et al., 1993; Lauwerys and Hoet, 2001; Prieto et al., 2003). Consequently, when the source of 2,5-hexanedione is unknown, determination of the parent compound from breath may be preferable (Periago et al., 1993; Hamelin et al., 2004). Other factors that may complicate the use of metabolites as biomarkers of exposure are changes in metabolism resulting from co-exposure to other solvents or gases or from metabolizing enzyme induction because of repeated exposure. In the case of n-hexane, after short-term, acute co-exposure with methyl ethyl ketone, a decrease in the concentration of 2,5-hexanedione was observed, whereas after repeated, chronic co-exposure with the methyl ethyl ketone, the urinary excretion of 2,5-hexanedione increased (Cardona et al., 1993; van Engelen et al., 1997). Repeated co-exposure of n-hexane with toluene tended to reduce and repeated co-exposure with acetone tended to increase the urinary excretion of 2,5-hexanedione (Cardona et al., 1993, 1996). While after co-exposure of n-hexane with other solvents the urinary concentration of 2,5-hexanedione does not necessarily reflect the exposure concentration of n-hexane, the 2,5-hexanedione level may be a useful marker of the assessment of these solvent mixtures' neurotoxic potential (Ichihara et al., 1998).

Isopropanol is another example where a metabolite could be used for biomonitoring. Not only was the correlation between alveolar and environmental concentrations of unmetabolized isopropanol found to be high (i.e., r = 0.92) but also the correlation between the concentrations of acetone (the chief metabolite of isopropanol) in the blood and the alveolar air and the alveolar isopropanol level (Brugnone et al., 1983). Additionally, the urinary acetone concentration was found to increase in proportion to the isopropanol exposure intensity (r = 0.84) (Kawai et al., 1990). Hence, in addition to isopropanol itself, acetone may be used as a biomarker of isopropanol exposure. Unfortunately, as acetone can also signal acetone exposure, caution must be exercised when it used as a biomarker of isopropanol exposure (Lauwerys and Hoet, 2001).

In addition to the parent compound, the metabolites of toluene, one of the most widely used organic solvents, are also used as biomarkers of toluene exposure (Cosnier et al., 2013, 2014). Numerous articles reported good correlation between alveolar air toluene concentrations and environmental air toluene concentrations (e.g., r = 0.84, 0.82, and 0.99 [Ghittori et al., 2004; Brugnone et al., 1980; Caro and Gallego, 2009, respectively]), showing that toluene is a good biomarker of toluene exposure. In addition, highly significant correlations between the urinary metabolites of toluene and the concentration of toluene in both blood and ambient air were found (Angerer and Krämer, 1996). The highest correlation coefficient was obtained for o-cresol, a metabolite of toluene, and toluene in ambient air. Therefore, in addition to employing toluene as a biomarker of toluene exposure, its o-cresol metabolite can also be used for this purpose. Unfortunately, when co-exposure to other solvents sharing similar metabolic pathways with toluene occurs (e.g., co-exposure with xylene), o-cresol levels, hence the correlation between o-cresol levels and exposure to toluene, can be significantly affected, rendering o-cresol to be unsuitable as a biomarker of toluene exposure (Tardif et al., 1998). Other metabolites of toluene (e.g., p-cresol and hippuric acid) are less suitable, or even outright unsuitable, as biomarkers of toluene exposure because of high and/or highly variable background levels from endogenous and dietary sources (Angerer and Krämer, 1996; Pierce et al., 1998; Tardif et al., 1998). For instance, at high toluene exposure levels, there was a good correlation (r = 0.87) between toluene exposure and urinary levels of hippuric acid; however, at low exposure concentrations (i.e., 10 ppm toluene), the excretion of hippuric acid was only slightly above the mean background level, rendering it unsuitable for biomonitoring low levels of toluene exposure (Tardif et al., 1998).

Benzene itself, just like toluene, can be its own biomarker of exposure. Like toluene, some of its metabolites are also suitable biomarkers of its exposure, while others are not. Because of their lack of specificity, phenol, hydroquinone, and catechol (metabolites of benzene) are not suitable biomarkers for the assessment of environmental or even occupational benzene exposure (Arnold et al., 2013). On the other hand, S-phenylmercapturic acid (SPMA), a minor metabolite of benzene, is generally regarded as a reliable and specific urinary biomarker of benzene exposure, as, so far, no background for SPMA has been found in nonexposed humans (Boogaard, 2009). However, the use of SPMA has its drawbacks. Like other mercapturates, it is unstable in alkaline urine, and as such, freezing or acidification of the sample is required. This sampling issue may potentially impact

the interpretation of this biomarker. Furthermore, it is only a biomarker of recent occupational and nonoccupational benzene exposure but not mid- or long-term exposure, as SPMA has a relatively short mean half-life of 9–13 h and it does not bioaccumulate. Another metabolite of benzene, *trans, trans*-muconic acid (ttMA), is also used as an occupational biomarker of benzene exposure. A correlation of r = 0.816 was found for benzene levels in the breath zone of workers and levels of urinary ttMA (Inoue et al., 1989). As ttMA may have high and variable background levels present in the urine from smoking or dietary sources, it is not a sufficiently specific biomarker of low levels of benzene exposure (Pezzagno et al., 1999). Moreover, urinary ttMA levels were found to be suppressed in the case of co-exposure of toluene and benzene, further complicating the use of ttMA as a biomarker of benzene exposure (Inoue et al., 1989).

N,N-dimethylformamide (DMF) is a commonly employed solvent. As DMF is absorbed both via inhalation and through the skin, ambient air monitoring is not sufficient to assess individual body burden (Hennebrüder and Angerer, 2005). The urinary DMF metabolites N-methylformamide (NMF) and N-acetyl-S-(N-methylcarbamoyl)cysteine (AMCC) have been the most widely used biomarkers of DMF exposure (Wang et al., 2004; Imbriani et al., 2002a,b; Kim et al., 2004; Käfferlein et al., 2004). Unfortunately, co-exposure to other chemicals may affect the suitability of using DMF urinary metabolites as biomarkers of exposure; co-exposure of DMF with toluene was found to reduce the excretion of NMF in urine (Yang et al., 2000). Other examples of metabolites of some toxic solvents utilized as possible biomarkers of exposure are listed in Table 34.3.

The Use of Adducts as Biomarkers of Toxic Solvent and Gas Exposure

Parent compounds and/or their metabolites may form adducts with macromolecules such as protein or DNA. These adducts may also be used as biomarkers of exposure and/or effects. The human body is able to

repair and eliminate DNA adducts. The rate and speed of repair of different DNA adducts are variable and often unknown. Hence, their use as biomarkers of exposure or effect may be limited (Needham et al., 2007; Pavanello and Lotti, 2014). On the other hand, hemoglobin (Hb) adducts, especially smaller ones, may not impact the life span of the erythrocyte. Furthermore, these adducts may accumulate in the body, and large quantities of Hb can be easily isolated from small volumes of blood for analysis. Consequently, Hb adducts can be utilized as biomarkers of exposure (Angerer et al., 2007). Protein (e.g., albumin) adducts are also used for biomonitoring. Albumin adducts are very useful for this purpose, as albumin is present in large quantities in the blood. Unlike DNA adducts, albumin adducts (like Hb adducts) are not prone to repair mechanisms and are chemically stable.

The above-mentioned adducts are also employed for biomonitoring exposure to toxic solvents and gases. An example of this is ethylene oxide, a reactive gas that induces nausea and vomiting, causes CNS depression, irritates the eyes, skin, and respiratory tract, and is mutagenic. Chronic exposure to it is associated with an increased risk of various cancers. It is commonly used for numerous industrial processes as an intermediate, as a sterilizing agent for medical supplies and foods, as a fumigant, and as an insecticide. In the case of this toxic gas, its 2-hydroxyethyl adduct with Hb can be used as a biomarker of ethylene oxide exposure (Csanády et al., 2000). Unfortunately, it is also a biomarker of ethylene exposure, as ethylene is biotransformed to ethylene oxide. The lack of specificity of biomarkers is also a problem in the case of CO. CO exposure is monitored with the help of carboxyhemoglobin (a complex of CO and Hb) levels in the blood. Unfortunately, this complex is not specific to CO; dichloromethane, an important but toxic solvent, and diiodomethane form the same complex with Hb as they are metabolized to CO (Boogaard, 2009).

Regarding DMF, in addition to its two urinary metabolites mentioned earlier (NMF and AMCC), its N-methylcarbamoyled-Hb-adduct can also be used for biomonitoring (Mráz et al., 2002). The DNA adduct of DMF (N^4-methylcarbamoylcytosine) was also reported as a possible biomarker to monitor occupational exposure to DMF using human urine (Hennebrüder and Angerer, 2005). According to Arnold et al. (2013), in addition to benzene and its metabolites, biological adducts of benzene may also be utilized as biomarkers of exposure. Multiple benzene metabolites (e.g., benzene oxide, benzoquinones, hydroquinone, and muconaldehyde) can bind to DNA. Unfortunately, while DNA adducts of benzene metabolites are potential biomarkers of benzene exposure, they cannot yet be employed as such in humans because of the lack of sensitive and specific

analytical methods for their detection. Hb and plasma protein adducts of benzene oxide are also potential markers of benzene exposure, though Hb adducts might be diagnostically less sensitive than adducts of plasma proteins. Regrettably, currently available methods are not sensitive enough to monitor environmental benzene exposure using these Hb and plasma protein adducts, and they are also unsuitable for routine applications. Furthermore, the Hb and albumin adducts of 1,2- and 1,4-benzoquinone were found to be nonspecific biomarkers of benzene exposure. Nonetheless, unlike blood and urinary benzene and urinary SPMA levels, all of which are only suitable for detecting recent exposures, serum albumin adducts could provide a means of detecting older exposures because of their relatively long half-life ($\sim$21 days). Hence, further development of even more sensitive methods for the detection and quantitation of benzene oxide adducts is desirable. In addition, these methodologies must be automated for routine analysis.

The Use of Novel Biomarkers of Toxic Solvent and Gas Exposure

Alterations in gene expression can serve both as biomarkers of exposure and as early effects of exposure. An example is benzene, exposure to which is widespread in the population. Chronic industrial benzene exposure has been associated with an increased incidence of aplastic anemia (deficiency of platelets and red and white blood cells) because of bone marrow damage (Snyder, 2012). In addition, it is a leukemogen; the first reports of the association between benzene and leukemia are about a century old. The mechanisms of leukemogenesis and development of aplastic anemia have been the subjects of much research. Identification of biomarkers of effects often clarifies the mode of action. Furthermore, these biomarkers of effects could also serve as biomarkers of benzene exposure. Forrest et al. (2005) examined the effects of benzene exposure on peripheral blood mononuclear cell (PBMC) gene expression. Numerous genes were found to be affected by benzene, four of which were the most significantly and consistently affected and could be used as potential biomarkers of exposure. Two of these genes (CXCL16 and ZNF331) were consistently upregulated in exposed individuals, whereas two other genes (JUN and PF4) were consistently downregulated in exposed individuals.

Aberrant DNA methylation is common and has a role in the pathogenesis and prognosis of hematological cancers (Yang et al., 2014). Benzene is known to induce global DNA hypomethylation, and this may be a key mechanism underlying benzene hematotoxicity. Hence, examining DNA methylation profiles and alterations

in mRNA expression in blood cells may serve as biomarkers for both benzene exposure and effect. DNA methylation profile from PBMCs of people chronically exposed to benzene was performed to identify new biomarkers of chronic benzene exposure. Aberrant hypomethylated STAT3 was found to be a potential biomarker of chronic benzene exposure. STAT3 was also shown to be upregulated. Activation of STAT3 is important in maintaining the characteristics of malignant tumors, and its inhibition may induce leukemic cell apoptosis, and as such, its potential in the treatment of certain types of leukemias is of interest. In summary, identification of novel biomarkers may serve as biomarkers of both exposure and effect and may help us understand the mechanisms of toxicity.

BIOMARKERS OF EFFECTS OF TOXIC SOLVENT AND GAS EXPOSURE

Biomarkers of effects reflect changes induced by toxic chemicals. Target organs of toxic solvents are the liver, kidney, and CNS, along with others. Multiple biomarkers of effects have been identified in these target organs. Unfortunately, as the selected examples below demonstrate, these biomarkers of effects are specific neither to a solvent nor to solvent or gas exposure. As biomarkers of effects are nonspecific in nature and humans are exposed to a variety of chemicals in their everyday lives that may or may not interact, relating these biomarkers of effects to a specific exposure is either challenging or outright impossible, and as such, they have limited use for health risk assessment (Boogaard, 2009).

The liver is an important target of many toxic solvents (e.g., DMF, carbon tetrachloride, dimethylacetamide, trichloroethylene, tetrachloroethylene, chloroform, and toluene). The liver transaminases alanine transaminase and aspartate transaminase are sensitive markers of liver injury and therefore can be used to monitor liver damage after solvent exposure (Silins and Högberg, 2011). Increased bilirubin, sorbitol dehydrogenase, gamma-glutamyl transpeptidase, and serum bile acid levels, along with other markers, may also signal liver injury after solvent exposure. Unfortunately, these biomarkers of effects are specific neither to a solvent nor to liver damage resulting from toxic solvent exposure and may be elevated because of various diseases and disorders (e.g., nonalcoholic fatty liver disease, alcoholic liver disease, medication-associated liver injury, viral hepatitis, and hemochromatosis).

The kidney is also a frequent target of toxic solvents. Numerous markers of kidney damage, such as increased urinary albumin and N-acetyl-beta-D-glucosaminidase levels, have been identified. In solvent (e.g., toluene or tetrachloroethene) exposed workers, albumin excretion exceeding the upper limit of the normal range may occur more frequently than in the corresponding control groups (Voss et al., 2005). Consequently, urinary albumin levels may be used to monitor effects of nephrotoxic solvents. However, this biomarker and other biomarkers of effects of nephrotoxic solvents are not specific to a solvent or to kidney injury due to solvent exposure. Nonetheless, periodic determination of urinary albumin levels is a useful tool for monitoring kidney damage in solvent-exposed workers. For a more detailed discussion on biomarkers of different target organs of chemicals, refer to the chapters in the *Systems Toxicity Biomarkers* section of this book.

INTERPRETATION AND USE OF BIOMONITORING DATA

The purpose of biomonitoring data is to assess exposure and, ultimately, health risk. Therefore, proper interpretation of the data is paramount. To interpret the data and derive quantitative reference or guidance values, knowledge of the quality of the analytical data and understanding of toxicokinetics of the toxic solvent or gas are necessary (Boogaard, 2009). Comprehension of the toxicokinetics of the substance of interest is essential, as some metabolites may form endogenously or from dietary ingredients or may originate from other chemicals that share the same metabolite with it. As the presence of a biomarker simply indicates exposure, one also needs to know the dose—response relationship to assess health risk; biomonitoring data must be correlated with toxicity data. Information on toxicity usually comes from animals, and sometimes humans, exposed to very high levels of toxic solvents or gases. These data are then extrapolated to lower exposures. Unfortunately, this method makes it hard to predict effects at low or very low levels of exposure. For a general discussion of how biomarkers fit into toxicological evaluation and risk assessment considerations and how risk assessment with the potential use of biomarkers is integrated into the development of chemical regulations, refer to Chapter 67.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Biomonitoring is a viable tool for assessing exposure, effects, and susceptibility. Nonetheless, it is not without limitations, and still much work is left to be done. Ongoing challenges include the development and validation of more specific and sensitive biomarkers of

exposures and effects, as well as of sensitive, specific, and standardized analytical methods to detect and measure biomarkers and of finding ways to use these biomarkers for the prediction of disease risk or disease progression and outcome. Moreover, most of the currently used biomarkers of toxic solvent and gas exposure are only suitable for detecting fairly recent exposures. Finding biomarkers for detecting exposures from months, years, or decades ago is an area with much left to accomplish. In addition, exposure to mixtures, rather than to a single substance, is commonplace. Simultaneous exposure to multiple solvents and/or gases complicates biomonitoring of exposure and effects of a specific substance. More information is needed on co-exposure to multiple chemicals and their effects on specific biomarker(s) and the toxicity of a solvent or gas. Finally, ethical issues (such as confidentiality) in human biomonitoring also need to be addressed.

Freshwater Cyanotoxins

Gurjot Kaur

Human and Environmental Toxicology, Department of Biology, University of Konstanz, Konstanz, Germany

INTRODUCTION

Cyanobacteria, commonly known as blue-green algae, are photosynthetic prokaryotic bacteria that contribute to the normal microbial inhabitation on the surface of marine and freshwaters. Cyanobacteria are important primary producers in many freshwater ecosystems and are present in varying densities in most surface freshwaters worldwide. They may proliferate and form high-density blooms under certain conditions, particularly in abundance of specific nutrients. Cyanobacteria are of toxicological interest because many genera have the ability to produce toxins that affect aquatic organisms and terrestrial species such as wildlife, livestock, pets, and even humans on ingestion of contaminated water or seafood (Buratti et al., 2017).

The main energy source for photosynthesis in cyanobacteria is the green pigment chlorophyll-a. The name "blue-green algae" is derived from their ability to produce accessory photosynthetic blue pigments, phycobilins or phycocyanins, important for photon capture during photosynthesis. Red to brown accessory photosynthetic pigments, called phycoerythrins, are also produced, and depending on the levels of phycobilins and phycoerythrins, the colors of cyanobacteria vary between different shades of blue and green and, less commonly, brown to red. Being oxygenic phototrophic bacteria, cyanobacteria contain both type-1 and type-2 reaction centers or photosystems with a unique "phycobilisome" antenna network that feeds these reaction centers. Unlike plants and green algae, this special phycobilisome consists of 3-7 MDa large multimeric assemblies that associate with the surface of the chloroplast thylakoid membrane. The phycobilisome supplies excitation energy to both reaction centers by forming a megacomplex. Each phycobilisome is built of many units of chromophore-binding phycobiliproteins, phycocyanin, phycoerythrin, and allophycocyanin, and non-chromophore-binding linker proteins.

The phycobiliproteins are responsible for the absorption of cyanobacteria at the 500−680 nm range and less commonly 710 nm due to specialized phycobilisomes (Liu et al., 2013).

The mere presence of a toxin-producing cyanobacterial species in surface water does not constitute a valid risk. Toxins are not always produced and may not be produced at toxicologically significant levels. Furthermore, toxin production is influenced by genetic and environmental factors. Although certain environmental features, including nutrient concentrations, water temperature and pH, play a role in triggering and maintaining toxin production, the critical parameters involved are not fully understood. Toxin production is also linked to cyanobacterial cell densities and growth rates, which are determined by the availability of nutrients, light intensity, water temperature, and interactions with other aquatic organisms. Important interactions include predation and competition for nutrients. Toxin production is generally more common during warmer summer weather but can occur at any time of the year. Occurrences of high densities of cyanobacteria, visible as discolorations of the water and/or the formation of algal scum, are often referred to as algal blooms. When algal blooms have the potential to cause harmful effects, they are referred to as harmful algal blooms (HABs). The incidence of HABs is recorded in many regions and is usually linked to human activities such as agriculture that results in excess nutrient inflow into surface water bodies. It can also be linked to the creation of lakes and ponds that provide suitable habitats for cyanobacteria. Following a toxic HAB formation, the risk of poisoning depends on the level of exposure. In the past, human exposures have occurred through drinking water, recreational water use, contaminated food or dietary supplements, and contaminated hemodialysis water. The toxins produced by freshwater cyanobacteria can be classified based on their toxic effects, their molecular structure, or their origins (Dai et al., 2016). Due to

this chapter's focus on biomarkers (Table 35.1), we will use a classification based on toxic effects.

HEPATOTOXINS

Microcystins

Introduction

Microcystins are cyclic heptapeptides and are arguably the most important cyanotoxins in terms of their worldwide impact on health and water quality. Microcystis spp., *Microcystis aeruginosa* in particular, are common and widespread producers of microcystins, but they can also be produced by several other genera of freshwater cyanobacteria, including *Anabaena, Planktothrix, Nostoc, Oscillatoria*, and *Anabaenopsis*. Microcystin concentrations are generally correlated with cyanobacterial cell density, with increasing correlation at high cell densities. People are often exposed when swimming, skiing, or boating in contaminated waters. Other routes of human exposure include drinking water, contaminated seafoods or nutritional supplements, and, in one tragic and lethal event, contaminated water in dialysis bags (Jochimsen et al., 1998). Terrestrial animals, including pets, livestock, and wildlife, are typically exposed when drinking from contaminated lakes and ponds. Aquatic species living in contaminated waters may also be affected. The ever-expanding number of new lakes and ponds created for water management, recreation, and drinking water for farm animals creates opportunities for microcystin production and exposure in susceptible populations. Potentially poisonous concentrations of microcystins are reached relatively frequently in lakes and ponds with high nutrient concentrations, and the frequency appears to be increasing in many regions due to the expansion of intensive agriculture, industrial development, and urbanization.

Chemistry

The cyclic heptapeptide structure of microcystins (Fig. 35.1) allows for considerable structural variability, and over 200 naturally occurring structural variants have been identified. Six amino acids, including four nonprotein and two protein, form a ring structure. One nonprotein amino acid, referred to as ADDA (3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca-4,6-dienoic acid), forms a side chain. The ADDA side chain is consistent between microcystin variants and can be used to quantify microcystins independent of the variant type. The two protein amino acids, at positions 2 and 4 in the ring structure, contribute significantly to the structural variability. Microcystin variants are named based on the protein amino acids at these two variable positions. One of the most common variants

TABLE 35.1 Biomarkers of Exposure to Freshwater Cyanotoxins

Toxin	Specific Biomarkers	Nonspecific Biomarkers
Microcystin	Toxin isolation in tissues	Sphingolipid in liver
	Protein phosphatase (PP) inhibition	Bcl proteins in liver
	PP2A in liver	Lipid peroxidation
		Heat shock proteins
		8-Oxo-7,8-dihydro-2′-deoxyguanosine in liver
		Alkaline phosphatase in plasma
		Alanine transaminase in plasma
		Methemoglobinemia
		Hydroperoxidase
		Superoxide dismutase
		Muscle DNA/RNA ratio (chronic)
		Hormone levels (testosterone, estradiol)
		miRNA-122-5p
Cylindro-spermopsin	Toxin isolation in tissues	Urine protein
		Urine specific gravity
		Glutathione
		Lipid peroxidation
		Protein oxidation
		DNA oxidation
		Superoxide dismutase
		NADPH oxidase
		Catalase
		Gamma-glutamyl-cysteine synthetase
Anatoxin-a	Toxin isolation in tissues	Acetylcholinesterase (AChE)
		Lactate dehydrogenase
Anatoxin-a(s)	Toxin isolation in tissues	AChE
Saxitoxins	Toxin isolation in tissues	Glutathione peroxidase
		Lipid peroxidase
		Glutathione peroxidase
		Superoxide dismutase
FIGURE 35.1   Microcystin chemical structure.

contains leucine and arginine at the protein amino acid positions and is referred to as microcystin-LR (Fig. 35.1). Microcystins are not excreted by cyanobacterial cells and are therefore strongly associated with cells as long as the cells remain intact. However, microcystins may be released into the surrounding water when cyanobacterial cells disintegrate. Microcystins are stable, with a typical environmental half-life of 10 weeks. The rate of breakdown is increased under direct sunlight, at high environmental temperatures (40°C), and at extremely low (<1) or high pH (>9) (Harada et al., 1996). Microcystin concentrations may be reduced by boiling or heating in a microwave oven. However, the concentration of free microcystins in muscle tissue from exposed fish may increase after boiling, due to the release of phosphatase-bound microcystins (Gutierrez-Praena et al., 2013).

Toxic Effects

Most of the available toxicological data on microcystins have been based on microcystin-LR. Other microcystin variants appear to be similar to microcystin-LR in their toxicological effects but different in potency. It should be noted that data used for determining toxicological relevance have been largely derived from experiments in rodents using intraperitoneal injection as the route of exposure using either extracts of complex crude mixtures derived from toxic algal blooms or purified components. Extrapolation between routes of exposure and between the toxicities of different complex mixtures makes the comparison of data from different studies challenging.

Many incidences of human exposure have come to light. One such incident is the exposure of 131 patients to microcystins in dialysis cartridges at a hemodialysis clinic in Caruaru, Brazil, in 1996. Eighty-nine percent of patients experienced early symptoms of toxicity such as visual disturbances, nausea, vomiting, and muscle weakness. Consequently, 100 patients developed acute liver

failure and succumbed to death. It was conferred that this syndrome, now known as "Caruaru Syndrome," was a result of the dominant cyanobacteria population in water supply reservoir (Jochimsen et al., 1998).

The clinical effects of microcystin poisoning depend on the route and level of exposure and the mixture of components involved in the exposure. In typical exposures of mammals to toxic blooms, low to mild exposure levels are associated with irritant effects, resulting in inflammatory responses in the skin, respiratory system, and gastrointestinal system. Higher exposure levels, particularly oral exposures, result in liver damage and, if the liver damage is severe, liver failure (Briand et al., 2003). The earliest detectable signs of liver damage include liver swelling and increased concentrations of liver enzymes (alanine aminotransferase and aspartate aminotransferase) in the blood. Early symptoms typically appear within minutes to hours of exposure and include inappetence, depression, and vomiting, followed by diarrhea, which may become extreme and hemorrhagic. Inappetence and depression become progressively worse. The final stages of lethal poisoning may be associated with recumbency and coma (van der Merwe et al., 2012). An important difference between exposures in aquatic and terrestrial organisms is the chronic low-dose exposure in aquatic environments over days or weeks. In fish, exposures to microcystins cause cellular damage (particularly liver damage), similar to the effects seen in mammals (Tencalla and Dietrich, 1997). Mature fish are generally more resistant to microcystin toxicosis compared with juvenile fish. Although fish have the ability to avoid areas of accumulation of toxic algae, sublethal liver damage in fish is associated with accumulation of microcystins in fish food items, such as mussels, snails, and zooplankton (Malbrouck and Kestemont, 2006). Fishes are also susceptible to decreased water oxygen levels associated with the decay of algal scum, and this effect may also play a role in fish deaths (Ibelings and Havens, 2008).

Lower doses of microcystin-LR induce apoptosis, while higher concentrations induce necrosis in lymphocytes in a time- and concentration-dependent manner. Reorganization of the actin cytoskeleton, cell shrinkage, and filopodia disappearance was also observed in phagocytes, indicating impairment of the immune system (Rymuszka and Adaszek, 2013). Epidermal exposure to microcystin resulted in irritation of the skin. In cases of skin damage, faster penetration to deeper cell layers and absorption to systemic circulation were expected. Persistent toxic effects such as on keratinocytes migration and cytoskeleton were only observed after longer exposures to the skin (Kozdeba et al., 2014).

Cellular Transport

It is well known that microcystin transport into the cell is a prerequisite for the associated apical cytotoxicity. Following ingestion and release from cyanobacterial cells, microcystins are absorbed into the portal circulation from the small intestine via bile acid transporters in the intestinal wall. Microcystins are then accumulated in hepatocytes via organic anion transporting polypeptides (OATPs, OATP1B1 and OATP1B3) in hepatocyte membranes. In addition to the liver, human OATPs are also located in the blood-brain barrier (BBB) and kidney cells (Hagenbuch and Meier, 2004). At this stage, we must recall the aforementioned incidence of human exposure. Dialysis patients at a hemodialysis clinic in Caruaru, Brazil, who were exposed intravenously to varying concentrations of microcystin congeners developed immediate signs of neurotoxicity, e.g., dizziness, tinnitus, vertigo, with a later onset of hepatotoxicity and nephropathy leading finally to multiorgan failure (Jochimsen et al., 1998). Similar pathological changes have also been observed in mice and fish. Microcystins are transported across the BBB in an OATP-dependent manner and are able to induce neurotoxicity via inhibition of protein phosphatases (PPs) (Feurstein et al., 2009). It is no surprise that the presence of OATPs in proximal renal epithelial cells coupled with the kidney's role in toxin elimination predisposes renal cells in humans to nephrotoxicity. However, the exact OATP uptake kinetics is not established in the brain or kidney.

Secretion of biochemically active microcystin into the bile of rainbow trout corroborates an active efflux of microcystins from hepatocytes (Sahin et al., 1996). One report has linked efflux transporter in Zebrafish (zf-MDR3) to microcystin excretion (Lu et al., 2015). However, no information is yet available in humans as to which efflux transporters, if any, are important for microcystin efflux. The secretion of microcystin into bile also indicates the potential for enterohepatic recirculation of toxins, further endorsed by reports of microcystin conjugates (Sahin et al., 1996). Microcystin-glutathione (-GSH) and -cysteine (CYS) conjugates are reported to be the main routes of excretion of free microcystin after exposure in mice (Kondo et al., 1992) and aquatic organisms (Pflugmacher et al., 1998). Interestingly, it has to be noted that microcystin-GSH and microcystin-CYS conjugates show similar in vitro inhibition of PP1 and PP2A to that of microcystin-LR but lower toxicity when intratracheally administered in mice possibly because of lowered uptake into the liver or more rapid elimination into the bile. This indicates the presence of a detoxification mechanism to actively excrete microcystin conjugates out of the cell necessitating identification of involved efflux transporter(s).

Mechanism of Action

It is well established that cytotoxicity, after cellular uptake of microcystin congeners, microcystin-LR, microcystin-RR, microcystin-LW, and microcystin-LF, progresses through covalent binding and inhibition of PPs, mainly PP1 and PP2A. This, in turn, leads to an increase in cell phosphorylated-protein load and subsequent deregulation of fundamental cellular processes and apoptosis. The interaction occurs between the hydrophobic groove, the C-terminal groove, and the catalytic site of PP1 and the glutamate, methyl aspartate, and ADDA residues of the toxin (Goldberg et al., 1995) and covalently between the Sγ atom of cysteine-269 of PP2A and the terminal carbon atom of the Mdha side chain of the toxin (Xing et al., 2006). Microcystin-LR may also bind to ATP synthase, leading to hepatocyte apoptosis (Mikhailov et al., 2003). The microcystin-interacting PPs are ubiquitous and are found in all tissues and across species from mammals to plants to bacteria. In nature, PPs reverse the active state of kinases through the hydrolytic removal of the phosphoryl group from kinases. On inhibition, alterations in the cytoskeleton occur, such as hyperphosphorylation of cytokeratins, reorganization, disassembly of actin and microtubules, and ultimately disruption of cellular architecture (Huang et al., 2015; Zeng et al., 2015). PP2A inhibition also leads to MAPK pathway activation (ERK1/2, JNK, p38) and apoptosis. Microcystin-LR also impairs PP2A ability to bind tubulin and thus destabilizes the microtubules. Hepatotoxicity proceeds through changes in cytoskeletal architecture and cell viability by MAPK activation, hyperphosphorylation of p38, ezrin, and ERK1/2 (Komatsu et al., 2007).

The main pathway of microcystin toxicity occurs through oxidative stress. This oxidative stress is dose-dependent and proceeds with marked alterations in cytotoxicity markers such as Lactate dehydrogenase (LDH) leakage, lipid peroxidation, reactive oxygen species (ROS) production, and antioxidant enzymes. In addition, microcystin-LR induces JNK activation, which affects enzymes involved in energy metabolism and mitochondrial dysfunction, ultimately leading to hepatocyte apoptosis and oxidative liver injury. Microcystin-LR also induces intracellular ROS production due to a calcium-mediated loss of mitochondrial membrane potential. The differential toxicity of microcystin-LR and microcystin-RR has been linked to the differential expression of proinflammatory molecules, IL-6 and IL-8, wherein IL-8 production varies with the microcystin congener in intestinal cells. It has recently been shown in the liver of fish that microcystin-LR—mediated oxidative stress occurs with an increase in hydroxyl radicals and a subsequent induction of apoptosis-related genes (p38, JNKa, Bcl-2),

wherein application of N-acetylcysteine provides protection against this stress. Research on mice has identified the role of Nrf2 and related antioxidant proteins, Keap1 and Cullin 3, as important protective proteins in oxidative stress mediated microcystin toxicity. In a normal cell, Keap1 regulates degradation and thus expression of Nrf2. During stress, Keap1 activity is disrupted, resulting in increased Nrf2 levels and activation of the oxidative defense system. In the absence of Nrf2 and Keap1 pathways, the microcystin-GSH conjugation pathway becomes an important pathway for cell protection (Valerio et al., 2016b).

Calcium has long been known to be important for microcystin-mediated toxicity. Its involvement may trigger mitochondrial dysfunction as discussed before (Ding et al., 2001). Ceramide has also been identified as another secondary messenger involved in microcystin toxicity (Li et al., 2012). Ceramide is known to be important for PP2A activity. It is involved in microcystin-induced toxicity through PP2A subunit regulation, subcellular localization and inhibition, and cytoskeletal destabilization. Desipramine, a ceramide synthase inhibitor, protects the cells against cytoskeletal destabilization, detachment, and apoptosis (Li et al., 2012). Nitric oxide production, another secondary messenger, has an emerging role in microcystin-associated toxicity (Ji et al., 2011).

As microcystin-LR crosses the BBB via brain-specific OATPs (Fischer et al., 2005), it induces hyperphosphorylation of *tau*, a neural microtubule-associated protein, in a biphasic and concentration-dependent manner, which in turn may lead to neuronal degeneration (Meng et al., 2015). ROS production is involved in this hyperphosphorylation and impairment of neurological functions. Microcystin also modulates the immune system. Microcystin-LR has been shown to induce Fas receptor, ligand, and NF-κB, important signals for apoptosis, and immune responses in cell culture models (Feng et al., 2011; Ji et al., 2011). Studies on the male reproductive system indicate a risk for toxicity (Chen et al., 2013a). Male mice have alterations in testes and epididymis after *M. aeruginosa* extract administration (Ding et al., 2006). Death of Leydig cells and subsequent decrease in testosterone production are also seen (Li et al., 2008). Similar cytotoxicity is observed in Sertoli cells (Chen et al., 2013b). Female mice display a reduction in ovary weight and loss of primordial follicle pool (Wu et al., 2014).

Microcystin-LR is now classified as a potential class 2B carcinogen to humans. Involvement of ERK1/2 pathway, increased expression of protooncogenes, c-fos, c-jun, and c-myc in mouse, and p53 after microcystin-LR-induced tumor is now shown. In addition, there are indications that microcystin-LR tumorigenesis is regulated by NF-κB, IFN-α, and TNF-α

(Valerio et al., 2016b). Involvement of the glycolytic-oxidative-nitrosative stress pathway in microcystin-LR-induced toxicity in mice has been published, wherein coenzyme Q10 was capable of ameliorating the associated toxicity along with implications in cancer treatment (Lone et al., 2017). Increased thyroid hormones resulting in thyroid dysfunction was demonstrated in mice injected with microcystin-LR intraperitoneally. Disruption in glucose, triglyceride, and cholesterol levels concurrent with hyperphagia, polydipsia, and weight loss was also seen (Zhao et al., 2015). These are the first indications of endocrine toxicity in mammals and may have human relevance.

Biomarkers

Research on biomarkers of microcystin exposure has expanded in recent years, particularly in efforts to identify preclinical biomarkers of exposure, the detection and characterization of sublethal chronic exposures, and potential ecotoxicological impacts in aquatic species. Much of our understanding of the biomarkers of microcystin exposure has been derived from *in vivo* and *in vitro* laboratory studies using microcystis extracts, as opposed to pure toxins. Analysis of several studies demonstrated that crude extracts have toxicity characteristics that are different from pure microcystins (Falconer, 2007). The variability in the toxicological characteristics of complex mixtures associated with crude extracts, as is the case in most exposures, complicates the expression of biomarkers. However, PP inhibition and the detection of microcystins in tissues and body fluids serve as consistent and specific biomarkers of microcystin exposure. In the liver, markers of microcystin damage include increased sphingolipid concentrations, decreased PP2A levels, and decreased expression of Bcl-2 proteins (Billam et al., 2008).

Analysis of biomarkers in aquatic species revealed a high degree of variation between studies (Puschner and Humbert, 2007). Detoxification biomarkers such as reduced GSH and glutathione S-transferase (GST) were particularly inconsistent, presenting opposite expression trends in different studies. Biomarkers associated with oxidative stress, including superoxide dismutase, catalase, GSH peroxidase, GSH reductase, and lipid peroxidation, were more consistent in their trends. However, with the exception of lipid peroxidation, they were not associated with a sufficiently long half-life or systematic response. In a study using Japanese rice fish (*Oryzias latipes*) as a model, gender differences were observed in the toxic threshold to microcystin-LR, using PP inhibition and heat shock protein (Hsp60) as biomarkers (Deng et al., 2010). The DNA oxidative damage marker 8-oxo-7,8-dihydro-20-deoxyguanosine was found to be an indicator of microcystin-LR exposure in

rat liver, both for *in vitro* and *in vivo* exposure, at levels that did not result in morphologically apparent cell damage (Maatouk et al., 2004). Chronic exposure to sublethal doses of microcystin-LR in mice indicated that nonspecific biomarkers of liver damage, such as increases in liver enzymes (alkaline phosphatase, aspartate transaminase, and alanine transaminase) in plasma, and indicators of oxidative stress, such as methemoglobin, hydrogen peroxides, and superoxide dismutase, are correlated with exposure (Sedan et al., 2013). Similar biomarker data showing involvement of oxidative stress were also shown in *Goodea gracilis*, fish found endemically in water bodies of Central Mexico, contaminated with microcystin-producing cyanobacteria (Olivares-Rubio et al., 2015). Sublethal exposures in Sacramento splittail (*Pogonichthys macrolepidotus*) were correlated with declining nutritional status, as indicated by a decreased RNA/DNA ratio in muscle (Acuna et al., 2012). A recent study on the water flea, *Daphnia magna*, showed that short-term microcystin exposure increased GST levels, whereas long-term exposure decreased levels. The same study also measured changes in antioxidant markers (catalase, Cu, Zn, and Mn superoxide dismutase) (Lyu et al., 2016). 17β-Estradiol, testosterone, 11-ketotestosterone, and follicle-stimulating hormone (FSH) levels were increased in the serum of females as compared with males in Zebrafish exposed to microcystin, although levels of testosterone, FSH, and luteinizing hormone were also changed in males (Liu et al., 2016). Proteomic profiling of *Saccharomyces cerevisiae* cells using 2D electrophoresis and Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry (MALDI-TOF/TOF) after microcystin-LR exposure identified ∼14 differentially expressed proteins that were involved in metabolism, genotoxicity, cytotoxicity, and stress response including PP1 and PP2A. Most genes were related to oxidative stress and apoptosis (Valerio et al., 2016a). Many recent studies have revealed the presence of huge amounts of microRNAs from damaged cells following a xenobiotic insult. An increase in miR-122-5p, liver-enriched microRNA, on microcystin-LR exposure in the blood plasma of whitefish *Coregonus lavaretus* was detected, wherein a rapid increase in miR-122-5p levels was observed after 8h, which continued till the end of the experiment. This has the potential to be a new generation diagnostic biomarker in fish that may help in noninvasive diagnosis of liver damage (Florczyk et al., 2016).

Cylindrospermopsin

Introduction

Cylindrospermopsin is an alkaloid cyanotoxin produced by several freshwater genera, including *Cylindrospermopsis, Aphanizomenon, Anabaena, Lyngbya, Umezakia*, and *Raphidiopsis* It is found worldwide in surface freshwaters and is a potential toxicant in drinking water supplies for a large human populace, as well as animals (Guzman-Guillen et al., 2013a). It was first reported after a hepatoenteritis outbreak due to a *Cylindrospermopsis raciborskii* bloom in a local drinking water supply in Australia in 1979 (Bourke et al., 1983).

Chemistry

Cylindrospermopsin is a polyketide alkaloid consisting of a tricyclic guanidine coupled with hydroxymethyluracil (Fig. 35.2). It is a highly water-soluble molecule because of its zwitterionic nature. There are two known structural variants: highly toxic 7-epicylindrospermopsin (Banker et al., 2001) and the relatively less toxic deoxycylindrospermopsin (Norris et al., 1999). Two more variants, 7-deoxy-desulfo-cylindrospermopsin and 7-deoxy-desulfo-12-acetyl-cylindrospermopsin, were later identified in the Thai strain of *C. raciborskii* (Wimmer et al., 2014). Cylindrospermopsin is resistant to high temperatures, sunlight, and pH extremes. Unlike microcystins, cylindrospermopsin is often secreted from cyanobacterial cells into the surrounding water (Rucker et al., 2007). It bioaccumulates, particularly in organisms, in lower level of the food chain, such as gastropods, bivalves, and crustaceans (Kinnear, 2010).

Toxic Effects

Impact on human health is asserted from many reported incidents. Mild skin irritation is usually reported. A major outbreak of poisoning in humans with 148 cases occurred in 1979 near a reservoir on Palm Island, Queensland, Australia. Unfortunately, a dense bloom of cylindrospermopsin-producing *C. raciborskii* was observed after a copper sulfate treatment of a reservoir. Eventually, algal cell lysis and discharge of harmful toxins occurred in the water. Prolific users living close to the reservoir were affected with a syndrome consisting of hepatic and kidney damage and severe gastroenteritis. Symptoms included hemorrhagic diarrhea, vomiting, fever, hepatomegaly, dehydration, electrolyte imbalances, acidosis, and hypovolemic shock. However, the potential role that the copper sulfate water treatment could have
FIGURE 35.2   Cylindrospermopsin chemical structure.

played in the disease process remains uncertain. Intraperitoneal injection of extracts from *C. raciborskii* collected from the reservoir produced similar liver and kidney damage in mice (Griffiths and Saker, 2003).

Cylindrospermopsin was also isolated from water used in dialysis in Brazil, which caused liver failure in dialysis patients. However, the role of cylindrospermopsin in the disease process was not clear because the water was also contaminated with toxic concentrations of microcystin. *C. raciborskii* can cause mild skin irritation in some individuals, unfortunately, with no clear known mechanism, possibly because of unrelated components in animals and humans. While cylindrospermopsin outbreaks have been recently reported, there are many cases of co-occurrence with other cyanotoxins, making understanding of the relative contribution to symptoms difficult. Similar outbreak, popularly known as "Barcoo fever," was reported in Australian outback (Hayman, 1992).

Pure cylindrospermopsin injected into tilapia caused progressive tissue damage over a period of 5 days in the liver, kidney, heart, and gills (Gutierrez-Praena et al., 2013). In mice administered pure cylindrospermopsin, a dose-dependent increase in liver and kidney weight and alteration in hepatic and renal toxicity markers were observed after 11 weeks. Concomitant histopathological changes at the higher doses were also seen (Humpage and Falconer, 2003). Liver and kidney damages are consistently observed in laboratory rodents following exposure to acutely toxic doses of cylindrospermopsin-containing extracts. Typical liver pathology includes lipid infiltration and necrosis, mostly in the periacinar region of the prostate (Shaw et al., 2000). Dose-dependent DNA damage in mammalian cells is also observed, which can be prevented by CYP450 inhibitors, indicating an involvement of metabolic enzymes in progressing toxicity (Humpage et al., 2005). No reliable cylindrospermopsin-mediated human carcinogenicity, genotoxicity, and reproductive/developmental toxicity data are yet available.

Mechanism of Action

Previously, it was speculated that the main target tissue of purified cylindrospermopsin toxicosis is the liver, but lately the kidney has been shown to be the more sensitive target of toxicity. Four sequential phases of hepatocyte damage were identified by a time series analysis, including protein synthesis inhibition, membrane proliferation, lipid infiltration, and necrosis. Kidney pathology includes necrosis of the proximal tubules and protein accumulation in the distal tubules (Nair et al., 1999). Studies using crude extracts report higher potency and a wider range of effects compared

with studies using purified cylindrospermopsin only, indicating that other components contribute to the toxic effects (Shaw et al., 2000).

Other tissues such as the thymus and heart are also affected (Terao et al., 1994). Cylindrospermopsin is a known potent inhibitor of protein synthesis in a concentration-dependent and irreversible manner, as confirmed both *in vitro* (Froscio et al., 2003) and *in vivo* (Terao et al., 1994), but the exact mechanism of action in different tissues is not fully elucidated. Interestingly, a decrease in cylindrospermopsin toxicity by the administration of cytochrome P450 inhibitors has been reported, suggesting an alternative toxicity mechanism possibly through metabolite formation. Cylindrospermopsin causes DNA fragmentation *in vitro* using metabolic activation by a cytochrome 450 enzyme as a necessary step (Bazin et al., 2010). New evidence suggests a cylindrospermopsin-induced upregulation of phase I enzymes (CYP1A1, CYP1B1, ALDH1A2, and CES2) and phase II enzymes (UGT1A6, UGT1A1, NAT1, and GSTM3) (Alja et al., 2013). Activation of p53 transcription factor and thus its target genes due to cylindrospermopsin stress has been detected in cell culture models (Bain et al., 2007). In addition, subtoxic concentrations of cylindrospermopsin are confirmed to modify protein levels involved in DNA repair and nucleosomal histones (Huguet et al., 2014). The role of oxidative stress is confirmed by increased ROS production, increased GSH content, and eventual apoptosis (Lopez-Alonso et al., 2013).

Biomarkers

Currently, satisfactory biomarkers for cylindrospermopsin toxicity are not known and only a tentative list of emerging biomarkers is provided. In a study of mice exposed to sublethal doses, no consistent changes were found in hematology or serum chemistry, indicators of liver and kidney damage. However, increased protein concentrations and changes in urine specific gravity were observed after 120 days of exposure (Humpage and Falconer, 2003).

On the contrary, change in several markers of oxidative stress indicates that oxidative stress plays a key role in the toxic effects seen in fish (Guzman-Guillen et al., 2013a). Chronic cylindrospermopsin exposure leads to a depletion of GSH, which precedes the appearance of clinical signs (Runnegar et al., 1994). Several other biomarkers of oxidative stress have been linked to the toxic effects of cylindrospermopsin, including the ratio of reduced GSH to oxidized GSH, lipid peroxidation, protein oxidation, DNA oxidation, and the activities of superoxide dismutase, NADPH oxidase,

catalase, and gamma-glutamylcysteine synthetase (Guzman-Guillen et al., 2013b). Measurement of acetylcholinesterase (AChE) activity and lipid peroxidation levels are closely associated to cylindrospermopsin-associated neurotoxicity in tilapia fish. Histopathological changes in the brain, liver, kidney, intestine, and gills were also seen. The biochemical parameters inclusive oxidative stress biomarkers could be reversed by 3 days of depuration while the histopathological changes by 7 days of depuration (Guzman-Guillen et al., 2014). Cylindrospermopsin toxin markers have been recently detected using analytical pyrolysis (Py-GC/MS) and thermally assisted hydrolysis and methylation (TCh-GC/MS) coupled to GC/MS in environmental samples with an estimated 5 ppm detection threshold (Rios et al., 2014).

NEUROTOXINS

Anatoxin-a

Introduction

Anatoxin-a is a potent neurotoxin and is considered to be a major cyanotoxin of public health concern. It occurs worldwide in freshwaters and is produced by several genera of cyanobacteria, including *Anabaena, Aphanizomenon, Microcystis, Planktothrix, Raphidiopsis, Arthrospira, Cylindrospermum, Phormidium, Nostoc*, and *Oscillatoria*. Exposures occur mainly through consumption of contaminated drinking water but can also occur from recreational use of lakes and through contaminated dietary supplements (Osswald et al., 2007).

Chemistry

Anatoxin-a is a bicyclic amine alkaloid (Fig. 35.3). It contains a homotropane scaffold derived from glutamic acid. Stoichiometrically, it is chiral with two symmetric centers. Only the (+)-anatoxin-a enantiomeric form is naturally produced with the pKa of 9.4, indicating that it is mostly protonated under typical environmental
FIGURE 35.3 Anatoxin-a chemical structure.

pH conditions. Anatoxin-a is stable under sterile conditions but is susceptible to microbial biodegradation (Wonnacott and Gallagher, 2006). The half-life in a reservoir is reported to be 5 days under typical environmental pH conditions (Smith and Sutton, 1993). A structural analog, called homoanatoxin-a or methylene-anatoxin-a, has been isolated from *Oscillatoria formosa* (Skulberg et al., 1992). Small quantities of anatoxin-a are produced synthetically for use in acetylcholine receptor research.

Toxic Effects

Anatoxin-a was originally called Very Fast Death Factor because of its rapid lethal effects, within 2−7 min, in laboratory mice. Acute deaths following exposure to anatoxin-a have been recorded in multiple species, including dogs, cattle, and wildlife, and species differences in susceptibility to anatoxin-a have been observed even within animal types. Mallard ducks, for example, are more sensitive compared with ring-necked pheasants (Carmichael and Biggs, 1978). Anatoxin-a is rapidly absorbed from the gastrointestinal tract, as indicated by the rapidity of clinical effects following oral exposure. Clinical effects of poisoning may appear within minutes to hours after exposure and include loss of muscle coordination, muscle tremors, fasciculations, convulsions, and respiratory distress. The principal lethal effect is respiratory failure following loss of control over respiratory muscles (Osswald et al., 2007).

Mechanism of Action

Anatoxin-a is an agonist of peripheral and central acetylcholine receptors, with a 100-fold selectivity for nicotinic receptors over muscarinic receptors. It binds to the acetylcholine receptor at the same position as acetylcholine (pre- and postsynaptically), causing sodium/potassium ion channels to open and induce a depolarizing blockade. Anatoxin-a is more potent than acetylcholine or nicotine. Binding of anatoxin-a to the nicotinic acetylcholine receptors at neuromuscular junctions results in uncontrolled action potential propagation, which manifests clinically as uncoordinated muscle contraction, muscle fatigue, and paralysis. Cholinesterase does not break down anatoxin-a, leading to persistent muscle stimulation (Wonnacott and Gallagher, 2006). Stimulation of nicotinic receptors in the cardiovascular system causes increased heart rate and blood pressure (Sirén and Feurstein, 1990). Stimulation of presynaptic nicotinic receptors in the central nervous system by anatoxin-a may also cause the release of neurotransmitters such as dopamine, which could

further increase the susceptibility of postsynaptic receptors to overstimulation (Wonnacott and Gallagher, 2006). Central nervous system receptors are, however, less sensitive to anatoxin-a when compared with peripheral receptors.

Biomarkers

The identification of biomarkers for anatoxin-a exposure, apart from the isolation of anatoxin-a from tissues, has remained elusive. Anatoxin-a appears to be a pure neurotoxin, with no characteristic blood chemistry changes and no gross or histological lesions associated with poisoning. The effect of sublethal doses of anatoxin-a, given intraperitoneally, on key enzyme activities (e.g., AChE, LDH, Isocitrate Dehydrogenase (IDH), Ethoxyresorufin-O-deethylase (EROD), GST) as biomarkers in muscle and liver of rainbow trout has been studied. An increase in AChE in muscle tissue and phase 1 and 2 enzymes, EROD and GST, in liver was observed. A similar increase in LDH activity, representative of anaerobic pathway induction, was noticed. All of these enzymes were upregulated to deal with the toxic response to anatoxin-a (Osswald et al., 2013). An analogous increase in AChE activity was observed in freshwater cladocerans following administration of *Anabaena spiroides* extract (Freitas et al., 2014).

Anatoxin-a(s)

Introduction

Anatoxin-a(s) is a natural organophosphate analog produced by cyanobacteria in the genus *Anabaena*. The (s) in the name of anatoxin-a(s) refers to salivation, which is a characteristic sign of poisoning observed in laboratory rodents following exposure. Anatoxin-a(s), although less frequently reported, has been detected in animal intoxications in Europe and the United States.

Chemistry

Structurally, anatoxin-a(s) is a cyclic N-hydroxyguanine with a phosphate ester moiety (Fig. 35.4) similar to typical synthetic organophosphate poisons. No structural variants have been described. Anatoxin-a(s) is rather unstable compared with other cyanotoxins (Matsunaga et al., 1989). Anatoxin-a(s) biosynthesis is not completely understood. Arginine is identified as a guanidine group precursor and erythro-4-hydroxyarginine as an intermediate product (Hemscheidt et al., 1995).
FIGURE 35.4 Anatoxin-a(s) chemical structure.

Toxic Effects

Anatoxin-a(s) poisoning is characterized by severe cholinergic stimulation of both nicotinic and muscarinic receptors. Clinical signs are indistinguishable from organophosphate poisoning. Muscarinic signs include salivation, lacrimation, urinary incontinence, and defecation, while nicotinic signs include muscle tremors, fasciculations, convulsions, and respiratory failure (Mahmood and Carmichael, 1986). The muscarinic effects of anatoxin-a(s) can be suppressed by atropine (Cook et al., 1990). Mice injected with *Anabaena flos-aquae* die because of respiratory arrest following convulsions within minutes of administration. Lowering of heart rate and blood pressure is also seen prior to decrease in respiratory function. As the AChE inhibition is irreversible, surviving mice show inhibition of erythrocyte cholinesterase for at least 8 days, indicating prolonged cholinesterase effects at sublethal doses (Cook et al., 1991).

Mechanism of Action

Similar to other organophosphate insecticides, anatoxin-a(s) is activated via oxidative metabolism and binds to AChE. It is a noncompetitive and irreversible inhibitor and, unlike the organophosphates, acts only on the peripheral nervous system in humans (Carmichael and Falconer, 1993). AChE is necessary for the inactivation of acetylcholine at the synaptic cleft hydrolysis. Inhibition of the enzyme therefore causes acetylcholine activity to build up at receptor sites, triggering excessive nicotinic and muscarinic receptor stimulation (Cook et al., 1990). In addition, as anatoxin-a(s) is a direct agonist at muscarinic receptors with indirect neuromuscular block, its effect can be temporarily blocked by atropine (Cook et al., 1991).

Biomarkers

As with other organophosphate poisonings, suppression of AChE in the brain and blood serves as a biomarker of exposure to anatoxin-a(s) (Freitas et al., 2016). No characteristic changes in blood chemistry

and no gross or histological lesions have been described in mammals. Mouse bioassays may be used for anatoxin-a(s), though it has been difficult to establish adequate analytical methods such as LC-MS to determine environmental toxin levels due to a lack of stable and commercially available toxin standards.

Saxitoxins

Introduction

Saxitoxins are also known as paralytic shellfish poisons. Most human saxitoxin toxicoses have been associated with the ingestion of marine shellfish, which accumulate the saxitoxins produced by marine dinoflagellates. However, saxitoxins are also found in freshwaters, produced by cyanobacteria in the genera *Anabaena, Aphanizomenon, Planktothrix, Cylindrospermopsis, Lyngbya*, and *Scytonema* (Wiese et al., 2010).

Chemistry

Saxitoxins are highly polar, nonvolatile, tricyclic perhydropurine alkaloids (Fig. 35.5) derived from imidazoline guanidinium. Various structural substitutions produce at least 57 analog. Activity is mediated through positively charged guanidinium groups. Saxitoxins are heat stable and water soluble. They are tasteless and odorless and are not destroyed by cooking (Wiese et al., 2010). Saxitoxins can bioaccumulate in freshwater fish such as *tilapia* (Galvao et al., 2009).

Toxic Effects

The clinical presentation of saxitoxin poisoning varies depending on the level of exposure. The lag time between exposure and the appearance of clinical signs is highly variable and can range from minutes to as long as 72 h. At relatively low exposure levels, moderate paresthesias, often described as a tingling sensation, are experienced around the mouth and extremities. Larger exposures lead to a spreading numbness of the mouth, throat, and extremities. High exposure levels may also cause acute muscle paralysis and respiratory failure (Garcia et al., 2004).

Mechanism of Action

Saxitoxins are selective but reversible blockers of voltage-gated sodium channel activity. They can cross the BBB and thus cause sodium channel blockage in the central nervous system, contributing to paralytic effects (Wiese et al., 2010). As these channels are important for propagation of action potentials in excitatory cells, binding of saxitoxin prevents ion flow (e.g., potassium) (Wang et al., 2003). Saxitoxin also blocks L-type calcium channels especially in the heart, resulting in early symptoms of a tingling sensation followed by paralysis and death by suffocation or cardiac arrest (Su et al., 2004).

Biomarkers

Exposure to saxitoxins is associated with ROS generation that can result in the activation of biomarkers of oxidative damage in fish, such as increased activities of GSH peroxidase, altered concentrations of lipid peroxidase, reduced GSH, and decreased activity of superoxide dismutase (Silva de Assis et al., 2013). Neuro-2A, a neuronal cell line-based bioassays, have attempted to provide reliable measurement of saxitoxin cytotoxicity using cell viability as a marker, although reliable indicators could not be observed with algal bioassays based on *Chlamydomonas reinhardtii*, which were tested in parallel (Perreault et al., 2011). However, as cytotoxicity is based on a myriad of factors, attempts have been made to determine functional endpoints. Microarray analysis did not produce gene expression as an important biomarker (Nicolas et al., 2015). A subsequent study to determine novel biomarkers in lower eukaryotic organisms identified multiple genes involved in copper and iron homeostasis and sulfur metabolism using quantitative real-time polymerase chain reaction. Generated expression profiles showed that genes tend to respond in a consistent manner. Important genes that undergo regulation after saxitoxin exposure include metallothioneins CUP1 and CRS5, ferric/cupric reductase FRE1, and the copper uptake transporter CTR1 (Cusick et al., 2009).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The hepatic and neurotoxic effects of common cyanotoxins are well understood down to the biochemical level with the exception of cylindrospermopsin. When
FIGURE 35.5   Saxitoxin chemical structure.

new biomarkers for toxicity have emerged, the selection and interpretation of biomarkers presents a complex problem. This is partly because of the fact that some cyanotoxins, particularly anatoxin-a, have a mechanism of action that does not result in easily determinable biomarkers. In addition, natural exposures to cyanotoxins as algal extracts under laboratory conditions involve complex mixtures of biologically active compounds including, but not limited to, the cyanotoxins of primary interest. The toxicity of complex mixtures is variable and difficult to predict. Without well-documented models of complex mixture effects, the theoretical basis for predicting toxic effects and biomarker behavior is equally unclear. Increasing our understanding of the mixture effects created by co-exposure to multiple toxicants in association with cyanotoxins is therefore an important requirement. Finally, as most of the literature available is either from *in vitro* model systems or animal models, careful risk assessment and extrapolation to human disease form is mandatory.

Mycotoxins

Robert W. Coppock[1], Margitta M. Dziwenka[2]

[1]Toxicologist and Associates, Ltd, Vegreville, AB, Canada; [2]Faculty of Medicine & Dentistry, Division of
Health Sciences Laboratory Animal Services, Edmonton, AB, Canada

INTRODUCTION

The term mycotoxin is generally restricted to chemicals synthesized by filamentous fungi. These chemicals, in concentrations that occur in nature, are toxic to vertebrates and other animals. Mycotoxins have variability in resisting degradation during the various heat- and fermentation-linked manufacturing processes. Milling of cereal grains can concentrate mycotoxins in the various fractions produced during milling operations. Mycotoxins can be present in raw commodities, processed raw ingredients, finished foods and feeds, and milling by-products. Animal source human foods can also contain mycotoxins. Any feedstuffs or foodstuffs that have supported the growth of toxigenic fungi can be contaminated with mycotoxins and they can be heterogeneously distributed in foodstuffs and feedstuffs. The FAO (2008) has estimated that 25% of the world food supply is contaminated with mycotoxins, and contamination may be substantially increased by regional adverse weather conditions and agricultural practices. Climate change is predicted to likely increase contamination of human and animal foods with mycotoxins (Medina et al., 2017). It is estimated that 5 billion people a year are exposed to mycotoxins (Pizzolato Montanha et al., 2018). When one mycotoxin is present, the risk of other mycotoxins being present is also increased (Lee and Ryu, 2017). A private laboratory reported that 72% of 17,316 samples were contaminated with one mycotoxin and 38% of the contaminated samples contained more than one mycotoxin (Streit et al., 2013). Foods can be contaminated by a succession of fungi that can produce multiple mycotoxins (Coppock and Jacobsen, 2009). In fact, the majority of mycotoxicoses linked to foodstuffs, that have been investigated in detail, predominantly show that the individual or animal was exposed to a mixture of mycotoxins. The most important recognized toxigenic fungi are in the genera *Aspergillus*, *Penicillium*, and *Fusarium* (Coppock and Jacobsen, 2009). The population structure of microorganisms in foodstuffs and feedstuffs is dependent on abiotic conditions of available water, temperature, and gas composition. Growth of pests and microorganisms can dynamically change these biotic conditions (Coppock and Jacobsen, 2009). For commodities, pest management before and after harvest, kernel damage during threshing and handling operations, and the presence of foreign material and debris in storage all contribute to increased microbial growth. Humans and animals are exposed to mycotoxins by the oral, inhalation, and dermal routes. Of these routes of exposure, oral and inhalation are the most important. Mycotoxins have diverse chemical structures and mechanisms of intoxication. All organ systems in the body can be targets for mycotoxins.

Biomarkers can be strategic tools to show exposure and adverse effects of exposure to mycotoxins. Biomarkers enable qualitative and quantitative assessment of exposure, assessment of internal dose, assessment of toxicological effects, and assessment of susceptibility. Proof that a diet containing mycotoxins has been consumed is proof of oral exposure, and quantitation of the mycotoxin(s) in foodstuff(s) provides input data to estimate the dose of mycotoxin(s) entering the body. Showing that ambient air is contaminated with mycotoxins and the proof that the contaminated air has been inhaled demonstrate exposure to mycotoxins. Documenting exposure to a mycotoxin can also be accomplished by assaying bodily tissues and fluids for the parent mycotoxin and its metabolites. The levels of mycotoxins and their metabolites inside the body are referred to as the internal dose. Biomarkers of the toxic effect can be specific adducts or some other chemical product showing upregulation or downregulation of critical biochemical chemical products or alteration of an enzyme system. The biological response to the

mycotoxin can be determined by histopathological procedures, clinicopathologic parameters, biochemical and clinical observed impairment of bodily function, changes in metabolic and system regulatory profiles, and medical observations that define a syndrome for a particular mycotoxicosis. Biomarkers of susceptibility can also exist and generally these are differences in enzyme activities in biotransformation pathways that exist between individuals, races, and species. If the excretion of the parent mycotoxin, its metabolites in body fluids including bile, etc., or levels in serum have been shown to be temporally correlated with external dose, these parameters can be used to estimate dietary levels. Internal dose can be correlated with adverse biological effects, adverse changes in metabolic profiles, endocrine functions and cell regulatory profiles, histopathology, etc., and can be used to estimate the damage that is occurring from exposure to mycotoxins. Levels of the parent mycotoxin or its metabolites in tissues document exposure.

AFLATOXINS

Background

It is estimated that at least 4.5 billion people worldwide are at risk of exposure to foodstuffs containing aflatoxins (AFs). Exposure to AFs is by the oral, inhalation, and dermal routes. The most commonly recognized aflatoxigenic fungi are *Aspergillus flavus*, *Aspergillus parasiticus*, and *Aspergillus nomius*, but other genera and species have been identified. These fungal species are also capable of forming other mycotoxins. For example, *A. flavus* also produces the mycotoxins cyclopiazonic acid, aspergillic acid, asperfuran, paspalinine, paspaline, and sterigmatocystin (STC). The general growth conditions for aflatoxigenic species require moisture contents in equilibrium at 80%−85% or more and temperatures of 13−42°C with optimum growth at 25−37°C (Coppock et al., 2018). The most common commodities contaminated with AFs are cereal grains, peanuts, nuts, oil seeds, spices, and condiments. Workers in feed mills, food processing facilities, poultry houses, grain storage and transportation operations, and textile works can be exposed to airborne AFs. Consumption of feedstuffs containing AFs can result in AF residues in edible animal products, including milk (Coppock et al., 2018). Dietary intake of AFs results in breast milk being contaminated with AFs, and for AFs and ochratoxin A (OTA), the milk/plasma ratio changes with the stage of lactation (Warth et al., 2016). The milk/plasma ratio of mycotoxins may increase because of the transfer of serum albumen in the mammary gland during early lactation. Breast milk can be considered the safer alternative for infants and young children because it contains a substantially less percentage of AFs than exist in available foodstuff consumed by the family. Essentially all fermented foods/feedstuffs and beverages can be contaminated with AFs if conditions favor the growth of aflatoxigenic fungi during fermentation and storage. AFs are classified as a human and animal carcinogen (Anon, 2012). It has been estimated that AFs are linked to 4.6%−28.2% of all global hepatocellular carcinomas, and at least 750,000 deaths from hepatocellular carcinomas occur each year (Livingstone et al., 2017). The AFs classified as carcinogens are AFB_1, AFG_1, and AFM_1 (Anon, 2012). Of these AFB_1 and AFM_1 are of the greatest concern for human exposure.

Chemistry and Legal Regulation of Aflatoxins

AFs have a difuranocoumarin chemical structure, and the primary AFs in order of decreasing toxicity are B_1, G_1, B_2, and G_2 (Coppock et al., 2018). AFs are heat stable and are not destroyed by cooking and processing of foodstuffs and feedstuffs. There are two chemical groups of AFs, the difurocoumarocyclopentenone series (denoted AFB_1, AFB_2, AFB_{2A}, AFM_1, AFM_2, AFM_{2A}, and aflatoxicol) and the difurocoumarolactone series (denoted AFG_1 and AFG_2). The "B" Group fluoresce blue in long-wavelength ultraviolet light and the "G" Group fluoresce green. The primary AFs of concern in feedstuffs are AFB_1, AFB_2, AFG_1, and AFG_2. Analytical results for AFs generally are the sum of the concentrations of AFB_1, AFB_2, AFG_1, and AFG_2. Generally, the levels of these four AFs are regulated under safe foods and feeds laws. AFB_1 is the most potent AF and this chemical form is generally the most abundant in feedstuffs and foodstuffs. Hydroxylated AF metabolites are excreted in milk and the important metabolites are AFM_1 and AFM_2 (Warth et al., 2016; Becker-Algeri et al., 2016). AFM_1 is the toxic metabolite of AFB_1, and AFM_2 is the hydroxylated form of AFB_2. Although AFM_1 and AFM_2 are commonly associated with milk and other edible animal products, aflatoxigenic fungi, when favorable growing conditions exist, can also produce these compounds in the processed and finished foods and feeds.

Toxicokinetics of Aflatoxins

The gastrointestinal tract in the rat rapidly absorbs AFs and there are data to support that other monogastric mammals have similar absorption kinetics. AFs are primarily found in portal blood with low levels in lymph drainage from the gastrointestinal tract (Coppock et al., 2018). Rats have been shown to absorb AFB_1 most efficiently from the duodenum and jejunum. The rate of AFB_1 absorption from the duodenum of rats in diestrus was greater than the rate of absorption of AFB_1 from the duodenum of rats in midlactation. High

starch diet increases the absorption of AFB_1 in cattle (Pantaya et al., 2016). Young animals absorb AFs more efficiently than do older animals. Fasted human volunteers were each given low doses of ^{14}C-labeled AFB_1 (30 ng) in gelatin capsules (Jubert et al., 2009). The toxicokinetics fit a two-compartment model with peak plasma concentration occurring at approximately 1 h after administration. The first phase (α) half-life is 2.86 h and the β phase half-life is 64.5 h. The subjects excreted 29%−33% of the ^{14}C-AFB_1 dose within 72 h. AFs cross the placental barrier (Partanen et al., 2010). AFB_1 is absorbed through the rumen mucosa and is metabolized to AFM_1 in the rumen (Cook et al., 1986). Cattle were given a single oral dose of AFs from rice culture (42% AFB_1 and 27% AFB_2) in gelatin capsules. Thirty minutes later, AFB_1 and AFM_1 were observed in venous blood (jugular vein) and reached maximal levels at 4−8 h. AFs are distributed in the body and eliminated by first-order kinetics. The primary excretion route is bile, followed by urine, and parent AFs can be identified in urine. Milk is also an excretion route for AFs, and dietary AFB_1 to milk AFM_1 ranges from 0.09% to 0.43% (Warth et al., 2016; Becker-Algeri et al., 2016). The liver and kidney have the highest tissue concentrations of AFs. In a model using surgically obtained abdominal human skin, AFB_1 had a low level of absorption with a permeability coefficient of $Kp = 2.11 \times 10^{-4}$ cm/h (Boonen et al., 2012).

Aflatoxin Metabolism and Chemical Biomarkers of Aflatoxin Exposure

Differences in the biotransformation of AFs explain the majority of sensitivity observed between animal species and races and breeds within species (Dohnal et al., 2014). Diet also has an endogenous effect on the enzymes that biotransform AFs (Gross-Steinmeyer and Eaton, 2012). For AFB_1, the major biotransformation pathways are epoxidation, hydroxylation, O-dealkylation, and ketoreduction. The epoxidation toxication reaction for AFB_1 is the formation of the AFB_1-8,9-epoxide by the CYP1A2, CYP3A4, CYP3A5, and other CYP enzymes. AFs are not inducers of CYP enzymes, but dietary constituents, drugs, and other substances that upregulate or downregulate CYP1A2, CYP3A4, CYP3A5, and other CYP enzymes also increase or decrease the toxicity of AFB_1, respectively. The important detoxification route for AFB_1-8,9-epoxide is conjugation with glutathione and excretion as the AFB-mercapturic acid. Hydroxylation products of AFB_1 are AFM_1 and AFQ_1. The major metabolite from O-dealkylation is AFP_1 and ketoreduction is aflatoxicol. Of these biotransformation products, the AFB_1-8,9-epoxide is the most toxic followed by AFM_1. The AFB_1-8,9-epoxide binds to DNA to form the AFB-N7-guanine adduct (8,9-dihydro-8-(N7-guanyl)-9-

hydroxyaflatoxin B_1). The AFB_1-N7-G adduct is unstable and rapidly depurinated and the AFB_1-N7-G is excreted in urine. The AFB_1-exo-8,9-epoxide is unstable and is hydrolyzed to AFB_1-8,9-dihydrodiol, which reacts with albumen to give the lysine adducts at Lys455 and Lys548 in bovine albumen and likely the same in human albumen (Sabbioni and Turesky, 2017). The AFB_1 DNA and albumen adducts plateaued in rats following 7 and 14 days of treatment, respectively. The half-life of the serum AFB_1-lysine adduct in rats is approximately 2.31 days and has first-order elimination kinetics (Qian et al., 2013). AFB_1 also forms stable noncovalent interactions with human, bovine, and rat serum albumen (Poor et al., 2017). Upregulation of hepatic miRNAs has been demonstrated in rats exposed to AFB_1 and maybe of initiation indicators of hepatocellular carcinoma type neoplasia (Livingstone et al., 2017). Upregulations observed by Livingstone et al. (2017) are miR-122-5p (5× increase), 34a-5p (13× increase), and 181c-3p (170× increase) and have biomarker potential. AFB_1 exposure causes a mutation in codon 249 (R249S) of TP53, and the R249S mutation of TP53 is a surrogate marker of AFB_1 exposure in humans with hepatocellular carcinoma (Nault, 2014). For dairy herds, the ratio of AFM_1 in milk to AFB_1 in diet can be used to predict reductions in AFM_1 when the diet is adjusted to reduce dietary levels (Coppock et al., 2018) Chemical biomarkers of AFs in humans are summarized in Table 36.1.

Histopathological Biomarkers of Exposure to Aflatoxins

AFs cause characteristic histopathology of the liver, and these lesions collectively are a biomarker of aflatoxicosis (Coppock et al., 2018). The lesions induced by AFs

vary with level and duration and level of exposure. The histopathology observed includes bile duct proliferation (hyperplasia), hepatocyte necrosis, and early fibrosis of the liver. The cytology of hepatocytes can be altered by abnormal variation in cell size by the formation of megalocytic and multinucleated cells. Species differences occur in the specific histopathology of AFs. Hyperplasia of the bile duct cells occurs rapidly in ducklings and may be present in horses, dogs, and chickens, and mild bile duct cell hyperplasia may be seen in cattle and pigs. The pattern of hepatocellular necrosis may vary with the species. In the rat, monkey, and duckling, the necrosis is reported to be periportal, whereas in cattle, pigs, horses, goats, and sheep, the pattern is reported to be centrilobular. In dogs, the lesion pattern may be either or both periportal or/and centrilobular, while in the rabbit the pattern is reported to be midzonal. In dogs, regeneration of hepatocytes may occur, and nodular hyperplasia may be present in turkeys, trout, and ducklings. Multinucleated hepatocytes have been observed in dogs, cattle, and other species. Reactive fibroblasts have been observed in dogs. Humans infected with hepatitis B virus appear to be at greater risk for hepatic neoplasia when they are exposed to AFs (Erkekoglu et al., 2017). Chronic liver injury and regenerative hyperplasia are considered critical for the development of liver neoplasia. Dividing liver cells is more likely to form DNA adducts.

STERIGMATOCYSTIN

STC is considered an emerging mycotoxin. The most common source of STC is *Aspergillus versicolor* (EFSA Panel, 2013). It is also produced by *A. flavus*, *A. parasiticus*, and *Aspergillus nidulans*, and in total, 55 toxigenic species are known to produce STC. STC is a precursor in the AFB_1 synthetic pathway, is structurally similar to AFB_1, and can also be produced as the end product by toxigenic fungi. The chemical name for STC is (3aR,12cS)-8-hydroxy-6-methoxy-3a,12c-dihydro-7H-furo[3′,2′:4,5]furo[2,3-c]xanthen-7-one. STC can exist as 1% of the biomass in *A. versicolor*. Microsomes form exo-STC-1,2-oxide that reacts with DNA to form the 1,2-dihydro-2-(N7-guanyl)-1-hydroxy STC adduct. STC is a carcinogen in rats and has been associated with stomach and liver cancer in humans. The glucuronide conjugate of STC is excreted in the urine of cattle consuming STC-contaminated rice straw supporting the growth of *Aspergillus niger*, and conjugated STC has been identified in the urine of cattle and horses consuming rice straw bedding (Fushimi et al., 2014; Takagi et al., 2018) Pathology of STC is hepatic necrosis, nuclear pleomorphism, multinucleated cells, and moderate biliary hyperplasia.

OCHRATOXINS

Production and Occurrence

OTA, B, and C are primarily produced by species of *Aspergillus* and *Penicillium* (Coppock and Jacobsen, 2009). The ochratoxins identified, in decreasing order of toxicity, are OTA, ochratoxin B, and ochratoxin C. Of these OTA is considered to be of clinical importance and is the most studied. For OTA production, generally, the *Penicillium* spp. are the most important toxigenic fungi in temperate climates and *Aspergillus* spp. are important in tropical climates (Wang et al., 2016). Chemically, ochratoxins consist of a polyketide-derived dihydroisocoumarin moiety linked at the 7-carboxy group to L-β-phenylalanine (Tao et al., 2018). The IUPAC nomenclature for OTA is (2S)-2-[[(3R)-5-chloro-8-hydroxy-3-methyl-1-oxo-3,4-dihydroisochromene-7-carbonyl]amino]-3-phenylpropanoic acid (NCBI, 2018). OTA can be produced in a variety of raw agricultural commodities, foodstuffs, fruits and nuts, raw materials used for beverages and spices, and finished beverages (FAO, 2008; Coppock and Jacobsen, 2009; Wang et al., 2016). OTA can also be present in meats as a residue from the food-producing animals being fed ochratoxin-contaminated feedstuffs or from fungal growth in processed and smoked meats and fish (Ringot et al., 2006; Pizzolato Montanha et al., 2018).

Toxicokinetics and Biotransformation of Ochratoxin A

OTA, in most species, is rapidly absorbed from the gastrointestinal tract and binds to serum proteins (Ringot et al., 2006). The pK_a for OTA is important for gastrointestinal absorption. The pK_a is 4.2–4.4 for the carboxyl group of the phenylalanine and 7.0–7.3 for the phenolic hydroxyl group of the isocoumarin moiety (Ringot et al., 2006). Passive diffusion, when in the nonionic and monoionic forms, is considered the predominant mechanism for absorption. OTA is fully protonated (nonionic) in acidic pH conditions. Likely due to decreasing ruminal pH, high starch diet increases the absorption of OTA in cattle (Pantaya et al., 2016). Diffusion of OTA, influenced by pH, is considered to be the primary mechanism for absorption in the stomach. Both diffusion and multidrug resistance-associated protein are likely important for absorption of OTA from the small intestine (Ringot et al., 2006; Vettorazzi et al., 2014). The efficiency of OTA absorption varies among species, and fish appear to have a low bioavailability of OTA (Bernhoft et al., 2017). OTA in ethanol had a high bioavailability in a human volunteer after oral administration on an empty stomach (Studer-Rohr et al., 2000).

Greater than 90% of the absorbed OTA in humans is bound to serum proteins, especially albumen and smaller proteins, and protein binding is almost identical to that of warfarin (Koszegi and Poor, 2016). The potential for protein binding is up to 99% and the nonsaturable range is 1−100 nmol. Protein binding of OTA varies among animals studied with fish, Atlantic salmon (*Salmo salar*), and carp (*Cyprinus carpio*), having the lowest level at 22% OTA bound to serum proteins (Bernhoft et al., 2017). The binding of OTA to plasma proteins in pigs, cattle, and humans is generally considered to be high. Of the species studied, humans have the longest serum half-life for OTA, estimated at 23.5−35.5 days, and carp the shortest at 0.68 h; the half-life of OTA in the serum or plasma of pigs and calves is estimated at 72 and 77.3 h, respectively (Sreemannarayana et al., 1988; Studer-Rohr et al., 2000; Ringot et al., 2006).

Human plasmas or sera levels of OTA have been reviewed and the levels vary for different geographic areas (Soto et al., 2016). There is some suggestion that OTA may be higher in the plasma of males than in the plasma of females. In a model using surgically obtained abdominal human skin, OTA was rapidly absorbed as shown by a permeability coefficient of $Kp = 8.20 \times 102^4$ cm/h (Boonen et al., 2012). In the majority of species, OTA has slow elimination. Urinary and fecal excretions are the primary methods by which OTA is cleared from the blood. OTA is excreted in bile and is reabsorbed from the gut with enterohepatic circulation occurring (Ringot et al., 2006). Excretion of OTA in bile is a major excretory route in laying hens for orally administered OTA (Armorini et al., 2015). In some species, hydrolysis of the ochratoxin conjugates by intestinal microorganisms is important in the hepatoenteric recycling. In goats and calves, fecal excretion can account for more than 50% of the dose administered, whereas in sheep less than 10% of the dose was excreted as ochratoxin-α (OTα) (Nip and Chu, 1979; Sreemannarayana et al., 1988). Renal excretion and secretion of ochratoxin occurs (Ringot et al., 2006; George et al., 2017). In the nephron, the organic anion transporters transport OTA from the glomerular filtrate into the tubular cells, and the multidrug resistance-associated protein 2 and other transporters may secrete OTA into the nephron (George et al., 2017). The toxicokinetics of OTA has been studied in sheep (Blank et al., 2003). Sheep were fed diets containing 0, 9.5, 19.0, and 28.5 OTA/kg body weight for 29 days, and the levels of OTA and metabolites were measured in rumen contents, serum, urine, and feces. Serum levels of OTA increased linearly with increased dose of OTA, and OTA and OTα in serum increased with time. OTA

and OTα were identified in urine. Rumen flora and fauna metabolize OTA to OTα and diet has shown to alter the metabolism of OTA by rumen microorganisms (Xiao et al., 1991). Sheep on a high-roughage diet (hay) metabolized OTA in the rumen at a higher rate than sheep fed a diet high in grain. Sheep on a diet containing 70% concentrate and 30% grass silage and administered 9.5, 19.0, and 28.5 µg OTA/kg body weight consistently excreted 7%−8% of the dose in the urine predominantly as the OTα hydroxylated metabolite. The mean serum levels of OTA, in ascending order of dose, on the last day (day 29) of the study were 3.0, 6.7, and 9.9 ng/mL. OTA is absorbed from the lungs and occupational exposures occur from OTA-contaminated dust.

Important OTA biotransformation reactions are hydrolysis, hydroxylation, conjugation, and lactone opening (Heussner and Bingle, 2015; Koszegi and Poor, 2016). Microbes in the lower gut and rumen hydrolyze OTA to OTα, which is absorbed and excreted in urine. Cell cultures have been shown to produce OTα. The CYP enzymes hydroxylate OTA to 4S-OH-OTA, 4R-OH-OTA, 7′-OH-OTA, 9′-OH-OTA, 5′-OH-OTA, and ochratoxin B. Ochratoxin conjugates are excreted in bile and to a lesser extent in urine (Munoz et al., 2017). Lactone opening is considered to increase the toxicity of OTA and the lactone-open OTA has been identified in rat bile and chyme.

Chemical Biomarkers of Ochratoxin A

OTA crosses the placental barrier and at birth is present in fetal blood (Malir et al., 2013). In the species studied, OTA levels in maternal serum are not a good predictor of OTA levels in fetal serum at the time of birth. Finding OTA in the neonate before nursing, e.g. cord blood or other tissues, and in breast milk, are biomarkers of maternal to fetal and maternal to neonatal exposures, respectively. In horses, OTA has also been shown to cross the placental barrier (Minervini et al., 2013). OTA is also transferred from plasma to milk (Soto et al., 2016). Because OTA is bound to serum proteins, it is likely that both simple diffusion and transport mechanisms are involved in the shift of OTA from blood to milk. Colostrum is the highest in OTA and this may be due to the glandular transfer of OTA bound to plasma proteins into glandular colostrum (Munoz et al., 2014). The transfer rate of OTA from blood to milk may change with the percentage of OTA that is bound to serum proteins. The milk/blood ratio in rats has been shown to be 0.4−0.7 after the animals were administered 50 µg OTA/kg body weight 5 days a week for 21 days, and similar results were observed in a single oral dose

study (Breitholtz-Emanuelsson et al., 1993). Soto et al. (2016) in a recent review reported the range of OTA in breast milk to be 0.002—13.1 ng/mL. Dietary habits of the mother influence the levels of OTA in breast milk, with consumption of foods high in OTA resulting in the higher levels in milk. Plasma/breast milk ratio has been reported at 0.40 ± 0.26 for colostrum, and after lactation onset (15 days—4 months) the plasma/milk ratio decreases to 0.15 ± 0.26 (Warth et al., 2016). Field sampling of cow milk has revealed the presence of OTA in milk sampled from tanker trucks and bulk tanks in different parts of Europe and market basket sampling in China. Hens fed a diet containing 5 ppm OTA had OTA appearing in the eggs after 5 days of feeding the contaminated diet and the level of OTA peaked in the eggs at 7.4 ± 1.03 ng/g on day 21 (Zahoor et al., 2012). Laying hens fed a diet containing 2 ppm OTA for 3 weeks did not have detectable levels (0.5 μg/kg) of OTA in their eggs (Denli et al., 2008). Other studies have shown that poultry diets with less than 2 ppm OTA do not result in detectable levels being transferred to eggs (Battacone et al., 2010).

Histopathologic Biomarkers of Exposure to Ochratoxins A

The kidney, in natural exposure conditions, is considered to be the primary target of OTA (Gupta et al., 2018). The renal toxicopathy of OTA has been reported for various species. In pigs, the temporal sequence of renal tubular histopathology is swelling of proximal tubular epithelial cells, appearance of eosinophilic hyaline droplets, condensation of the nuclei progressing to cellular necrosis, appearance of eosinophilic protein casts, inflammatory exudate, diffuse glomerular atrophy progressing to sclerosis and interstitial fibrosis (Stoev et al., 2012). In the rat, the pathogenesis of renal tubular histopathology is swelling of proximal tubular epithelial cells, appearance of eosinophilic hyaline droplets, condensation of the nuclei, and appearance of eosinophilic protein casts, progressing to cellular necrosis. Cell loss in the straight segment of proximal tubular epithelium can be accompanied by cell proliferation and nuclear enlargement, and these lesions progress to focal hyperplasia, tubular cell adenoma, and tubular cell carcinoma (Rached et al., 2007). OTA is a potent carcinogen in laboratory animals and a suspected human carcinogen (Anon, 1993). In the glomerulus, swelling and blebbing of the endothelial cells occur along with endothelial cellular necrosis. Interstitial nephropathy is also observed. Similar changes have been observed in poultry, rabbits, pigs, and dogs (Stoev et al., 2012; Prabu et al., 2013) and in intoxication with citrinin.

FUMONISINS

The fumonisins are primarily produced by *Fusarium verticillioides* (*Fusarium moniliforme*), *Fusarium proliferatum*, *Fusarium oxysporum*, *Fusarium globosum*, other *Fusarium* spp., and *Alternaria alternata*, which commonly infect maize and other foodstuffs (Coppock and Jacobsen, 2009; Scott, 2012; WHO, 2017). The occurrence of fumonisin in maize is important because maize is the third most important cereal grain for human consumption. Cereals in all land continents are contaminated with fumonisins (Lee and Ryu, 2017). Other foodstuffs that have been shown to contain fumonisin B_1 (FB_1) are garlic powder, black tea, peanuts, figs, soybeans, and cows' milk (Gazzotti et al., 2009; Scott, 2012). FB_1 has been shown to cause leukoencephalomalacia in horses, pulmonary edema in pigs, renal disease in sheep and other domestic species, and neoplasia in rats and mice. In humans, FB_1 is associated with neoplasia, stunting of children, and interference with folic acid uptake and therein associated with folic acid deficiency-linked birth defects (Coppock and Jacobsen, 2009; Gelderblom and Marasas, 2012).

Chemistry of Fumonisins

Fifteen different fumonisins have been described and by chemical properties grouped into categories A, B, C, and P (WHO, 2017). Of these categories groups A and B are considered toxic and the FB_1 group is considered to be the most toxic. There are at least 28 FB_1 isomers. The IUPAC name for FB_1 is (2S)-2-[2-[(5S,6R,7R,9R,11S,16R,18S,19S)-19-amino-6-[(3S)-3,4-dicarboxy-butanoyl]oxy-11,16,18-trihydroxy-5,9-dimethylicosan-7-yl]oxy-2-oxoethyl]butanedioic acid. FB_1 is structurally similar to sphingosine and inhibits sphinganine N-acetyltransferase (ceramide synthase), which is a group of enzyme for sphingolipid synthesis, and FB_1 is classed by IRAC as a Group 2B possible human carcinogen (Anon, 1993).

Toxicokinetics, Metabolism, and Chemical Biomarkers

FB_1 is a charged molecule and has a low level of gut absorption and a high rate of elimination. In the monogastric species studied, FB_1 has oral bioavailability, from 1% to 6% of the dose absorbed (Gelderblom and Marasas, 2012). The majority of kinetic studies (intravenous administration) suggest a two-compartment open model for the elimination of FB_1. Parenterally administered FB_1 has a half-life of 17 min in bile cannulated pigs, 18 min in rat, 40 min in vervet monkey, 49 min in laying hens, 85 min in turkey, and an estimated

128 min in human (Shephard et al., 2007; Tardieu et al., 2008). The half-life after oral administration of FB_1 is 214 min in turkeys (Tardieu et al., 2008). Approximately 6% of the absorbed FB_1 is bound to plasma proteins and other constituents. The absorbed FB_1 is rapidly cleared by the liver and excreted in the bile. There is evidence that hepatic-enteric circulation of FB_1 occurs. The majority of ingested FB_1 is eliminated in the feces and small amounts are eliminated in the urine (Shephard et al., 2007). FB_1 residues are found in the liver and kidney.

In vertebrates, muscle and fat have low levels of FB_1, whereas higher levels are found in the liver and kidney. Less than 1% of the FB_1 ingested is excreted in urine when humans consume biscuits and tortillas made from market basket flour contaminated with FB_1 (Riley et al., 2012). A study in South Africa provided estimates that 0.054% of FB_1 dietary intake was excreted in the urine, and urinary output was correlated with dietary intake (van der Westhuizen et al., 2011). In a model using surgically obtained abdominal human skin, FB_1 had a nondetectable permeability (Boonen et al., 2012). A long-term chronic study in nonhuman primates using culture material of *F. verticillioides* strain MRC 602 showed that FB_1 and metabolites were deposited in hair (Gelderblom et al., 2001; Sewram et al., 2003). Discarded barbershop hair was collected from a high maize consumption region of South Africa and assayed for FB_1 as a biomarker of chronic exposure to FB_1 (Sewram et al., 2003). The mean levels from the different geographic regions ranged from 22.2 to 33.0 µg/kg of hair. Using hair analyses and exposure data from a study in nonhuman primates, Sewram et al. (2003) estimated the chronic human exposure to be 18.4−27 µg of fumonisins/kg body weight. Another study concluded that FB_1 in human hair is a function of dietary intake of FB_1 (Bordin et al., 2015). A study in piglets fed diets containing 0, 3.1, 6.1, or 9.0 µg FB_1/g of feed for 28 days found a significant correlation between dietary FB_1 and the FB_1 incorporated into hair (Souto et al., 2017). FB_1 has been identified in market basket samples of milk. Eight out of 10 samples were positive for FB_1 and the values ranged from 0.26 to 0.43 µg/kg (Gazzotti et al., 2009). FB_1 is also present in breast milk from mothers consuming FB_1-contaminated foods, and breast milk is considered the safest infant food (Magoha et al., 2014; Warth et al., 2016). In de novo sphingolipid synthesis, sphinganine N-acetyltransferase (ceramide synthase) catalyzes acetylation of the sphingoid base sphinganine to form dihydroceramide. Changes in the sphingoid bases can occur before or at the onset of fumonisin toxicity. In horses and pigs, changes in the sphinganine/sphingosine ratio have been reported to occur in blood and urine before other indicators of intoxication occur (Bucci et al.,

1998). Studies in poultry have shown increase in serum sphinganine/sphingosine ratio following exposure to FB_1 (Weibking et al., 1994; Tardieu et al., 2007, 2009). Studies in humans living in areas where FB_1 contamination of diets is endemic have shown that sphinganine/ sphingosine ratios are not good predictors of individual dietary exposure to FB_1, but blood spot sphinganine 1-phosphate levels are positively correlated with individual urinary excretion of FB_1 (Xu et al., 2010; van der Westhuizen et al., 2013; Riley et al., 2015). Increased serum and tissue levels of sphinganine 1-phosphate in mice, rats, pigs, and horses have been proposed as a biomarker of exposure to FB_1 (Kim et al., 2006; Shephard et al., 2007).

Histopathological Biomarkers

Histopathology is an indicator of intoxication with FB_1. Apoptosis and dyssynchrony of the cell cycle may be an important pathological mechanism (Wang et al., 2013). FB_1-linked kidney lesions have been observed in essentially all animal species studied. In pigs, the renal lesions are pericapillary edema and granular degeneration of the proximal tubular cells, intermittent necrotic tubular epithelial cells, and granular casts (Colvin et al., 1993; Stoev et al., 2012). In nonhuman primates, renal lesions observed were cellular atrophy of the proximal tubular cells (Gelderblom et al., 2001). Degeneration of proximal tubular cells with individual cellular necrosis and apoptosis are observed and the lesion can continue into the outer strip of the medulla (Bucci et al., 1998). Urinary enzymes are considered a sensitive indicator of damage of the renal epithelium in rodents. There are few reports of their being studied and used as biomarkers of FB_1-linked renal damage in other species. FB_1 has been shown to be hepatotoxic in several species (Javed et al., 2005). The histopathology of hepatotoxicity is characterized in chickens by multifocal single-cell hepatocellular cytoplasmic swelling and fatty degeneration to pleomorphic vacuolated hepatocytes with marked hydropic degeneration and hepatocellular swelling in the higher dosage groups. Degenerative changes can occur in the biliary epithelial. Numerous mitotic figures in regenerative areas can be observed and periportal fibrosis can occur. In turkeys and ducks, the pathology is generalized hepatocellular hyperplasia. Liver pathology has been reported in pigs on a diet containing 190 ppm FB_1 fed for 83 days (Casteel et al., 1993). The observed liver pathology was hepatocellular necrosis occurring in the centrilobular to midzonal regions and diffuses hepatocellular vacuolation, biliary hyperplasia, and the presence of hyperplastic nodules. In field cases of FB_1 intoxication in pigs (dietary levels of 20−330 ppm

FB$_1$), pulmonary pathology is characterized by accumulation of acidophilic fibrillar material in alveoli, eosinophilic hyalinized alveolar capillary thrombi, and interlobular edema. Neurologic lesions in leukoencephalomalacia were characterized by degeneration of the white matter with inflammatory exudates and perifibrosis of blood vessels. Leukoencephalomalacia in horses is considered a biomarker of FB$_1$ intoxication (Maxie and Youssef, 2007).

DEOXYNIVALENOL TRICHOTHECENE

Deoxynivalenol (DON, vomitoxin) is one of the most prevalent mycotoxins in human foods and animal feeds. It is generally regarded as being heat stable, but there is evidence that some degradation may occur at bread-baking temperatures. DON is a member of the Group B trichothecene group of mycotoxins. It is a small sesquiterpenoid with an embedded epoxide at the 12−13 position. Chemically DON is identified as (3β,7α)-3,7,15-trihydroxy-12,13-epoxytrichothec-9-en-8-one. Important producers of DON are *Fusarium graminearum* (sexual state *Gibberella zeae*), which causes red ear rot of corn and *Fusarium* head blight (scab) of wheat and barley, and *Fusarium culmorum*, and *Fusarium pseudograminearum* (Coppock and Jacobsen, 2009). These species of *Fusarium* can also produce other trichothecenes and zearalenones (ZENs). The occurrences of DON contamination are linked to cereal grains being infected with species of *Fusarium*. Acetylated derivatives of DON (3-acetyl deoxynivalenol and 15-acetyl-deoxynivalenol) also can exist in foods and feeds (Payros et al., 2016). Plants deactivate DON by forming the DON-3β-ᴅ-glucopyranoside and this form is not detected by many analytical procedures. DON-3β-ᴅ-glucopyranoside is substantially less toxic than DON. Gut bacteria can hydrolyze these conjugates and liberate DON. DON is ribotoxic and inhibits protein synthesis and causes a cascade of cellular dysfunctions and oxidative stress. The gastrointestinal tract and immune, reproductive, endocrine, and nervous systems are targets for DON (Coppock et al., 1985; Maresca, 2013).

Toxicokinetics, Biotransformation, and Biomarkers

The toxicokinetics of DON varies with species, age, and sex (Payros et al., 2016). Rodent data show that males receiving the same oral dose of DON have higher plasma levels that females, and males are more sensitive

to the toxic effects of DON (Clark et al., 2015). Absorption of DON varies from 7% in mature ruminants to 89% in chronically exposed piglets (Maresca, 2013; Payros et al., 2016). Pigs absorb 54%−89% of the DON ingested and there is evidence that absorption efficiency increases with chronic exposure possibly because of the toxic effects of DON on enterocytes (Goyarts and Danicke, 2006). Approximately 9% of the DON in blood is bound to plasma proteins (Meky et al., 2003). The intestinal cells, liver, and kidney detoxify absorbed DON by the formation of DON-glucuronides, and these are rapidly excreted predominantly in the urine with a small amount in the bile, and DON itself is also excreted in the urine. Microorganisms in the forestomach and gastrointestinal tract form the de-epoxide diene derivatives of DON and destruction of the 12−13 epoxide and greatly reduces toxicity. The 13-depoxy DON (DOM-1) microbial metabolite of DON has been regionally identified in human urine suggesting regional differences in gut microbial metabolism of DON, and there are also regional differences in the formation of DON conjugates (Chen et al., 2017). The DON-3-sulfate is excreted by several animal species and is likely excreted by humans. Very little parent DON is excreted in milk, and DOM-1 is excreted in milk and urine. Urinary excretion of DON-glucuronide has been studied as a biomarker of human and animal exposure and is considered to be a biomarker of exposure at least in moderately exposed populations (Meky et al., 2003; Thanner et al., 2016; Chen et al., 2017). The interval between food consumption and urine collection can affect the urinary level of DON and its metabolites.

ZEARALENONE

Background

ZEN is a mycotoxin with xenoestrogen activity that mimics 17β-estradiol and is considered an endocrine disruptor (Bandera et al., 2011; Kowalska et al., 2016). The IUPAC name for ZEN is (2E,11S)-15,17-dihydroxy-11-methyl-12-oxabicyclo[12.4.0] octadeca-1(14), 2,15,17-tetraene-7,13-dione, and it is also chemically described as 6-(10-hydroxy-6-oxo-trans-1-undecenyl)-β-resorcylic acid ʟ-lactone. ZEN is produced by *F. graminearum*, *F. culmorum*, *Fusarium equiseti*, and *Fusarium cerealis* (*Fusarium crockwellense*) (Coppock and Jacobsen, 2009; Oldenburg et al., 2017). ZEN is a contaminate of foods, feeds, and beer and occurs in grain dust (Tangni and Pussemier, 2007). ZEN is gaining attention because of it being an endocrine disruptor, and some evidence

that it is a growth—maturation disruptor in humans and may contribute to increased occurrences of breast cancer (Belhassen et al., 2015; Bandera et al., 2011).

Toxicokinetics, Biotransformation, and Biomarkers

The toxicokinetics and biotransformation of ZEN in food-producing animals has recently been reviewed (Danicke and Winkler, 2015). ZEN can be ingested as the aglycone and sulfate conjugates (ZEN-14-O-β-glucoside, ZEN-16-β-O-glucoside, and ZEN-14-sulfate). The aglycone forms of ZEN can be liberated by chyme-associated hydrolysis in the digestive tract. The aglycone forms of ZEN are not detected by many routine analytical procedures. The absolute absorption of ZEN is difficult to determine because of its rapid clearance by the liver and excretion into bile and biotransformation by gastrointestinal mucosal cells. Plasma levels of ZEN and its metabolites are low in poultry and rats after oral administration of ZEN (Danicke and Winkler, 2015; Devreese et al., 2015). This may be due to biotransformation in the gastrointestinal cells, hepatic clearance, and excretion in bile. Bolus doses of ZEN administered to poultry are primarily excreted in bile. The major pathways of ZEN biotransformation are hydroxylation and conjugation with glucuronic acid and sulfate. Oxidation of ZEN can occur by the CYP enzymes and in subsequent reactions can form reactive oxygen intermediates that form DNA adducts. Reduction of ZEN by 3α- and 3β-hydroxysteroid dehydrogenases forms α-zearalenol (α-ZEL) and β-zearalenol (β-ZEL), respectively.

Biotransformation of ZEN to α-ZEL is generally considered a toxication reaction because the estrogen receptors in many species have a 500-fold higher affinity for α-ZEL than ZEN. Conversely, the formation of β-ZEL is considered a detoxication reaction because there is, depending on the animal species, a 15-fold reduction in estrogenic activity. The rate of biotransformation of ZEN to α-ZEL and β-ZEL varies between species. ZEN, α-ZEL, and β-ZEL can be mutually transformed in hepatocytes. α-ZEL and β-ZEL, in the animal species studied, are the major metabolites of ZEN. ZEN, α-ZEL, and β-ZEL and their conjugates are excreted in bile. Bile levels can be 2.5 and 17 times higher than liver and urine, respectively, and bile is considered the best analyte for ZEN and metabolites including zeranol (α-zearalanol) (Lega et al., 2017). In chickens, oral exposure to ZEN results in ZEN, α-ZEL, and β-ZEL being excreted in the feces. In most food-producing species, ZEN, α-ZEL, and β-ZEL are excreted predominantly as glucuronide (α-ZEL-Glu, β-ZEL-Glu) and sulfate conjugates (Danicke and Winkler, 2015; Yang et al., 2017). In ZEN-exposed humans, pigs, and poultry, ZEN and α-ZEL and their conjugates are the main metabolites excreted. Cattle fed diets containing ZEN excrete ZEN and β-ZEL in their urine, and lactating cattle excrete β-ZEL, ZEN, and α-ZEL in milk. The milk/diet carryover rate is 0.008. Survey studies in horses suggest that ZEN is metabolized to β-ZEL in horses and ZEN, β-ZEL, and α-ZEL were identified, including glucuronide conjugates, in serum and urine (Schumann et al., 2016; Takagi et al., 2018). Humans excrete ZEN in breast milk. Humans excrete free ZEN, α-ZEL, and β-ZEL and ZEN-Glu, α-ZEL-Glu, and β-ZEL-Glu in urine with the glucuronide conjugates predominating (Mally et al., 2016). There appears to be regional differences in the biotransformation of ZEN by humans.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Worldwide, mycotoxins are an underappreciated cause of disease. Advances in diagnosis of mycotoxicoses are linked to advances in chemical, molecular, and histologic methods of diagnosis. The increased use of microchips to identify gene expression, protein signatures, and other molecular changes is advancing diagnosis of mycotoxicoses. Metabolomics has a high likelihood of being a sensitive method to assess the adverse metabolic effects of mycotoxins. Current studies are showing that adverse metabolic effects of chronic exposure to low levels of mycotoxins are underappreciated (Toda et al., 2017). Simplified analytical methods for simultaneously measuring multiple mycotoxins are showing that exposure to multiple mycotoxins is a frequent occurrence. Preventing the formation of mycotoxins by reducing conditions for mold growth and mycotoxin production is the best way forward.

Poisonous Plants: Biomarkers for Diagnosis

Kip E. Panter, Kevin D. Welch, Dale R. Gardner

United States Department of Agriculture, Agricultural Research Service, Poisonous Plant Research Laboratory, Logan, UT, United States

INTRODUCTION

Poisonous plants and the toxins they produce result in major economic losses to the livestock industries throughout the world. In the 17 western United States, it was estimated that more than $340 million in annual losses were attributed to poisonous plants (Nielsen et al., 1988; Nielsen and James, 1992). This cost estimate used 1989 figures and only considered death losses and measureable reproductive losses in cattle and sheep. A revised estimate of over $500 million annually using more current animal prices was recently reported (Holechek, 2002). Less obvious costs such as lost grazing opportunities, additional feed costs, increased health-care costs, management adjustments, increased culling costs, lost weight gains, delayed or failed reproduction, and the emotional stress accompanying many poisonous plant cases were not included in the Nielsen and James or Holechek analyses. When one considers these other costs, inflation, and current animal values, and when all pastures and ranges in the United States are factored in, the economic cost of poisonous plants to the livestock industry is significant. In addition, an often ignored cost is the environmental impact on plant biodiversity from invasive species, many of which are poisonous. These invasive and poisonous species are often aggressive invaders and reduce optimum utilization of private, federal, and state-managed forest, range, and pasture lands. This aspect alone has far-reaching implications, not only for livestock producers but also for many other segments of society.

Animals graze poisonous plants for a number of reasons. In some cases, it is a matter of survival. For example, in the arid and semiarid livestock-producing regions of the world, such as the western United States, regions of South Africa, Australia, China, South America, and others, browsing or grazing animals may have limited access to high-quality forage at certain times of the year and are forced to survive by grazing some poisonous species. In other instances, hay or harvested forages from areas where poisonous plants are abundant may be contaminated with a high percentage of poisonous plants, and when animals are fed contaminated hay, they may be poisoned. On many ranges, poisonous plants are a normal but small part of the animal's diet as they are highly nutritious, i.e., larkspurs, locoweeds, and lupines, to name a few.

Poisonous plant problems are often exacerbated during periods of below normal rainfall when the abundance of grasses is reduced. Frequently, the animal's diet selection changes during the season when grasses and palatable forbs mature and senesce; for example, the consumption of some poisonous plants such as lupines, locoweeds, or larkspurs, which stay green longer into the season, may increase as the season progresses. Pine needles and junipers are often consumed in the winter. In other instances, poisoning occurs early in the season when poisonous plants such as lupine or death camas have emerged ahead of grasses. To restate the obvious, poisoning by plants only occurs when animals eat too much too fast or graze it over extended periods. Therefore, management strategies utilizing multiple factors are required to minimize losses from poisonous plants.

Over the last 20 years, research at the USDA-ARS Poisonous Plant Research Laboratory in Logan, Utah, has provided information utilized by livestock producers and land managers to significantly reduce losses from poisonous plants and improve economic sustainability in rural communities. Part of this research has emphasized identifying biomarkers of poisoning for diagnostics and research. Although much more research is required, new information presented here will assist clinicians and diagnostic laboratories in diagnosing cases

of poisonous plant toxicoses. This chapter is not intended to be all inclusive but focuses on some of the most economically important and geographically widespread poisonous plants to livestock producers in the United States.

ASTRAGALUS AND OXYTROPIS SPECIES (LOCOWEEDS, NITROTOXIN SPP., AND SELENIUM ACCUMULATORS)

Of all the poisonous plants found on rangelands and pastures in the United States, the *Astragalus* and *Oxytropis* genera cause the greatest economic losses to the livestock industry in the western states (Graham et al., 2009; Cook et al., 2009c). There are three toxic syndromes associated with these species: (1) locoweed poisoning caused by species containing the indolizidine alkaloid swainsonine (~24 species); (2) species containing nitrotoxins (~356 species and varieties); and (3) selenium accumulators (~22 species).

Locoweeds

Locoweed poisoning was one of the first poisonous plant problems recognized by stockmen and was reported as early as 1873. There are about 24 known species of *Astragalus* and *Oxytropis* that contain swainsonine and have been implicated in livestock poisonings. The term "loco" is Spanish, meaning crazy, and colloquially describes the aberrant behavior of locoweed-poisoned animals. All species of *Astragalus* and *Oxytropis* containing swainsonine are collectively referred to as locoweeds.

Toxicology

There are numerous effects of locoweed on animals, but the classic syndrome from which the term "locoism" derived is one of the central neurological dysfunctions, resulting in aberrant and often aggressive and unpredictable behavior. The disease is chronic, developing after weeks of ingesting locoweeds, and begins with depression, dull-appearing eyes, and incoordination, progressing to uncharacteristic behavior, including aggression, staggering, solitary behavior, wasting, and eventually death if continued consumption is allowed. Other problems associated with locoweed ingestion include reproductive failure, abortion, birth defects, weight loss, and enhanced susceptibility to brisket disease at high elevations (Panter et al., 1999b).

Locoweed poisoning affects all animals but because of the transient nature of the poisoning, animals removed from the locoweed early in the toxicosis will recover most of their function and may be productive

animals. In the final stages of locoism, central nervous system tissue shows swelling of axonal hillocks (meganeurites) and growth of new dendrites and synapses. This altered synaptic formation in nervous tissue in severely affected animals is permanent and may be the cause of some irreversible neurological signs. Because of neurological dysfunction and apparent permanence of some lesions in the nervous system, horses are believed to be unpredictable and therefore unsafe to use for riding or draft, but they may remain reproductively sound once they have recovered from the poisoning.

Toxin

The indolizidine alkaloid swainsonine (1) was first isolated from the Australian plant *Swainsona canescens* (Colegate et al., 1979) and then soon thereafter isolated with its *N*-oxide from locoweeds (Molyneux and James, 1982).

Swainsonine (1)
The locoweed poisoning syndrome is a lysosomal storage disease in which α-mannosidase is inhibited, resulting in prevention of hydrolysis of mannose-rich oligosaccharides in cells and accumulation of these oligosaccharides resulting in cellular dysfunction.

Pryor et al. (2009) discovered that swainsonine in *Astragalus* and *Oxytropis* species is produced by a fungal endophyte, *Undifilum oxytropis* (formerly called *Embellesia oxytropis*). A positive correlation was shown to exist between swainsonine concentrations found in the plant and concentrations of swainsonine produced by the endophytic fungus cultured from the same plant (Ralphs et al., 2008; Cook et al., 2009a). This same correlation was demonstrated for *Oxytropis glabra*, an important poisonous plant in the Inner Mongolia steppe (Ping et al., 2009).

Research results have shown that inhibition of α-mannosidase is relatively transient and quickly reversible once animals stop eating locoweed (Stegelmeier et al., 1994). Blood serum clearance of swainsonine is rapid (half-life of ~20 h); thus, the effects of locoweed should be reversible if tissue damage has not become extensive and permanent. This suggests that intermittent grazing of locoweed could be an effective means of reducing locoweed poisoning. There is also an apparent threshold dosage where severity of cell damage is more time-dependent than dosage-dependent. Once the threshold

dosage is reached, which appears to be relatively low (0.35 mg/kg BW in the rat), eating more locoweed does not accelerate the toxicosis. Therefore, increasing animal numbers on loco pastures and reducing time of grazing is also a logical method to reduce economic impact yet utilize infested pastures.

Many locoweeds are biennials or perennials that flourish periodically under optimum environmental conditions. Historically, losses are regional and sporadic, with large regional economic impact. Individual cases of significant losses are frequent, and some historical cases are reported in James and Nielsen (1988).

Conditions of Grazing

In cows, preference to graze locoweed is relative to the amount and condition of other available forage. Many locoweeds are cool-season species that green up and start growth early in the spring, flower, set seed, and go dormant in summer, and then resume growth in fall. Livestock generally prefer the green, growing locoweeds to dormant grass. Sheep preferred the regrowth foliage of Green River milkvetch to dormant grasses during late fall and early winter on the desert range in eastern Utah (Ralphs et al., 2001). Horses selected green spotted locoweed instead of dormant grasses in the spring in Arizona (Pfister et al., 2003). Cattle readily grazed Wahweap milkvetch in proportion to its availability on desert winter range in southeastern Utah. In a series of grazing studies in northeast New Mexico, cattle readily grazed white locoweed in March—May but stopped grazing it in June as warm-season grasses became abundant and white locoweed matured and became coarse and rank. Stocker cattle grazed white-point locoweed on shortgrass prairies in May and early June, but weight losses continued throughout the summer, even though they had stopped eating locoweed. On mixed-grass prairies on the eastern foothills of the Rocky Mountains in northern Colorado, cattle ceased grazing white-point locoweed when it matured following flowering in mid-June and became rank and less palatable. However, they continued to graze it throughout the subsequent summer when abundant summer precipitation caused the locoweed to remain green and succulent (Ralphs et al., 2001).

Biomarkers of Poisoning (AST, GGTP, White Cell Count, Cellular Vacuolation, Serum Swainsonine, α-Mannosidase)

Clinically, locoweed poisoning in all classes of livestock and wildlife include depression, loss of appetite, weight loss followed by intention tremors, dull hair coat, proprioceptive deficits, aberrant behavior, abortion in pregnant animals, and eventually death with prolonged exposure. Evaluation of serum swainsonine versus serum alpha mannosidase will indicate recent exposure to locoweed; however, elimination kinetics of swainsonine is short (t$^{1/2}$ elimination of 20 h) and recovery rate of α-mannosidase is relative to disappearance of swainsonine. Therefore, serum evaluation of swainsonine or α-mannosidase is of limited value in diagnosis. Currently, serum biochemistry provides some support for a diagnosis as aspartate aminotransferase (AST), Lactic Acid Dehydrogenase (LDH), Gamma-Glutamyl Transferase (GGTP), and white blood cell counts are all elevated with locoweed poisoning. However, these are not pathognomonic to locoweed poisoning and without a history of locoweed ingestion would be of limited value as biomarkers. Currently, the best diagnosis for locoweed poisoning can only be obtained after necropsy and follow-up histopathology. Although there are few gross lesions seen in locoweed poisoned animals, there are many characteristic microscopic lesions. Most organ systems are affected; however, the nervous and endocrine systems are extremely sensitive and diseased cells of these organs are swollen and filled with dilated vacuoles described as cellular constipation. This cellular foamy vacuolation is readily observed in thyroid, pancreas, kidneys, testes, ovaries, and macrophages in nearly all tissues. Research at the Poisonous Plant Research Laboratory is focused on identifying selected abnormal proteins with a slow elimination kinetics as a biomarker to diagnose locoweed exposure and also as measure of prognosis for recovery.

Prevention of Poisoning and Management Recommendations

Prevention of poisoning remains a matter of management strategy adapted to individual grazing programs to minimize grazing of locoweed plants (Graham et al., 2009). Livestock should be denied access to locoweeds during critical periods when they are relatively more palatable than associated forages. On shortgrass prairies of northeastern New Mexico, stocker cattle should not be turned onto locoweed-infested rangelands until warm-season grasses start growth in late May or early June. Cattle on rangeland year-round should be removed from locoweed-infested areas in the spring when it is green and growing and warm-season grasses remain dormant. They can be returned to locoweed-infested pastures in summer when warm-season grasses are abundant.

Most locoweed species are endemic, growing only in certain habitats or on specific soils. Fences can be used to provide seasonal control of grazing. Reserving locoweed-free pastures for grazing during critical periods in spring and fall can prevent locoweed poisoning. Locoweed-free areas can be created by strategic herbicide use.

Currently, no broad management schemes or methods of treatment are known to generally prevent

locoweed poisoning. Management strategies for individual operations have been developed once the grazing practices and options are identified, allowing utilization of the particular range and yet minimizing losses. It was determined that cattle generally rejected woolly loco even under extreme grazing conditions, but once they were forced to start eating it, they continued to graze it and became intoxicated. Ranchers should watch for these "loco eaters" and move them to locoweed-free pastures. Shortage of feed with high grazing pressure, social facilitation (loco eaters teaching nonloco eaters to accept loco), or supplementing with alfalfa hay or cubes may compel cattle to start grazing woolly locoweed. White-point locoweed is more palatable than woolly locoweed and is green before spring grasses begin to grow in northeastern New Mexico. Therefore, cattle readily graze white-point locoweed in early spring while grasses are dormant, but once green grass starts to grow, cattle switch off of locoweed. Recommendations include creating locoweed-free pastures through herbicide use, fencing, or selection of low locoweed-infested pastures for early spring grazing and also to provide a place to move the identified locoweed eaters. This practice appears to reduce the impact of locoweed on these ranges.

Grazing pressure can also force cattle to begin grazing locoweed when they run short of desirable forage (Ralphs et al., 1994). Ranchers should not overstock locoweed-infested ranges but, rather, should ensure adequate forage is always available. Improper use of some grazing systems may encourage livestock to graze locoweed.

In a grazing study comparing breeds, Brangus steers consumed more locoweed than did Hereford or Charolais steers (Ralphs et al., 1994). It was suggested that the gregarious nature of Brangus steers facilitated their acceptance of locoweed first among the other breeds. Observations of breed differences were acknowledged as early as 1909. C.D. Marsh suggested that black cattle and black-faced sheep were more likely to graze locoweed and become poisoned. Although this has not been experimentally substantiated, we do believe breed difference may play a role in an animal's propensity to graze locoweeds and become poisoned.

Nitro-Containing *Astragalus* (Milkvetches)

There are more than 260 species and varieties (356 taxa) of nitro-containing *Astragalus* in North America (Barneby, 1964; Welsh et al., 2007). They are frequently referred to as milkvetches, as are some of the other *Astragalus* species. Nitrotoxins are therefore the most common toxin in the *Astragalus*, followed by swainsonine (locoweeds), then selenium. Major livestock losses occur in many regions of the western United States. These plants are very diverse and concentrated on the deserts, foothills, and mountains of the west.

Toxicology

The nitro-containing *Astragalus* species cause acute and chronic poisoning in sheep, cattle, and horses. The acute form results in weakness, increased heart rate, respiratory distress, coma, and death. Although blood methemoglobin is high (induced from nitrotoxin metabolism to nitrites) and a contributing factor to the respiratory difficulties, administration of methylene blue in cattle does not prevent death. Therefore, the methemoglobinemia is apparently not the primary cause of death. The chronic form is the most frequent form of poisoning observed and follows a course of general weakness, incoordination, central nervous system involvement resulting in knuckling of the fetlocks, goose stepping, clicking of the hooves, and "cracker heels" progressing to paralysis and death. A respiratory syndrome is also present in the chronic and acute forms, with emphysema-like signs causing the animals to force respiration: "roaring disease." Sheep manifest the respiratory syndrome more than the central nervous syndrome and are more resistant to poisoning compared with cattle.

The toxic principles are β-d-glycosides of 3-nitro-1-propanol (NPOH) or 3-nitropropionic acid (NPA). The glycoside conversion occurs more readily in the ruminant because of the microflora and is apparently the reason for increased toxicity. The glycoside (miserotoxin **2**) is metabolized to the highly toxic NPOH in the gastrointestinal (GI) tract of ruminants (Williams et al., 1970). Thus, NPOH is absorbed in the gut and apparently converted to NPA by the liver. Further metabolism yields inorganic nitrite and an unidentified metabolite that may be involved in toxicity. It appears that NPOH is more rapidly absorbed from the gut than is NPA; therefore, forage containing the alcohol form is the most toxic.
Miserotoxin (**2**)

Biomarkers of Poisoning (Clinical, Pathology, History of Ingestion, Methemoglobin)

The diagnosis of nitrotoxin-poisoned animals can be made by documenting exposure to the plant, identifying

the characteristic clinical signs of poisoning, measuring serum 3-nitropropionic acid concentrations, and histological examination. Studies have shown that 3-nitropropionic acid is rapidly absorbed, distributed, and eliminated. Consequently serum 3-nitropropionic acid concentrations may be below detectable limits within days of removal from the plant. This limits the diagnostic usefulness of serum 3-nitropropionic acid detection, as none may be detected in the serum even though the animals are demonstrating severe clinical signs. There are no hematological or serum chemistry changes of diagnostic value. However, cattle and sheep have been shown to have elevated methemoglobin concentrations, in excess of 20%. The gross pathological changes that occur are not distinctive but include hepatic congestion, pulmonary emphysema and edema, excess pericardial fluid, and abomasal ulceration. Microscopic lesions are also nonspecific, with the exception of changes in the brains of cattle with chronic exposure. These changes include the presence of foci of necrosis in the thalamus, moderate necrosis of the Purkinje cells in cerebellar folia, spongiosis in the white matter of the globus pallidus, distension of the lateral ventricles, and wallerian degeneration of the ventral and lateral columns of the spinal cord and the sciatic nerve. Clinical signs of respiratory distress from the pulmonary emphysema "roaring disease" and rear leg paresis "cracker heels" would suggest 3-nitropropionic acid (milkvetch or miserotoxin) poisoning and should be considered in the differential diagnosis.

Prevention and Treatment

There is no preferred treatment for milkvetch poisoning, although treatment with methylene blue appears to reverse the methemoglobinemia but may not prevent death in cattle. Oxidation of NPOH to NPA is prevented if alcohol dehydrogenase is saturated with ethanol or inhibited with 4-methylpyrazole before NPOH is given. This suggests that NPOH is a good substrate for the enzyme, alcohol dehydrogenase. This information could be useful in acute cases; however, its value in treatment of poisoning in the field is limited.

Livestock losses can be reduced by decreasing the density of the *Astragalus* species with herbicides or avoiding grazing livestock on infested areas when the plant is most poisonous. Wasatch milkvetch contains the highest concentration of miserotoxin from bloom to immature seed pod stage of growth. Nitro compounds are found in all parts of the plant, but the leaves contain the highest concentration. Once the leaves begin to dry and lose their green color, the nitro levels drop very rapidly, and the plant is relatively nontoxic. However,

the toxins in plants pressed green and preserved in herbaria appear to remain stable for years (Williams and Barneby, 1977). Herbicide treatment decreases the density of plants and also decreases the toxicity of the plants once they start to dry; therefore, spraying milkvetch appears to be the best method to reduce losses and still utilize infested ranges.

Seleniferous *Astragalus*

Approximately 22–24 species of *Astragalus* known to accumulate selenium (Se) have been identified (Rosenfeld and Beath, 1964; Welsh et al., 2007). These are less numerous and more geographically restricted than the nitro-containing species. Many of these species are referred to as Se-indicator plants because they only grow on soils high in bioavailable selenium; therefore, they are helpful in locating and identifying areas or soils high in selenium. The *Astragalus* species are deep-rooted plants and are thought to bring selenium (pump) from deeper soil profiles to the surface where shallow-rooted forbs and grasses will take up toxic levels. It is these facultative accumulators that create most of the subacute or chronic toxicity problems for livestock.

Toxicity

With selenium poisonings, one may observe acute, subacute, or chronic selenosis depending on the daily dose, Se type (organic vs. inorganic), and duration of exposure. Acute cases of selenium poisoning are rare and usually involve animals that have been exposed by one of four methods. (1) Forages that have superaccumulated selenium from seleniferous soils. (2) Environmental contamination from agricultural drain water, reclaimed soils from phosphate or ore mining, or from fly ash. (3) Accidental overdosing with pharmaceutical grade selenium such as Bo-Se in the treatment of white muscle disease. (4) Misformulated feed mixes. The signs of acute selenium poisoning include diarrhea, unusual postures, increased temperature and heart rate, dyspnea, tachypnea, respiratory distress, prostration, and death (Tiwary et al., 2006). Gross pathological findings are usually limited to pulmonary congestion, hemorrhage, and edema. Histologically, multifocal myocardial necrosis and pulmonary alveolar vasculitis are common (Tiwary et al., 2006).

Chronic selenium poisoning is most common and referred to as alkali disease because most areas with high concentrations of available selenium are alkaline in nature. Chronic selenosis occurs from prolonged ingestion of seleniferous forages containing 5–40 ppm

Se. Clinical signs include rough coat, hair or wool loss, poor growth, emaciation, abnormal hoof growth, lameness, dermatitis, and depressed reproduction (Rosenfeld and Beath, 1964; Raisbeck, 2000). In swine, a condition of paralysis (poliomyelomalacia or polioencephalomalacia) often occurs with cervical or lumbar involvement (Panter et al., 1996b). The description of a second chronic syndrome in cattle called "blind staggers" has been redefined and is now believed to be polioencephalomalacia induced by high sulfate water or high sulfate forage sources.

Selenium is found in soil and plants in both organic (3) and inorganic (4) forms. The organic forms are more bioavailable than the inorganic forms, resulting in higher animal tissue concentrations when administered at equivalent selenium doses (Tiwary et al., 2006; Davis et al. 2012). Although a dramatic difference in tissue selenium uptake between organic (selenomethionine) and plant (*Astragalus bisulcatus*) forms and inorganic (sodium selenate) forms occurs, the clinical and pathological syndromes are similar—i.e., poliomyelomalacia in pigs (Panter et al., 1996b) and pulmonary edema and hemorrhage in sheep and cattle (Tiwary et al., 2006; Davis et al. 2012).
Selenomethionine (3)
Sodium selenate (4)

Biomarkers of Poisoning (Liver Biopsy Se, Whole Blood Se, Enzyme, Hair, Mane, Tail, Hoof Samples)

A complete health history of the animals with excess selenium in the forages or feed supplementation providing the basis for suspecting selenium poisoning (acute or chronic) should be evaluated. Selenium is slowly excreted, requiring relatively long withdrawal times (weeks). Therefore, acute Se poisoning can be diagnosed by sampling numerous biological tissues, including whole blood, serum, liver biopsies, hair, tail, and hooves. Acute selenium poisoning can be easily diagnosed by sampling hair 3–4 weeks postexposure. Selenium appears to be excreted slightly slower from the liver; however, liver biopsies are a much more invasive procedure for diagnosis. Interestingly, selenium is excreted relatively slowly from the red blood cell, thus making whole blood a good tissue for analysis (Davis et al., 2012). The primary lesion in acute selenosis in cattle has been found to be myocardial necrosis with subsequent heart failure seen as passive congestion and centrilobular hepatic congestion with hepatocellular degeneration and necrosis. Consequently increases in serum creatine kinase and troponin can be used as biomarkers of acute selenosis. Chronic selenium poisoning results in bilateral hair loss over the withers of cattle and horses, tail and mane hair loss, overgrown coronary bands or separation and sloughing of the outer shell of the hooves, and an overall unkept appearance. In cattle excess selenium, or selenium deficiency, may reduce overall reproductive performance. In horses, sampling of the tail hair then cutting into 1 inch increments and performing selenium analysis on each of the 1 inch increments will provide a good history of selenium ingestion for up to a 3-year period depending on how long the tail hair is (Davis et al., 2014). In cattle, a hair sample should be clipped from the shoulder area close to the skin and divided into 2 or 3 samples based on hair length. This will provide a good evaluation of selenium status and an approximate time when selenium ingested. The 0.5 cm sample closest to the skin would indicate recent selenium exposure (0–7 days), whereas the center and outer samples would indicate more long-term exposure (Davis et al., 2012). In pigs, selenium poisoning (subacute and acute) manifests with cervical or lumbar paresis and lesions of polioencephalomalacia or poliomyelomalacia and chronic poisoning by hair loss, overgrown hooves, reduced growth rate, and overall poor or unkept appearance. In sheep, acute selenium poisoning is manifest by respiratory distress, depression, lethargy, and death within hours to a day or two after ingestion. There are few clinical signs associated with chronic selenium ingestion in sheep; however, reproductive performance may be impaired.

Prevention of Poisoning

There is no treatment for selenium poisoning except removal from the source, allowing spontaneous recovery in chronic cases. Treat overgrown hooves, i.e., trim horse's hooves frequently until normal hoof growth resumes (6–12 months). Monitoring soils in a particular area and understanding the plant communities can provide the management information to avoid poisoning. In areas where selenium is a problem, many ranchers have switched to grazing steers to avoid decreased

reproductive efficiency in cows. Sheep appear to be more resistant to chronic selenosis compared with cattle and are better adapted for some of these ranges. However, sheep are sensitive to acute selenium poisoning, as was observed when a large number of sheep died within days after grazing on mine reclamation sites that contained very high soil and plant selenium concentrations (Panter, personal communications, 2004). Monitoring for selenium concentrations and forms in soil, vegetation, as well as animal tissues and hair, can help avoid poisoning incidents. Likewise, deficiency problems can be rapidly resolved with frequent monitoring and trace mineral supplementation.

LARKSPURS (*DELPHINIUM* SPP.)

There are more than 80 wild species of larkspurs in North America, classified into two general categories based primarily on mature plant height and distribution: low larkspurs and tall larkspurs. The larkspurs are a major cause of cattle losses on western ranges. As early as 1913, C.D. Marsh reported that more cattle deaths on western ranges are caused by larkspurs than by any other poisonous plant except locoweed. Large sporadic losses continue to occur on ranges with both low and tall larkspur species.

Toxicology

Larkspurs (*Delphinium* spp.) are a serious economic problem for cattle producers utilizing valley, foothill, and mountain rangelands in western North America. The toxicity of larkspur plants is due to norditerpenoid alkaloids, which occur as one of two chemical structural types—the *N*-(methylsuccinimido) anthranoyllycoctonine (MSAL) type (**5**) and the 7,8-methylenedioxylycoctonine (non-MSLA) type (**6**). Although the MSAL-type alkaloids are much more toxic (typically more than 20 times) (Panter et al., 2002), the non-MSAL-type alkaloids are generally more abundant in *Delphinium barbeyi* and *Delphinium occidentale* populations and will exacerbate the toxicoses (Gardner et al., 2002, Welch et al., 2010, 2012). The effects of 7, 8-methylenedioxylycoctonine-type diterpenoid alkaloids may enhance the overall toxicity of tall larkspur (Delphinium spp.) in cattle. Consequently, for a larkspur plant to be toxic to livestock, a sufficient quantity of MSAL-type alkaloids is required. However, MDL-type alkaloids appear to potentiate the overall toxicity of the MSAL-type alkaloids and should be considered when predicting potential toxicity of larkspur populations (Welch et al., 2010, 2012).
Methyllycaconitine (**5**)
Deltaline (**6**)

Toxicity declines rapidly in tall larkspurs once pods begin to shatter. Measuring plant toxicity early in the growing season may allow prediction of grazing risk throughout the season (Ralphs et al., 2002). Because of the fact that the MSAL-type alkaloids are much more toxic than the MDL-type alkaloids, management recommendations for grazing cattle on larkspur-containing ranges are based primarily on the concentration of MSAL-type alkaloids in larkspur (Pfister et al., 2002; Ralphs et al., 2002).

Clinical signs of intoxication include muscular weakness and trembling, straddled stance, periodic collapse into sternal recumbency, respiratory difficulty, and death while in lateral recumbency. The primary result of larkspur toxicosis is neuromuscular paralysis from blockage at the postsynaptic neuromuscular junction (Benn and Jacyno, 1983). Cattle generally begin consuming tall larkspur after flowering racemes are elongated, and consumption increases as larkspur matures. Consumption usually peaks during the pod stage of growth in late summer, when cattle may eat large

quantities (25%–30% of diet as herd average; >60% on some days by individual animals). Because larkspur toxicity generally declines throughout the growing season, and cattle tend to eat more larkspur after flowering, this risk period of greatest danger has been termed the "toxic window" (Pfister et al., 2002). This toxic window extends from the flower stage into the pod stage, or approximately 5 weeks, depending on temperature and elevation. Many ranchers typically defer grazing on tall larkspur-infested ranges until the flower stage to avoid death losses. This approach is dangerous as it places cattle in larkspur-infested pastures when risk of losses is high. This approach also wastes valuable, high-quality forage early in the season when risk of grazing is much lower. An additional 4–6 weeks of grazing may be obtained by grazing these ranges early, before larkspur elongates flowering racemes. The risk of losing cattle is low when grazing before flowering, even though larkspur is very toxic, because cattle prefer the highly palatable lush grasses. Once pods mature and begin to shatter, larkspur ranges can usually be grazed with impunity because pod toxicity declines rapidly, and leaf toxicity is low.

Managing cattle on low larkspur pastures is quite different from that on tall larkspur pastures. Not all low larkspurs are high risk, and alkaloid analyses should be done before grazing. On pastures where toxic species of low larkspur grow, delayed grazing until after pods shatter and plants begin to dry up is the only safe approach. Based on limited studies, cattle increase consumption of low larkspur after flowering, and increases in grazing pressure increase amounts of low larkspur eaten by cattle (Pfister et al., 2002).

Biomarkers of Poisoning (Blood Alkaloid, Liver Alkaloid, Plant Fragment, or Rumen Sample)

For diagnostic purposes, the toxic larkspur alkaloids can usually be detected in the whole blood, liver, kidney, sera, and rumen content of poisoned animals. Because of the acute nature of larkspur toxicosis, if the animals survive the initial intoxication they will recover and have no lasting effects. Consequently, in general, when a diagnosis of a larkspur-poisoned animal is needed, it is for a dead animal. The diagnosis of larkspur poisoning is currently made by documenting exposure to the plant, identifying the characteristic clinical signs, identifying larkspur in the rumen contents, and measuring serum alkaloid concentrations. Studies have shown that the larkspur alkaloids are rapidly absorbed, distributed, and eliminated. Serum alkaloid concentrations can be detected for approximately 7 days after intoxication. Because of the difficulty for most diagnostic laboratories to accurately identify plant parts in rumen contents and

measure serum for larkspur alkaloids, experiments are being conducted to use PCR technology to identify larkspur plants in rumen contents. The use of a common and robust technology such as PCR will allow for most any veterinary diagnostic laboratory to determine if the plant was present in the rumen of the animal.

Prevention and Management of Poisoning

Grazing Management

A simple and low-risk grazing management scheme can often be used based simply on tall larkspur growth and phenology: (1) graze during early summer when sufficient grass is available until larkspur elongates flowering racemes (4–6 weeks, depending on elevation and weather); (2) remove livestock, or contend with potentially high risk from flowering to early pod stages of growth (4 or 5 weeks); and (3) graze with low risk during the late season when larkspur pods begin to shatter (4–6 weeks). This scheme can be refined substantially if livestock producers periodically obtain an estimate of the toxicity of tall larkspur, and if ranchers spend time periodically observing and documenting larkspur consumption by grazing cattle.

Management to reduce losses to low larkspur begins with recognition of the plant during spring. Vegetative low larkspur plants will typically begin growth before the major forage grasses. Low larkspur populations fluctuate with environmental conditions (Pfister, unpublished data). Risk of losing cattle is much higher during years with dense populations. During those years, recognizing the plant, and finding alternative pasture or waiting to graze infested pastures for 4–6 weeks until the low larkspur has dried up, will reduce losses. In addition, it is recommended that animals not be watered or provided mineral supplementation in areas that have high densities of larkspurs.

Drug Intervention

A variety of remedies have been applied in the field when ranchers find intoxicated animals, but most are without a solid scientific rationale. Treatment for overt poisoning is usually symptomatic, and recovery is often spontaneous if animals are not stressed further. Once the animal is observed showing muscular tremors, it should be allowed to drop back and proceed at its own pace. Poisoned animals should never be forced to continue moving because this will exacerbate the clinical effects and can result in death. Drugs that increase acetylcholine effectiveness at the neuromuscular junction have potential for reversing larkspur toxicosis or reducing susceptibility. The cholinergic drug physostigmine (0.08 mg/kg intravenous (i.v.)) has been successfully used under field and pen conditions to reverse clinical

larkspur intoxication (Pfister et al., 1994). Similarly, i.v. administration of neostigmine (0.04 mg/kg) significantly reduced clinical signs in cattle (Green et al., 2009), and neostigmine administered intramuscularly at 0.02 mg/kg can be used as a rescue treatment for cattle that are recumbent. This reversal lasts approximately 2 h, and repeated injections of neostigmine are sometimes required. Under field conditions, neostigmine temporarily abates clinical signs and animals quickly (~15 min) become ambulatory. Depending on the larkspur dose, the intoxication may recur. The use of physostigmine-based treatments may aggravate losses in the absence of further treatment if intoxicated, yet ambulatory animals later develop increased muscular fatigue, dyspnea, and death.

LUPINES (*LUPINUS* SPP.)

The *Lupinus* genus contains more than 150 species of annual, perennial, or soft woody shrub lupines. More than 95 species occur in California alone. The lupines are rich in alkaloids, responsible for most of the toxic and teratogenic properties. There are domestic lupines that, through plant breeding, are low in alkaloid content and have been selected for ornamental purposes or for animal and human food. Only the range lupines known to cause poisoning or birth defects are discussed here.

Stockmen have long recognized the toxicity of lupines when livestock, particularly sheep, were poisoned in the late summer by the pods and seeds of lupine. Major losses in sheep were reported in the 1950s, and individual flock losses of hundreds and even thousands were reported. Lupines are also poisonous to other livestock, and field cases of poisoning in cattle, horses, and goats have been reported. However, the most recognized condition of lupine ingestion is the "crooked calf syndrome," a congenital condition in calves resulting in skeletal contracture-type malformations and cleft palate after their mothers have grazed lupines during sensitive periods of pregnancy (Panter et al., 1999a). The condition was first reported in 1959 and experimentally confirmed after large outbreaks in Oregon and Montana in 1967.

Toxicology

Most lupine species contain quinolizidine alkaloids, a few contain piperidine alkaloids, and some contain both. The specific alkaloids responsible for crooked calf syndrome are anagyrine **(7)**, ammodendrine **(8)**, *N*-acetylhystrine, and *N*-methyl ammodendrine. Hence, risk is based on chemical profile and the presence and concentration of these teratogenic alkaloids. It is known that chemical profile and concentration differ, resulting

in changing levels of toxicity within and between species and populations. The chemical phenology has been studied in *Lupinus caudatus* and *Lupinus leucophyllus* (Lee et al., 2007). Total alkaloid concentration is high in the new early growth but diluted as the plant biomass increases. Pools of total alkaloids increase during the phenological growth stages and peak at the pod stage, concentrating in the pods. The teratogenic alkaloid anagyrine appears to be an end product in the biosynthetic pathway and accumulates in the floral parts and is stored in the seed. Following seed shatter, both concentration and pools of all alkaloids decline precipitously, leaving the senescent plant relatively nontoxic.
Anagyrine **(7)**
Ammodendrine **(8)**

The toxicity of lupines was first recognized in the early 1900s. Lupines can be toxic to sheep at 0.25%−1.5% of their body weight depending on alkaloid composition. A few cases of poisoning have occurred on young plants. Losses of 80−100 sheep in multiple bands have been reported during the past 5 years in Idaho and Wyoming (Panter, personal communication, 2005).

Poisoning by lupine plants should not be confused with lupinosis reported in Australia. Lupinosis is a condition that is entirely different, as it is a mycotoxicosis of livestock caused by toxins produced by the fungus *Phomopsis leptostromiformis*, which colonizes domestic lupine stubble. It affects livestock that graze lupine stubble and limits the use of this animal forage in Australia.

Historically, lupines were responsible for more sheep deaths than any other single plant in Montana, Idaho, and Utah. Most losses occurred from hungry sheep grazing seed pods. Poisoning occurred following trucking or trailing bands in late summer or fall, or after getting caught in early snowstorms that covered herbaceous vegetation. Hungry sheep nonselectively grazed

lupine pods, which are high in alkaloids, and were poisoned. Large losses have also occurred when lupine hay harvested in the seed pod stage was fed in winter.

Lupine-induced crooked calf syndrome was first reported in 1959 and 1960 and experimentally confirmed in 1967 (Panter et al., 1999a). Crooked calf syndrome includes various skeletal contracture-type birth defects and occasionally cleft palate. The skeletal defects are similar to an inherited genetic condition reported in Charolais cattle. Based on epidemiologic evidence and chemical comparison of teratogenic and nonteratogenic lupines, the quinolizidine alkaloid anagyrine was determined to be the teratogen (Keeler, 1973). A second teratogen, a piperidine alkaloid, ammodendrine, found in *Lupinus formosus*, was also demonstrated to cause the condition (Keeler and Panter, 1989). Further research determined that the anagryrine-containing lupine only caused birth defects in cattle and did not affect sheep or goats; however, the piperidine alkaloid-containing lupine, *L. formosus*, induced similar birth defects in cattle and goats (Keeler and Panter, 1989).

Cattle Grazing

Different lupines produce varying toxic syndromes in livestock, apparently because the alkaloid profile varies remarkably among plant species and between populations. Season and environment influence alkaloid concentration in a given species of lupine. Generally, alkaloid content is highest in young plants and in mature seeds. Alkaloids are not lost on drying, so wild hay may be highly toxic if young lupine plants or seed pods are present. For many lupines, the time and degree of seeding vary from year to year. Most losses occur under conditions in which animals consume large amounts of plant or pods in a brief period, such as when they are being driven through an area of heavy lupine growth, unloaded into such an area, trailed through an area where the grass is covered by snow but the lupines are exposed, or when feeding lupine hay with pods. Most serious poisonings may occur in the late summer or early fall because lupine remains green after other forage has dried, and seed pods may be present. Once the poisonings were understood, the practice of harvesting lupine hay for winter sheep feed was discontinued.

Lupine is not very palatable to cattle, although it has been considered fair to good quality feed on some ranges that are heavily utilized. Its palatability or acceptability depends on availability and maturity of other forage. In a grazing study of velvet lupine (*L. leucophyllus*) on annual cheatgrass ranges in eastern Washington (Ralphs et al., 2006), cows selected lupine in July and August after cheatgrass dried and other forbs were depleted or matured and became less palatable. The deep-rooted lupine remained green and succulent longer into the summer than the other forage. Lupine was higher in crude protein and lower in fiber (NDF) than the other forages throughout the season (the crude protein level in foliage was 15%, and in seeds it was 36%).

The abundance of lupine is another factor influencing the amount of lupine consumed. Lupine population cycles are influenced by weather patterns. Catastrophic losses from lupine-induced crooked calves occurred in the Channel Scabland region of eastern Washington in 1997. Annual precipitation from 1995 to 1997 was 33% above average, precipitating a population outbreak of lupine throughout the region. The density of velvet lupine plants has declined since then (Ralphs, unpublished data), and the incidence of crooked calves has returned to what has become an acceptable tolerance of 1%–5% incidence.

Clinical signs of poisoning are of muscular weakness (neuromuscular blockade) beginning with nervousness, frequent urination and defecation, depression, frothing at the mouth, relaxation of the nictitating membrane, ataxia, muscular fasciculations, weakness, lethargy, collapse, sternal recumbency followed by lateral recumbency, respiratory failure, and death. Signs may appear within 15 min to 1 h after ingestion or as late as 24 h, depending on the amount and rate of ingestion. Death usually results from respiratory paralysis.

The incidence of crooked calves is variable geographically and from year to year within a given herd. Up to 100% of a given calf crop may be affected, and individuals may be more severely affected than others. Affected calves are generally born alive at full term. Dystocia may occur when calves are severely deformed and assistance is required, often resulting in cesarean section.

Arthrogryposis is the most common malformation observed and is often accompanied by one or more of the following: scoliosis, torticollis, kyphosis, or cleft palate. Elbow joints are often immobile because of malalignment of the ulna with the articular surfaces of the distal extremity of the humerus. The part of the limb distal to the elbow joint is often rotated laterally. In crooked calf syndrome, the osseous changes observed are permanent and generally become progressively worse as the calf grows and its limbs are subjected to greater load-bearing stress. Frequently, minor contractions such as "buck knees," often attributed to lupine, will resolve on their own, and the calf will appear relatively normal.

The sensitive gestational period in the pregnant cow for exposure is 40–70 days with periods extending to day 100 (Panter et al., 1997). The condition has been experimentally induced with dried ground lupine at 1 g plant/kg BW and with semipurified preparations of anagyrine (the apparent teratogen) at 30 mg anagyrine/kg BW fed daily from 30 to 70 days of gestation

(Keeler et al., 1976). The dose range of anagyrine to cause crooked calves is 6.5–11.9 mg/kg BW/day for 3 or 4 weeks during gestation days 40–70. Crooked calf disease has also been induced by feeding the piperidine alkaloid-containing lupine, *L. formosus* (Keeler and Panter, 1989). The teratogenic piperidines—ammodendrine, *N*-acetylhystrine, and *N*-methyl ammodendrine—are absorbed quickly after ingestion and can be detected in blood plasma by 0.5 h, with peak levels maintained for more than 24 h (Gardner and Panter, 1993). The mechanism of action has been determined to be an alkaloid-induced reduction in fetal movement by a neuromuscular blocking effect during the critical stages of gestation (Panter et al., 1990a). This inhibition of fetal movement is due to stimulation followed by desensitization of skeletal muscle-type nAChR (Lee et al., 2006). This mechanism is a common factor for multiple alkaloids found in many species of lupines, poison hemlock (*Conium*), and wild tree tobacco (*Nicotiana glauca*), and research using TE-671 cells that express human fetal muscle-type nAChR and SH-SY5Y cells that express human autonomic-type nAChR supports this mechanism (Green et al., 2010).

Biomarkers of Poisoning (Clinical Effects, History of Ingestion, Serum Analysis, Liver, Urine, Crooked Calf Syndrome (CCS))

There are few biomarkers for diagnosing lupine poisoning. However, there are clinical signs that should be considered in a differential diagnosis such as incoordination, nictitating membrane partially covering the eye, muscular weakness especially after mild exertion and death after a history of potential lupine exposure. Alkaloid screening of the serum, liver, rumen content, or urine of poisoned animals with positive analysis for quinolizidine or piperidine alkaloids is diagnostic, especially if a history of lupine exposure exists. When newborn calves are presented with skeletal contractures especially arthrogryposis, scoliosis, torticollis, kyphosis, and/or cleft palate, lupine ingestion during pregnancy should be suspected. Because of the acute nature of lupine toxicosis, if mature animals survive the initial intoxication they will recover and have no lasting effects. However, if a pregnant cow is poisoned between the GD 40 and 100, the calf will likely be born with skeletal contractures. The diagnosis of lupine poisoning is currently made by documenting exposure to the plant, identifying the characteristic clinical signs, identifying lupine in the rumen contents, and measuring serum alkaloid concentrations. Studies have shown that the lupine alkaloids are rapidly absorbed, distributed, and eliminated. Serum alkaloid concentrations can be detected for approximately 3–4 days after intoxication.

Prevention, Management, and Treatment

Keeler et al. (1977) proposed a simple management solution to prevent crooked calves: graze lupine-infested pastures so that the susceptible period of gestation (40–70 days) does not overlap the flower and pod stage of growth when anagyrine is highest. Ralphs et al. (2006) refined Keeler's recommendations to restrict access during the susceptible period of gestation, when anagyrine concentration is still high in the flower and pod stage, only when cattle are likely to eat lupine and in years when it is abundant. Panter et al. (2013) suggested that intermittent grazing between lupine-infested pastures and lupine-free pastures would allow the fetus to regain normal movement for a few days during the sensitive stage of gestation. It has been hypothesized that inhibited fetal movement over a prolonged period is required for severe malformations to occur (Panter et al., 1999a).

Lupines are easily controlled with 2,4-D-type broadleaf herbicides (Ralphs et al., 1991); however, herbicide treatment alone rarely provides long-term solutions to poisonous plant problems. Seed reserves in the soil will rapidly reestablish the stands if grazing management practices are not implemented.

Death losses in sheep can be reduced by recognizing the variability in lupine toxicity with stage of growth and the conditions under which animals graze the plant. Providing a choice of other quality forages usually prevents excess lupine grazing. The dangerous period of plant growth for sheep exists mainly with plants in the pod stage. The hazard increases if sheep are hungry, as is often the case with crowding, hauling, driving, or overgrazed conditions. The hazard is reduced or eliminated after seed pods shatter.

Treatment for overt poisoning is usually symptomatic, and recovery is often spontaneous if animals are not stressed further. Once the animal is observed showing muscular tremors, it should be allowed to drop back and proceed at its own pace. Poisoned animals should never be forced to continue moving because this will exacerbate the clinical effects and can result in death. The elimination of the toxic alkaloids in the urine is quite rapid (t½ ∼ 6.3–6.9 h) and begins within hours of ingestion (Lopez-Ortiz et al., 2004). Therefore, allowing the animal to rest and move slowly will often result in full recovery within 24 h. There is no treatment for the malformations, and euthanasia is recommended for the serious skeletal defects and cleft palate. However, less severe contracture defects, particularly of the front legs (buck knees), will often resolve if the knee joint can be locked within 1 week after birth. If not, the defect generally becomes worse with growth and size, and although the animal will continue to grow, the front legs will break down until the animal is unable to survive.

POISON HEMLOCK (*CONIUM MACULATUM*)

Poison hemlock (*C. maculatum*) was introduced into the United States as an ornamental plant from Europe and has become naturalized throughout the United States (Kingsbury, 1964). The plant generally grows in waste places or habitats where there is adequate moisture to sustain populations. It is a biennial, however, where temperatures and adequate moisture allow seed germination in the fall the 2-year cycle for seed production may occur in one season. Poison hemlock has an interesting history as it is believed to be the plant from which a decoction (hemlock tea) was used to execute Socrates and others from that era. An interesting review describes the historical perspective of poison hemlock (Daughtery, 1995).

Toxicology

Eight piperidine alkaloids are known in poison hemlock, five of which are commonly discussed in the literature. Two alkaloids (coniine (9) and γ-coniceine (10)) are prevalent and likely responsible for toxicity and teratogenicity of the plant. γ-Coniceine is the predominant alkaloid in the early vegetative stage of plant growth and is a biochemical precursor to the other *Conium* alkaloids (Panter and Keeler, 1989). Coniine predominates in late growth and is found mainly in the seeds. γ-Coniceine is seven or eight times more toxic than coniine in mice (Lee et al., 2013). This makes the early growth plant most dangerous in the early spring, and the seedlings and regrowth again in the fall. This is also the time when green feed is limited to livestock and may impact their propensity to graze this plant. Frequently, poison hemlock encroaches into hay fields where it can be problematic in green chop or silage. Ensiling usually reduces toxicity; however, hot spots in silage pits increase risk of poisoning. Seeds, which are very toxic, can contaminate poultry and swine cereal grains (Panter and Keeler, 1989). Plants often lose their toxicity on drying, but seeds remain toxic as long as the seed coat is intact.
Coniine (9)
γ-Coniceine (10)

The clinical signs of toxicity are the same in all species and include initial stimulation (nervousness), resulting in frequent urination and defecation (no diarrhea), rapid pulse, temporarily impaired vision from the nictitating membrane covering the eyes, muscular weakness, muscle fasciculations, ataxia, incoordination followed by depression, recumbency, collapse, and death from respiratory failure (Panter et al., 1988). *Conium* plant and seed are teratogenic, causing contracture-type skeletal defects and cleft palate like those of lupine. Field cases of teratogenesis have been reported in cattle and swine and experimentally induced in cattle, swine, sheep, and goats (Panter et al., 1999a). Birth defects include arthrogryposis (twisting of front legs), scoliosis (deviation of spine), torticollis (twisted neck), and cleft palate. Field cases of skeletal defects and cleft palate in swine and cattle have been confirmed experimentally.

In cattle, the susceptible period for *Conium*-induced terata is the same as that described for lupine and is between days 40–70 of gestation. The defects, susceptible period of pregnancy, and probable mechanism of action are the same as those of crooked calf syndrome induced by lupines (Panter et al., 1999a). In brief, these alkaloids and their enantiomers in poison hemlock, lupines, and *N. glauca* were more effective in depolarizing the specialized cells TE-671, which express human fetal muscle-type nAChR, relative to SH-SY5Y, which predominantly express autonomic nAChRs, in a structure–activity relationship (Panter et al., 1990a; Lee et al., 2006, 2008; Green et al., 2010). In swine, sheep, and goats, the susceptible period of gestation is 30–60 days. Cleft palate has been induced in goats when plant, or toxins, was fed from 35 to 41 days of gestation (Panter and Keeler, 1992).

Field cases of poisoning have been reported in cattle, swine, horses, goats, elk, turkeys, quail, chickens, and Canada geese (Panter et al., 1999a). Poisoning in wild geese eating small seedlings in early spring was most recently reported (Panter, personal communication). Human cases of poisoning are occasionally reported in the literature, and a case of a child and his father mistakenly ingesting the plant has been reported. Field cases of teratogenesis have been reported in cattle and swine and experimentally induced in cattle, sheep, goats, and swine (Panter et al., 1990a). Pigs become habituated to poison hemlock, and if access to the plant is not limited, they will eat lethal amounts within a short time.

Biomarkers of Poisoning

There are no diagnostic lesions or serum biomarkers in poisoned animals, and diagnosis is based on clinical history of exposure and/or alkaloid (coniine, *N*-methyl coniine, or γ-coniceine) detection in the liver, urine, blood, or stomach contents. At necropsy, the presence

of plant fragments in the rumen and a characteristic pungent odor in the contents with chemical confirmation of the alkaloids is diagnostic. Characteristic contracture-type skeletal birth defects or cleft palate in cattle, sheep, or goats similar to those produced by lupines should be included in the differential diagnosis.

Prevention and Treatment

Prevention of poisoning is based on recognizing the plant and its toxicity and avoidance of livestock exposure when hungry. If a lethal dose has not been ingested, the clinical signs will pass spontaneously, and a full recovery can be expected. Avoidance of stressing animals poisoned on *Conium* is recommended. However, if lethal doses have been ingested, supporting respiration, gastric lavage, and activated charcoal are recommended. Control of plants is easily accomplished using broadleaf herbicides; however, persistent control measures are recommended because seed reserves in the soil will quickly reestablish a population.

The mechanism of action of the *Conium* alkaloids is twofold. The most serious effect occurs at the neuromuscular junction, where they act as nondepolarizing blockers such as curare. Systemically, the toxins cause biphasic nicotinic effects, including salivation, mydriasis, and tachycardia, followed by bradycardia as a result of their action at the autonomic ganglia. The teratogenic effects are undoubtedly related to the neuromuscular effects on the fetus and have been shown to be related to reduction in fetal movement (Panter et al., 1990a). Likewise, cleft palate is caused by the tongue interfering in palate closure during reduced fetal movement and occurs during days 30−40 of gestation in swine, 32−41 days in goats, and 40−50 days in cattle (Panter and Keeler, 1992).

WATER HEMLOCK (*CICUTA* SPP.)

Water hemlock (*Cicuta* spp.) is among the most violently poisonous plants known to humans. It is often confused with poison hemlock because of its name, growth patterns, and appearance. However, there are distinct differences in morphology and habitat.

Toxicology

The primary toxic principle in water hemlock is a long-chain, highly unsaturated alcohol called cicutoxin (**11**). Water hemlock acts on the central nervous system inducing violent grand mal seizures and death from respiratory failure.

Cicutoxin (**11**)

Tubers are the most toxic part of the plant, especially in early spring. The parsnip-like roots extending from the tuber are two to four times less toxic, and as the vegetative parts of the plant grow and mature, they become less toxic. Preliminary studies suggest that mature leaves and stems are much less toxic and are nontoxic after drying (Panter et al., 1988). Historically, water hemlock was believed to be most dangerous in early spring, and poisoning usually occurred when animals milled around in streambeds or sloughs and exposed tubers, which were then ingested. Although this is true, a recent case of poisoning and death in cattle after ingesting flower and green seed heads implicates this phenological stage as dangerous also (Panter et al., 2011). Chemical comparison of green seed and tubers combined with mouse bioassay studies showed that green seed is also toxic. Like tubers, the more mature vegetation, including leaves, flowers, and green seed heads, was palatable. The parsnip-like roots given free choice to hamsters showed that they were very palatable, and the hamsters actually preferred these roots to their normal laboratory chow. No signs of toxicoses were observed when hamsters had free choice to these roots. The roots are much less toxic compared with the tubers. Observations of cattle grazing early in spring suggest that the young shoots of water hemlock are very palatable because young plants growing in streambeds were frequently and extensively grazed without toxic sequelae (Panter, personal observation).

Clinical signs of poisoning appear within 10−15 min after ingestion and progress from nervousness, frothy salivation, ataxia, dyspnea, muscular tremors, and weakness to involuntary, spastic head and neck movements accompanied by rapid eye blinking and partial occlusion of the eyes from the nictitating membranes. This is quickly followed by collapse and intermittent grand mal seizures lasting 1 or 2 min each followed by relaxation periods of 8−10 min. Depending on the dosage, recovery may occur or seizures continue until death from exhaustion or respiratory failure. There appears to be a very narrow safety threshold in which a very small increase in dosage is all that is required to induce grand mal seizures (Panter et al., 1996a).

On necropsy, gross lesions are confined to pale areas in heart muscle and skeletal muscles, particularly the long digital extensor muscle groups (Panter et al., 1996a). Microscopic lesions include multifocal, subacute

to chronic myocardial degeneration characterized by granular degeneration of myofiber cytoplasm necrosis and replacement fibrosis in the heart. These areas correspond to the pale areas observed grossly. There is bilateral symmetrical, subacute to chronic myofiber degeneration, and necrosis of the long digital extensor muscle groups. Clinical serum chemistry changes of elevated lactic dehydrogenase, aspartate aminotransferase, and creatine kinase occur in relation to severity of seizures. The extent of gross and microscopic lesions in muscles and elevated clinical chemistries are a result of the muscle damage from the severe seizures. In an experimental setting, administration of barbiturates at the onset of clinical signs prevented the seizures, death, and lesions in sheep. Interestingly, the lethal effects of a $3\times$ lethal dose of water hemlock could be prevented with pentobarbital and no elevated serum chemistries or death occurred (Panter et al., 1996a).

Biomarkers of Poisoning (Blood Enzymes, CPK, AST, GGTP, Histological Lesions in the Heart, Long Muscles, Clinical Signs, History of Ingestion, Rumen Analysis)

Diagnosis can be made by documenting exposure to the plant, with positive identification of plant parts in the rumen, especially tubers or seeds. Additionally, cicutoxin may or may not be detected in stomach contents as the toxin is quite unstable and readily oxidized. Because of the acute nature of water hemlock poisoning, animals that survive the intoxication will not have any lasting effects, whereas severely poisoned animals are found dead, normally with indications of violent terminal grand mal seizures. Death normally occurs within 1–8 h after ingestion of the plant. In animals that do survive poisoning, elevations in serum LDH, AST, and CK from muscle damage induced by the seizures peaks 3 days after exposure then declines to normal levels within 8–10 days (Panter et al., 1996a). There are no consistent gross lesions, although bruises and lacerations may be evident on the skin, muscles, tongue, etc., resulting from the severe seizures. Small hemorrhages may be present in the long skeletal muscles, and white streaking may be evident on the surface of the heart. Microscopically, cardiac lesions, including multifocal pale areas in the left, right, and interventricular myocardium, may be evident with myocardial fibrosis. In the long digital extensor muscle groups there maybe acute to chronic, moderate, random myofiber necrosis with regeneration of skeletal myofibers. Because of the acute nature of water hemlock poisoning and narrow threshold between death and survival, successful treatment would require immediate response with appropriate drugs.

Prevention and Treatment

Prevention of poisoning is accomplished by recognizing the plant and avoiding exposing animals to it early in the spring or when in the flower/seed stage. Water hemlock is easily controlled with herbicides (2,4-D per manufacturer's specification); however, herbicide use is often restricted near natural water sources. If few plants are present, hand pulling (using appropriate gloves) may be accomplished using caution to discard tubers away from possible exposure to animals or humans.

Successful treatment with barbiturates or perhaps tranquilizers prevents death, lesion formation, and serum chemistry changes; however, treatment must be prompt (Panter et al., 1996a). This treatment has been successful in humans, but in animals it has never been demonstrated in the field and would require a veterinarian to respond very rapidly with appropriate drugs soon after the ingestion of the plant occurred.

PONDEROSA PINE NEEDLES (*PINUS* SPP.)

The needles of ponderosa pine have been known for years to induce abortion in pregnant cows when grazed during the last trimester of pregnancy (Gardner et al., 1999). Occasional toxicosis in pregnant cows occurs; however, cases of toxicosis in nonpregnant cows, steers, or bulls are not reported.

Toxicology

The toxin in ponderosa pine that induces abortion in cattle is the labdane resin acid isocupressic acid **(12)** (ICA; Gardner et al., 1994). Two related derivatives (succinyl ICA and acetyl ICA) also contribute to the induction of abortion after hydrolytic conversion to ICA in the rumen (Gardner et al., 1996). Other related labdane acids (agathic acid, imbricatoloic acid, and dihydroagathic acid) that are found in ponderosa pine needles at low levels may also contain abortifacient properties based on their similar chemical structure to ICA. Other genera and species have also been implicated in abortions, such as Monterey cypress (Parton et al., 1996), Korean pine (Kim et al., 2003), common juniper, lodgepole pine (Gardner et al., 1998), and other juniper species (Gardner et al., 2010; Welch et al., 2011a). Current research indicates that the concentration of labdane acids in ponderosa pine needles and western juniper bark is not uniform throughout the same tree, the concentrations can vary from location to location, and there is evidence for seasonal fluctuations as well (Cook et al., 2010, Welch et al., 2013a 2015).
Isocupressic acid (12)

The primary toxicological effect of ponderosa pine needles in cattle is premature parturition and associated complications, such as retained fetal membranes, metritis, and occasional overt toxicosis and death (Gardner et al., 1999). Pine needle—induced abortion appears to mimic normal parturition except that it is premature. The abortions generally occur in the last trimester of pregnancy in the late fall, winter, or early spring. Abortions have been induced as early as 3 months of gestation and have been reported by ranchers to occur any time; however, the closer to the time of normal parturition that ingestion of pine needles occurs, the higher the risk of abortion. Abortions may occur following a single exposure to the needles, but results from controlled experiments indicate the highest incidence of abortion is in cows eating the needles over a period of 2—3 days. Abortions have been associated with grazing of green needles from trees, needles from slash piles following lumber activity, and dead, dry needles from the ground.

Abortions are generally characterized by weak uterine contractions, incomplete cervical dilation, dystocia, birth of weak but viable calves, agalactia, and retained fetal membranes (Gardner et al., 1999). Calves born after 255 days of gestation will often survive with extra care but need to be supplemented with colostrum and milk from other sources until the dam begins to lactate. Cows with retained fetal membranes may need antibiotic therapy to avoid uterine infections.

Pine needles will induce abortion in buffalo, but sheep, elk, and goats do not abort. Pine needles, pine bark, and new growth tips of branches are all abortifacient, and new growth tips are also toxic (Panter et al., 1990b). A separate toxic syndrome has been described in addition to abortion in which the abietane-type diterpene resin acids cause depression, feed refusal, weakness, neurological problems, and death. Specific compounds include abietic acid, dehydroabietic acid, and other related compounds (Stegelmeier et al., 1996). At 15%—30% of the diet, pine needles have been shown to alter rumen microflora and affect rumen fermentation (Pfister et al., 1992). Rumen stasis is part of the toxic syndrome (Stegelmeier et al., 1996).

Biomarkers of Poisoning (Premature Parturition; Live-Premature Calf; Retained Fetal Membrane; Agathic or Tetrahydroagathic Acid in Serum, Rumen Content, or Calf Tissues; History of Ingestion)

Diagnosis of pine needle—induced abortions is currently made by documenting exposure to needles, birth of the calf at least 2 weeks early, retained fetal membranes (RFM) in the cow, and agalactia. Recent studies have demonstrated that metabolites of ICA, including tetrahydroagathic acid, can be detected in the serum of the cow and calf for several days after parturition. Additional experiments are being conducted to determine what tissues/fluids in the calf, including dead calves, are optimum for a positive diagnosis. Isocupressic acid and related labdane diterpene acids found in pine needles are metabolized in both the rumen and the liver. The three major metabolites include agathic acid, dihydroagathic acid, and tetrahydoagathic acid (Gardner et al., 1999). Of these metabolites, tetrahydroagathic acid remains in the cow serum for the longest period and has been found to be the most relevant diagnostic component from abortion case samples submitted (Gardner, personal communications). There is research evidence that tetrahydoagathic acid is also found in fetal fluids (stomach and thoracic fluids; Snider et al., 2015). For diagnostic purposes, sera samples should be taken from the cow as soon as possible to optimize detection of the ICA metabolites. Additional samples from the aborted fetus should include blood (sera), stomach, and thoracic fluids.

Prevention and Treatment

The only recommendation to prevent pine needle abortion is to limit access of late term pregnant cows to pine trees. There is no known treatment for cattle once ingestion of pine needles has occurred. Open cows, steers, or bulls are apparently unaffected by pine needles; likewise, sheep, goats (pregnant or not), and horses can graze pine needles with impunity and experience no adverse effects. Supportive therapy (antibiotic treatment or uterine infusion for retained fetal membranes) is recommended for cows that have aborted, and intensive care of the calf may save its life. Grazing of pine needles intensifies during cold, inclement weather and if other forage is in short supply. In spring, before green grass is available, cows will leave bedding grounds in search of green forage and frequently graze green needles from low-hanging branches or old, dry needles from surrounding trees where the snow has

melted. These cows are at risk and should be kept away from the pines. Research has also determined that cattle with low body condition are more likely to eat pine needles than cattle in adequate body condition (Pfister et al., 2008b). Consequently, it is recommended that pregnant cattle grazing in ponderosa pine areas be maintained in good body condition (Pfister et al., 2008). Anecdotal information suggests that pregnant llamas may be at risk from ingesting pine needles, but no research has been done to substantiate this (Panter, personal communications).

RAYLESS GOLDENROD (*ISOCOMA PLURIFLORA*)

White Snakeroot (*Eupatorium rugosum*)

Rayless goldenrod (*I. pluriflora*) and white snakeroot (*E. rugosum*) are toxic range plants of the southwestern and midwestern United States, respectively. The disease associated with toxicity has been referred to as "alkali disease" because originally it was associated with drinking alkali water. Currently, it is referred to as "milk sickness" or "trembles" (the same as white snakeroot in the midwest) because the toxin tremetone (**13**) is excreted in the milk and subsequently results in poisoning of humans and nursing offspring.

Toxicology

The toxic constituents of rayless goldenrod and white snakeroot are similar and the first reported toxin, tremetol, is actually a mixture of ketones and alcohols. Tremetone (**13**) (5-acetyl-2,3-dihydro-2-isopropenyl-benzofuran) was thought to be the principle toxic factor; however, 11 different compounds have now been isolated and identified (Lee et al., 2010). The elucidation of different chemotypes of white snakeroot partially explains the sporadic and unpredictable toxicoses reported in livestock throughout the midwestern United States.
Tremetone (**13**)

Clinical signs of poisoning may occur after ingestion of 1%—15% BW during a 1- to 3-week period. Signs begin with depression or inactivity, followed by noticeable trembling of the fine muscles of the nose and legs. Most cases of poisoning reported constipation, nausea, vomition, rapid labored respiration, progressive muscular weakness, stiff gait, standing in a humped-up position, dribbling urine, inability to stand, coma, and death. Signs are similar in cattle, sheep, and goats. The disease is often more acute and severe in horses than in cattle, and horses may die of heart failure after subacute ingestion of white snakeroot and presumably rayless goldenrod. Cattle have also been poisoned on a related plant (*Isocoma acradenia*) in southern California (Galey et al., 1991). In this case, 21 of 60 cattle died and 15 of 60 were affected but recovered.

Biomarkers of Poisoning (Blood Enzymes, CPK, Troponin, Histology, Lesions in Heart, Long Muscles, Clinical Signs, History of Ingestion, Myonecrosis)

Diagnosis of rayless goldenrod poisoning is made by documenting exposure to the plant and identifying the characteristic clinical and pathological signs. The primary lesion and cause of the clinical trembles in rayless goldenrod intoxication in goats is skeletal muscle degeneration and necrosis. As these subtle lesions are most consistently seen in the quadriceps femoris and diaphragm at low dose, these may be the best tissues to examine. However, if there are clinical signs of poisoning and lesions are severe, the large appendicular muscles, such as the triceps brachii, biceps femoris, quadriceps femoris, and adductor, are likely to show significant histologic change. Higher doses produced myocardial lesions. Serum enzyme activities, including CK, LDH, AST, and alanine aminotransferase (ALT), have been shown to be significantly changed in poisoned animals. Although the mean cardiac troponin-I concentrations are not consistently elevated in different poisoned animals, individual animals do have elevated amounts. Creatine phosphokinase and ketones were elevated, and severe myonecrosis was described in the dead animals.

Prevention and Treatment

Rayless goldenrod is not readily palatable, and toxicity results from animals being forced to graze the plant because of lack of good quality forage. Avoiding overgrazing will usually minimize poisoning in livestock. White snakeroot is relatively palatable and may be ingested as part of the diet in cattle and horses.

Treatment is generally symptomatic and supportive, providing dry bedding, good shelter, and fresh feed and water. Activated charcoal and saline cathartic may be beneficial. Treatment may include fluids, B vitamins, ketosis therapy, and tube feeding. Hay and water

should be placed within reach if the animal is recumbent. In lactating cows, frequent milking may facilitate a more rapid and complete recovery.

HALOGETON (*HALOGETON GLOMERATUS*)

Halogeton is an invasive, noxious, and poisonous weed introduced into the western United States from central Asia in the early 20th century. It was first collected along a railroad spur near Wells, Nevada, in 1934 and rapidly invaded 11.2 million acres of the cold deserts of the western United States (Young, 1999). There has been no appreciable spread since the 1980s because halogeton has filled all the suitable niches within its tolerance limits. It currently infests disturbed areas within the salt-desert shrub and sagebrush plant communities in the Great Basin, Colorado Plateau, and Wyoming's Red Desert physiographic provinces, which have 3—15 in of annual precipitation.

Halogeton's infamy began in the 1940s and 50s by causing large, catastrophic sheep losses. There were many instances of large dramatic losses; sometimes entire bands of sheep died overnight from halogeton poisoning. *Life* magazine ran a cover story titled "Stock Killing Weed" that focused national attention on halogeton (Young, 1999). Congress passed the Halogeton Act in 1952 with the intent to (1) detect the presence of halogeton; (2) determine its effects on livestock; and (3) control, suppress, and eradicate this stock-killing weed.

Federal research was reallocated from the Forest Service Experiment Stations to the Bureau of Plant Industries, creating a Range Research unit devoted specifically to "solving" the halogeton problem. It was realized that halogeton was not the problem but a symptom of a larger problem—that being degradation of desert rangelands (Young, 1999). It invaded disturbed sites where sheep congregated around railroad loading sites, trail heads, stock trails, road sides, and water holes. When hungry sheep were turned loose to graze, halogeton was the only feed available, and they consumed too much, too rapidly, and were poisoned.

Toxicology

The toxins are sodium and potassium oxalates (**14**), and *Halogeton* plants are frequently high (17%—29% total oxalates) in these oxalates in the fall and early winter resulting in death losses in sheep and cattle (Rood et al., 2014). Poisoning occurs when sheep consume more oxalates than the body can detoxify (James, 1999). Rumen microbes can adapt if animals are introduced slowly and prevented from eating too much halogeton.
Sodium oxalate (**14**)

Treatment of Poisoned Animals

Animals can be given excess water through a stomach tube to flush oxalates out in the urine, or supplemented with dicalcium phosphate in a drench to provide Ca that will combine with oxalates in the rumen and facilitate oxalate excretion. Intravenous injection of calcium gluconate can maintain blood Ca levels, but Ca oxalate crystals will continue to damage kidneys (James, 1999). Prevention is the key to avoid poisoning. Only hungry sheep are poisoned. Research has demonstrated that as little as 1 oz of soluble oxalates can be lethal to hungry sheep. Well-fed sheep grazing nutritious forage throughout the day can tolerate more than 4 oz of soluble oxalate. Sheep grazed in a desert plant community infested with halogeton consumed it in 5%—25% of their diets without ill effect. If other forage is available, they will likely not get a lethal dose. Historically, sheep were most often affected; however, multiple cases of cattle poisoning have recently been reported (J. Hall, personal communication, 2013).

Biomarkers of Poisoning (Blood or Ocular Calcium, Oxalate Analysis of Blood, History of Ingestion

Biomarkers of halogeton poisoning include serum hypocalcemia and oxalate crystals in the rumen and kidney. Diagnosis may be made by documenting exposure to the plant, identifying characteristic clinical and pathological signs of poisoning and histological examination. Blood calcium declines in poisoned animals, with concurrent increases in magnesium and phosphorus. There may also be an increase in serum LDH and Blood Urea Nitrogen (BUN), although these are not pathognomonic. Gross pathological lesions include the presence of fluid in the abdominal and chest cavities, as well as the pericardial sac. The lungs maybe filled with blood-tinged foam, and splotchy hemorrhages may be found on the surfaces of the heart, rumen, and other organs. The kidneys will be pale and swollen and contain oxalate crystals resembling glass shards and easily detected when the kidney tissue is cut with a knife. Microscopically the renal tubules will be filled with proteinaceous casts and calcium oxalate crystals, and the epithelium flattened and necrotic. There may also be edema and

hemorrhage of the rumen wall and oxalate crystals present in the submucosa stomach compartment and in the walls of vessels.

Management to Prevent Poisoning

Never turn hungry sheep or cattle onto dense halogeton-infested sites. Provide supplemental feed and plenty of fresh water following trucking or trailing. Introduce sheep and cattle gradually to halogeton to allow rumen microbes to adjust. Some sheep producers graze their sheep on shadscale ranges (which contain low oxalate levels) before going into halogeton areas. Do not overgraze; maintain desert range in good condition. This prevents halogeton invasion and provides an alternative food source.

Herbicide control of halogeton is not recommended because the waxy surface of the leaves hinders absorption of most herbicides. More importantly, however, desirable desert shrubs are killed, leaving the site open for further invasion and degradation by halogeton and other invasive weeds.

PYRROLIZIDINE ALKALOID-CONTAINING PLANTS

Pyrrolizidine alkaloid (PA)—containing plants are numerous and worldwide in distribution and in toxic significance (Cheeke and Shull, 1985). Three plant families predominate in PA-producing genera and species: Compositae (*Senecio* spp.), Leguminosae (*Crotalaria* spp.), and Boraginaceae (*Heliotropium*, *Cynoglossum*, *Amsinckia*, *Echium*, and *Symphytum* spp.). Not all of these occur in the western United States.

Toxicology

More than 150 DHPAs (Dihydro Pyrrolizidine Alkaloids) have been identified, and their structural characteristics elucidated. The PAs contain the pyrrolizidine nucleus and can be represented by the basic structures of senecionine (**15**) and heliotrine (**16**). The toxic effects of all PAs are somewhat similar, although their potency varies because of their bioactivation in the liver to toxic metabolites called pyrroles (Fig. 37.1). These pyrroles are powerful alkylating agents that react with cellular proteins and cross-link DNA, resulting in cellular dysfunction, abnormal mitosis, and tissue necrosis. The primary effect is hepatic damage; however, many alkaloid and species-specific extrahepatic lesions have been described. Small amounts of pyrrole may enter the blood and be transported to other tissues, but there is debate on this issue because most pyrroles are highly reactive and not likely to make it into the circulation (Stegelmeier et al., 1999). When PA metabolites circulate, they probably do so as protein adducts that may be recycled. Some alkaloids (monocrotaline) may dissociate from their carrier proteins and damage other tissues such as the lungs. Pigs seem more prone to develop extrahepatic lesions.
FIGURE 37.1 Simplified schematic of the hepatic metabolism of pyrrolizidine alkaloids to the highly reactive pyrroles that result in liver damage.
Senecionine (15)
Heliotrine (16)

There are marked differences in susceptibility of livestock and laboratory animals to PA toxicosis. Cows are most sensitive, followed by horses, goats, and sheep, respectively. In small laboratory animals, rats are most sensitive, followed by rabbits, hamsters, guinea pigs, gerbils, and mice, respectively. Among avian species, chickens and turkeys are highly susceptible, whereas Japanese quail are resistant (Cheeke and Shull, 1985). Humans, especially fetuses, neonates, and children are particularly susceptible to DHPAs in herbal products, and many countries limit what a pregnant women should consume (Edgar et al., 2015).

Detoxification mechanisms of PAs generally involve the liver and GI tract. Evidence of ruminal detoxification in sheep suggests that this contributes to the reduced toxicity in that species. There are also substantial species-specific differences in the rate of PA metabolism. Both probably contribute to species susceptibility. For example, *Echium* and *Heliotropium* PAs are easily degraded by certain rumen microflora, but there is little evidence of ruminal degradation of *Senecio* PAs. The PAs in *Senecio* are macrocyclic esters of retronecine as opposed to the open esters found in heliotridine. Therefore, the reason for the difference in *Senecio* toxicity between sheep and cattle is unlikely to be the rumen detoxification but more likely differences in species-specific enzymatic activation of *Senecio* PAs. For example, in in vitro studies, retrorsine metabolism has been shown to be high in those species that are most susceptible and lowest in animals of least susceptibility

(Brown et al., 2015). In addition, in vivo studies demonstrated that a higher pyrrole production rate occurred in cattle compared with sheep (Cheeke and Shull, 1985). Simple induction of liver microsomal enzymes by phenobarbitone increased pyrrole production and increased PA toxicity (LD_{50} in guinea pigs from ≈ 800 to 216 mg/kg). PA toxicity may disrupt other hepatic functions. Abnormal copper metabolism, clotting factors, NH_3 metabolism, protein metabolism, etc., may be affected in PA poisoning.

Biomarkers of Poisoning (Liver Enzymes, AST, LDH, GGTP, Cirrhosis, Histology, Pyrrole Analysis of Liver)

Toxicity of *Senecio*, *Heliotropium*, and *Echium* is largely confined to the liver, whereas *Crotalaria* will also cause significant lung damage. Typical histologic lesions are swelling of hepatocytes, hepatocyte necrosis, periportal necrosis, megalocytosis (enlarged parenchymal cells), karyomegaly (enlarged nuclei) fibrosis, bile duct proliferation, and vascular fibrosis and occlusion. Hepatic cells may be 10−30 times normal size, and DNA content may be 200 times normal (Brown et al., 2015).

In most species affected by PA poisoning, the liver becomes hard, fibrotic, and smaller. Because of decreased bile secretion, bilirubin levels in the blood rise, causing jaundice. Common clinical signs include ill thrift, depression, diarrhea, prolapsed rectum, ascites, edema in the GI tract, photosensitization, and aberrant behavior. In horses, "head pressing" or walking in straight lines regardless of obstacles in the path may occur. These neurological signs in horses are due to elevated blood ammonia from reduced liver function. PA poisoning may cause elevated blood ammonia, resulting in spongy degeneration of the central nervous system.

Elevated levels of serum enzymes such as ALT, AST, γ-glutamyl transferase (GGT), and alkaline phosphatase (ALP) are reported (Stegelmeier et al., 1999). Use of these tests for diagnosis is supportive but should not be relied on exclusively because they vary with animal species and other conditions. They may also be in the normal range even though liver damage has occurred, and they tend to be transient. Liver function tests such as bilirubin, bile acids, or sulfobromophthalein (BSP) clearance may be useful estimates of the extent of liver damage.

The sulfur-bound pyrrolic metabolites of PAs have been detected in tissues of poisoned animals after hydrolysis with an alcoholic silver nitrate solution and detection either by colorimetric methods or by GC-MS (Mattocks and Jukes, 1990; Seawright et al., 1991; Winter et al., 1993; Schoch et al., 2000). Mostly recently a modification of these methods has been used for detection of

the sulfur bond metabolites using LC-MS (Lin et al., 2011; Brown et al., 2015). The pyrrolic metabolites also bind to DNA, which can be isolated, enzymatically hydrolyzed and then specific DNA base—pyrollic adducts detected by LC-MS (Fu et al., 2010).

Prevention and Treatment

There are no effective methods of prevention or treatment except avoidance of the plant and controlling plant populations with herbicides or biological control. Resistance to PA toxicosis in some species suggests that the possibility may exist to increase resistance to PAs. Dietary factors such as increased protein, particularly those high in sulfur amino acids, had minor protective effects in some species. Antioxidants such as Butylated Hydroxytoluene (BHT) and ethoxyquin induced increased detoxifying enzymes such as glutathione S-transferase and epoxide hydrolase (Mattocks and Jukes, 1990; Seawright et al., 1991; Winter et al., 1993). Zinc salts have been shown to provide some protection against hepatotoxicosis from sporidesmin or lupinosis in New Zealand and Australia, and zinc supplementation reduced toxicity in rats from *Senecio* alkaloids (Burrows and Tyrl, 2013; Knight and Walter, 2001).

Many of these plants were introduced either inadvertently or intentionally. Without natural predators to keep populations in check, they experienced explosive growth and distribution followed by epidemic proportions of toxicity. Introduction of biological controls and natural population controls has reduced many of the plant populations and thus toxicoses have declined. Sheep, a resistant species, have been used to graze plants, particularly *Senecio jacobaea*.

PHOTOSENSITIZING PLANTS

Numerous plants cause photosensitization resulting in lost production to livestock producers. Photosensitization is the development of abnormally high reactivity to ultraviolet radiation or natural sunlight in the skin or mucous membranes. Primarily induced in livestock by various poisonous plants, the syndrome in livestock has been defined as primary or secondary photosensitization.

Toxicology

Primary

In primary photosensitization, the photoreactive agent is absorbed directly from the plant and reaches the peripheral circulation and skin, where it reacts with the ultraviolet rays of the sun and results in sunburn, particularly of unprotected areas of the body. Hypericin (**17**) and fagopyrin are polyphenolic

derivatives from St. John's wort and buckwheat, respectively, and are primary photodynamic agents (Cheeke and Shull, 1985). By definition, primary photosensitization does not induce hepatic damage. Most agents are ingested, but some may induce lesions through skin contact. Several of these plants are weedy in nature and can contaminate pastures and feed. Exposure to some plants is increasing as they are becoming widely used as herbal remedies and naturopathic treatments. In most cases, the photodynamic agent is absorbed from the digestive tract unchanged and reaches the skin in its "native" form (Stegelmeier, 2002).
Hypericin (**17**)

Secondary

In secondary or hepatogenous photosensitization, the photoreactive agent is phylloerythrin, a degradation product of chlorophyll. Phylloerythrin is produced in the stomach of animals, especially ruminants, and absorbed into the bloodstream. In normal animals, the hepatocytes conjugate phylloerythrin and excrete it in the bile. However, if the liver is damaged or bile secretion is impaired, phylloerythrin accumulates in the liver, the blood, and subsequently the skin, causing photosensitivity. This is the most common cause of photosensitization in livestock (Knight and Walter, 2001). Because chlorophyll is almost always present in the diet of livestock, the etiologic agent of secondary photosensitization is the hepatotoxic agent.

The dermatologic signs of photosensitization in livestock are similar regardless of the plant or toxicant involved. Degree or severity varies, depending on the amount of toxin or reactive phylloerythrin in the skin, degree of exposure to sunlight, and amount of normal physical photoprotection (hair, pigmentation, or shelter). First signs in most animals are restlessness or discomfort from irritated skin, followed by photophobia, squinting, tearing, erythema, itching, and sloughing of skin in exposed areas (i.e., lips, ears, eyelids, udder, external genitalia, or white pigmented areas) (Burrows and Tyrl, 2013). Swelling in the head and ears (edema) of sheep after ingestion of *Tetradymia* has been

referred to as big head. It was determined that sheep grazing black sagebrush (*Artemesia nova*) before *Tetradymia* were three times more likely to develop this photosensitization (Johnson, 1974). Tissue sloughing and serum leakage may occur where tissue damage is extensive. Primary photosensitization rarely results in death. However, in secondary or hepatogenic photosensitization, the severity of liver damage and secondary metabolic and neurologic changes of hepatic failure may ultimately result in death. Recovery may leave sunburned animals debilitated from scar tissue formation and wool or hair loss.

Biomarkers of Poisoning (Bilirubin, Liver Enzymes, Skin Biopsies, History of Ingestion)

Identifying chronic hepatic disease is complicated because many of the serum markers for hepatic disease have returned to normal. As normal hepatocytes become replaced with fibrous connective tissue, there are fewer damaged cells to elevate serum enzymes. Percutaneous liver biopsies are invaluable in identifying and diagnosing these cases (Stegelmeier et al., 1999).

Plant-induced hepatopathy generally results in characteristic histologic lesions. For example, PAs generally cause bridging portal fibrosis with hepatocellular necrosis, biliary proliferation, and megalocytosis. *Panicum* and *Tribulus* species generally produce a crystalline cholangiohepatitis. Liver biopsy also provides prognostic information. The degree of damage is correlated directly with the animal's ability to compensate, recover, and provide useful production. Note that the liver reacts to insult in a limited number of ways, and most histologic changes are not pathognomonic. Hepatic cirrhosis (necrosis, fibrosis, and biliary proliferation) involves nonspecific changes that can be initiated by a variety of toxic and infectious agents (Stegelmeier et al., 1999).

Prevention and Treatment

Prevention of poisoning lies in controlling plants with photosensitizing potential and providing adequate quality forage to animals. Treatment after poisoning involves removing animals from sun exposure, treating areas of necrosis and sunburn, antibiotic therapy, and supplementing young animals when access to sunburned udders is prevented because of nursing discomfort to dams.

DEATH CAMAS

All death camas (*Zigadenus*) species are assumed to be toxic; however, variation in toxicity exists between species and even within species depending on season,

climate, soils, and geographical locations. Poisoning in sheep, cattle, horses, pigs, fowl, and humans has been reported. Because of their grazing habits, the largest losses generally occur in sheep. Death camas is generally not palatable to livestock but is one of the earliest species to emerge in the spring. Poisoning most frequently occurs in spring when other more palatable forage is not available, or on overgrazed ranges where there is a lack of more desirable forage. Poisonings have resulted due to management errors in which hungry animals were placed in death camas–infested areas (Panter et al., 1987).

Toxicity of Death Camas to Livestock

The toxins in death camas are of the cevanine steroidal alkaloid type—i.e., zygacine **(18)**. Zygacine is a very potent compound with an i.v. LD_{50} of 2 mg/kg and an oral LD_{50} of 130 mg/kg in mice (Welch et al., 2011b). Clinical signs of toxicosis are similar in all livestock poisoned by *Zigadenus*, irrespective of the species of plant involved. Excessive salivation is noted first, with foamy froth around the nose and muzzle that persists, followed by nausea and occasionally vomition in ruminants (Panter et al., 1987). Intestinal peristalsis is dramatically increased, accompanied by frequent defecation and urination. Muscular weakness with accompanying ataxia, muscular fasciculations, prostration, and eventual death may follow. The pulse becomes rapid and weak, and the respiration rate increases but the amplitude is reduced. Some animals become cyanotic, and the spasmodic struggling for breath may be confused with convulsions.
Zygacine **(18)**

Similarity in clinical signs of toxicosis between certain species of these plants suggests that the same alkaloids are present; however, differences in concentrations can explain the differences in relative toxicity of different species.

Biomarkers of Poisoning (Alkaloid Analysis of Serum, Liver, Pathology, History of Ingestion)

The heart fails before respiration, and at necropsy the heart is usually found in diastole. A comatose period may range from a few hours to a few days before death. Pathological lesions are those of pulmonary congestion. Gross lesions of sheep include severe pulmonary congestion, hemorrhage, edema, and subcutaneous hemorrhage in the thoracic regions. Microscopic lesions include severe pulmonary congestion with infiltration of red blood cells in the alveolar spaces and edema. Diagnosis of poisoning may be established by clinical signs of toxicosis, evidence of death camas being grazed, histopathological analysis of tissues from necropsied animals, and identification of death camas in the rumen or stomach contents (Panter et al., 1987). Zygacine has been detected in rumen content from field cases and in serum from sheep and mice experimentally dosed (Welch et al., 2011b, 2013b, 2016).

Management and Prevention

Conditions conducive to poisoning by death camas include driving animals through death camas–infested ranges; not allowing animals to graze selectively; unloading hungry animals in infested areas; lambing, bedding, watering, or salting livestock in death camas–infested areas; or placing animals on range where little forage is available. Poisoning generally occurs in the early spring when death camas is the first green forage available, and the young immature foliage is the most toxic. Single flock losses of 300–500 sheep have been reported (Panter et al., 1987). Three key factors contribute to sheep losses: (1) driving sheep through heavily infested areas of death camas when the sheep are hungry; (2) bedding sheep for the night near death camas–infested areas, providing immediate access to death camas the following morning; and (3) forcing sick sheep to travel will contribute to the stress, exacerbating the toxic effects and increasing the losses.

KNAPWEEDS: *CENTAUREA* SPP.

The knapweeds are a large group of plants with primarily noxious, invasive characteristics. Although this genus is not a great risk for livestock producers, a serious disease of horses called nigropallidal encephalomalacia warrants its inclusion in this chapter. There are 450–500 species of *Centaurea*, and 29 species have been described in North America (Burrows and Tyrl, 2013). Most of these have been introduced and have had a huge negative impact on rangelands in the western United States. Although most species are opportunists and will aggressively invade rangelands, especially those that have been overgrazed, burned, or disturbed, only two species are of any toxicologic significance— *Centaurea repens* (Russian knapweed) and *Centaurea solstitialis* (yellow star thistle).

Toxicology

The compounds isolated from knapweeds include a large class called sesquiterpene lactones. Although the putative toxin causing the neurological disease in horses has not been specifically identified, six of these compounds have been screened for cytotoxicity in an in vitro neuronal cell bioassay. The rank order of activity is repin (**19**) > subluteolide > janerin > cynaropicrin > acroptilin > solstitialin (Riopelle and Stevens, 1993). Toxicity of solstitialin A-13 acetate and cynaropicrin to primary cultures of fetal rat substantia nigra cells has been demonstrated. These sesquiterpene lactones are quite unstable, and it has been hypothesized that they are precursors to the ultimate neurotoxin. Also, there are aspartic and glutamic acids present in these plants, and they possess neuroexcitatory properties.
Repin (**19**)

Clinical Signs

Thus far, only yellow star thistle and Russian knapweed have been implicated in toxicoses in the United States, and only in horses (Panter, 1991). Apparently, ruminants are not affected, and the *Centaurea* spp. may be useful forage for sheep and goats. However, in other countries, toxicoses in ruminants have been reported. For example, in South Africa, *C. repens* fed to sheep at 600 g doses for 2 days caused an acute digestive upset and pulmonary edema and ascites. In Azerbaijan, *C. repens* is reported to cause a neurological disease in buffalo similar to that which has been described in horses. However, no neuropathology similar to that seen in

horses was observed in the buffalo. Toxicity generally occurs in summer and fall when forage is depleted and horses are forced to graze less palatable species. Ingestion often occurs for several months or more before an abrupt onset of neurological dysfunction is observed.

Often, the disease progresses to dehydration, starvation, and bizarre behavior, including submergence of the head in water to allow water to flow into the esophagus or lapping water like a dog. *C. repens* appears to be more toxic than *C. solstitialis*, but prolonged ingestion is required by both before disease appears. The amount of plant ingested to induce the clinical effects is reported to be 60% or more of body weight for *C. repens* and 100% or more of body weight for *C. solstitialis*. Intermittent grazing can prevent disease, indicating that there is not a cumulative effect but, rather, a threshold must be exceeded before neurological signs are observed (Cordy, 1978). Once neurological signs are observed in horses, prognosis for recovery is poor and euthanasia should be considered.

Biomarkers of Poisoning (History of Ingestion, Pathology Brain Lesions, Horses Only)

Impaired eating and drinking are often the first observable signs. Depression and hypertonicity of the lips and tongue follow, and a constant chewing may be observed, hence the name "chewing disease." Abnormal tongue and lip postures may be observed, and other neurological signs include locomotor difficulties such as aimless walking, drowsy appearance, and inactivity with the head held low. The neurological disease is considered permanent, and although some improvement may be seen, difficulty eating and drinking may preclude long-term recovery.

The lesions are very specific and limited to the globus pallidus and the substantia nigra (nigropallidal encephalomalacia), where distinct pale yellowish to buff-colored foci or softening and cavitation are seen (Cordy, 1978). The lesions are typically bilateral and symmetrical. This specificity of the lesions for the basal ganglia has prompted more investigations into unraveling the mysteries of human diseases associated with dopaminergic pathways, such as Parkinson's or Huntington's disease, and tardive dyskinesia. This disease in horses is often called equine Parkinsonism. This unusual disease is manifest by an almost immediate onset after prolonged ingestion, suggesting an all-or-none type of acute neurological crisis. The lesions develop quickly and completely, and progressive stages of degeneration rarely occur except for some changes in the adjoining neurons adjacent to the necrotic foci in the globus pallidus and the pars reticularis of the substantia nigra (Cordy, 1978). Microscopically, there is extensive necrosis of neurons, glia, and capillaries within sharply defined margins of the involved brain centers. Occasionally, lesions may be observed in the gray and white matter of the brain.

Prevention and Treatment

Good veterinary care and supportive therapy, including good feed, easy access to water, supplemental vitamins, and good nursing care, is essential for survival. Treatment of the disease once it is manifest is not generally successful. However, in Argentina, affected horses have been treated with glutamine synthetase and a bovine brain ganglioside extract given daily intramuscularly for 1 month with some success (Selfero et al., 1989). When animals are first observed grazing *Centaurea* spp., they should be immediately removed to better pastures. Prevention of the disease is easily accomplished by knowing the plants that exist in one's pastures, by providing good quality and adequate amounts of forages and feed, and by frequent observation of one's animal's grazing patterns and behavior.

Control of plant invasion by good range/pasture management to prevent overgrazing and loss of other competitive grasses and forbs is important. Herbicide control is quite easily accomplished with broadleaf products, including 2,4-D, dicamba, and picloram. These plants are prolific seed producers, and follow-up treatment is required to eliminate the populations. Seeds are often distributed through contaminated hay or other feed sources, and initial populations often start near feed bunks and spread from there. Because of their morphology, size, and parachute-like structures, seeds are easily spread by wind and water. Understanding one's weeds and close monitoring of populations will help in the control of these highly invasive species.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Even with our ever-increasing knowledge about poisonous plants and their toxins, poisonings continue to occur, some catastrophic, on livestock operations. Poisoning in humans and companion animals from toxic plants also continues to be a significant risk, especially to pets and children. Identification of specific biomarkers of poisoning from plants is relatively new and is often limited to pathology after the fact or chemical analysis of biological fluids or tissues. Research at the Poisonous Plant Research Laboratory continues to emphasize methods and biomarkers that will improve early diagnosis and ultimately reduce losses from poisonous plants.

Biomarkers of Drug Toxicity and Safety Evaluation

Arturo Anadón, María Rosa Martínez-Larrañaga,
Irma Ares, María Aránzazu Martínez

Department of Pharmacology and Toxicology, Faculty of Veterinary Medicine, Universidad Complutense de Madrid, Madrid, Spain

INTRODUCTION

The costs of drug research and development continue to increase, and the total number of approved drugs continues to decrease, down 50% since 1999. On the average, it takes 10–15 years to get one new drug from molecule to medicine because of the specific requirements for approval of new drug candidates. The low productivity crisis in pharmaceutical research and development suggests that the current paradigm of drug discovery and development used in the past 30 years is unsustainable. Some new approaches have improved the success rate; for example, approximately 50% of the drug failures were attributed to unacceptable pharmacokinetics (i.e., absorption, distribution, metabolism, and excretion) and toxicity. Hence, filtering and optimizing kinetics and toxicity properties in early stage of drug discovery are widely applied to reduce the high attrition rate. However, drug safety remains a major concern. The costs of bringing a single new drug to market now exceed $800 million (Adams and Brantner, 2010) as a consequence of substantial increases in the cost of clinical and preclinical studies, longer development times, and an increase in the number of failed drugs in late phases of drug development, in particular, phase III clinical trials, because of lack of efficacy and toxicity; furthermore, promising drug candidates are frequently pulled from development based on preclinical toxicities that are not readily monitored in humans.

Drug safety assessment is a complex process that involves many preclinical tests and clinical evaluations to ensure the highest level of drug safety profiles. Therefore, interpreting the interaction between drugs and genes, including drug–protein interactions, drug–micro-RNA (miRNA) associations, drug–single-nucleotide polymorphisms associations, among others events, is a critical stage to improve drug toxicity evaluation and enable precision medicine (Hong et al., 2010). These interactions or associations can appear at molecular, cellular, organ, and or organism levels.

Biomarkers are used in the drug development programs in both nonclinical species and in human beings to assess safety and efficacy of novel pharmacologically active substances. Therefore, development of new, predictive safety and efficacy biomarkers is expected to reduce the time and cost of drug development. Recent late-phase drug withdrawals for safety concerns, as experienced by a number of pharmaceutical companies, increase the pressure to change preclinical and early clinical safety testing. To improve drug safety and deliver better treatments to patients, it is critical to advance our understanding of mechanisms of toxicity and to apply new technologies, for example, molecular biomarkers, to the challenge of predicting drug safety and improving mechanism-based risk assessment to ensure the safe use of new pharmaceutical drugs. Industry and regulatory agencies expect that new and better toxicity biomarkers (also known as *safety biomarkers*) will play an important role in improving key aspects of the drug development process. Successful translation of many biomarkers into clinical practice is now increasing. However, as indicated previously, to be more efficient, considerable improvement in the use of novel technical tools (omics-based technology) for effective safety assessment is needed. Omics technology is now accepted as essential methodological part of systems or integrative biology, and it is possible to observe global changes of transcripts

(genomics), proteins (proteomics), or metabolites (metabolomics) in cellular systems or tissues.

To date in the pharmaceutical industry, safety biomarkers are applied both preclinically (for early detection of toxicity, the selection of the safest drug candidate, sensitive safety monitoring in regulatory toxicity studies, and selection of dosing regimens) and clinically (for translation into human studies, safety monitoring in late clinical phases, development of personalized health-care strategies, and postmarket safety surveillance) (Dieterle et al., 2010). In preclinical, the goal of using novel qualified predictive safety biomarkers is to assist in selecting drug candidates that are more likely to be tolerated in humans. Limitations of the current standards and a lack of adequate sensitive, specific, and easily accessible biomarkers in current clinical practice underscore the need for medical research aimed at developing novel safety biomarkers that are widely available. During lead discovery, a biomarker can assist in the screening of chemicals, based on the ability of the candidate molecule to modulate the activity of a specific process, such as a biochemical pathway.

Although biomarkers have been used in drug development and treatment of disease for a long time, the identification of new predictive safety and efficacy biomarkers is expected to reduce the time and cost of drug development. Biomarkers offer a means to affect rational drug design early in the development process and accelerate translation of drug development from animal to man. The analytical and clinical validity of biomarkers must be demonstrated using relevant clinical samples in drug development and clinical practice.

CLINICAL DRUG DEVELOPMENT

The objective of the clinical development is to bring about translation into human safety monitoring in late clinical phases, allowing the development of personalized medicine strategies and postmarket supporting safety. In clinical trials, biomarkers from blood and urine, together with a variety of imaging approaches, are often the only available sources to address concerns raised by histopathological analysis in preclinical safety studies. In clinical development, however, access to organ biopsies is in most cases not possible, and drug development decisions rely on conventional clinical diagnosis and biomarker measurements. It is important, therefore, that new safety biomarkers be able to reflect tissue changes that have historically been monitored using histopathology. Ideally, peripheral biomarkers could be correlated to the severity and time course of an organ-specific toxicity as detected by histopathology, show reversibility, and then be translated to early human studies.

Clinical drug development includes different segments: Phase I, II, and III clinical trials, pharmacokinetics,

pharmacodynamics, and studies to investigate special toxicities. Phase IV clinical trials for postmarket drug safety surveillance are conducted to identify and evaluate the long-term effects of new drugs and treatments over a lengthy period for a greater number of patients.

An initial set of studies, typically studies of appropriate length by the route intended for humans, is performed in both a rodent (typically rat) and a nonrodent (usually a dog or a primate). This is required to support Phase I clinical testing. During Phase I trials, a drug is tested in healthy volunteers (almost always males) to assess indication of toxicity, safety in terms of pharmacokinetics, the mechanism characterization of toxicity, general biological effects, and possible side effects and to define the tolerance (maximum tolerated dose). Phase II trials are conducted in volunteers who have the disease to determine the safety of the drug, the correct dosage (therapeutic efficacy), more details on pharmacokinetics and metabolism, and the short-term side effects. Phase I and Phase II are considered to be early clinical development. Efficacy and safety biomarkers need to be identified as early as possible in drug development (e.g., in Phase II or earlier) to incorporate their proper use in the late-phase trials for clinical validation and qualification. Phase III clinical trials (or late clinical development) confirm efficacy seen in Phase II trials. In the Phase III trials (which are large, long, and expensive), the drug is typically tested in double-blind, placebo-controlled trials to demonstrate effectiveness and establish the side effects and adverse events associated with use. Patient groups selected for Phase III trials are large and homogeneous to produce proof of safety and efficacy of the human drug. By the time Phase III testing is completed, some additional preclinical safety tests must also generally be in hand; these include the three separate reproductive and developmental toxicity studies and carcinogenicity studies in both rats and mice (unless the period of therapeutic usage is intended to be very short). Some assessment of genetic toxicity will also be expected (Gad, 2009). Based on all the data submitted to regulatory authorities for review, a human medicine is either accepted or rejected for approval.

During early clinical development, when fewer numbers of subjects are studied, the value of pharmacokinetics/pharmacodynamics (PK/PD) modeling is in its ability to quantitatively relate the dose with exposure and changes in biomarkers that are causally linked to clinical outcomes. In the last years, PK/PD modeling and simulation has been routinely applied during medicine research and development to help in the design, analysis, and interpretation of clinical trial data. Thus, PK/PD reasoning is likely to be a core discipline at all stages of medicine research and development in the near future. Clinical development of potential medicines has undergone a drastic change in recent years; early-stage testing

at present is geared toward "learning" about potential safety and efficacy dose-response of drugs and the later stage toward "confirming," in large trials, the acceptable safety and efficacy profile at one dose. Biomarkers, combined with PK/PD analysis, have played a key role in enabling this learn–confirm paradigm, which has made clinical development more efficient than before. In the next few years, drug discovery and preclinical development are also ready to undergo a similar change—experiments in highly unreliable animal models of diseases are likely to be replaced by ones more focused on learning about the target and disease pathways in animal models and human tissues. Biomeasures, combined with systems pharmacology analysis, will aid integration of the generated data into translatable models. Success of both these approaches will depend on the availability of reliable biomarker and biomeasure data such as -omics, receptor-level, and intracellular bioanalytical assays (Roskos et al., 2011). Systems pharmacology (i.e., pharmacological application of systems biology) integrates the classical pharmacology data with "omics" data, empowering construction of mechanism-based predictive models for application of biomarker-based drug safety assessment in drug discovery and development, as well as regulatory evaluation. The goal of biomarker-based drug safety assessment is to explore and characterize all biological mechanisms-mediating drug toxicity and side effects. Additionally, bioinformatics resources are of much interest for the development of predictive models for biomarker-based drug safety assessment. There are four main types of bioinformatics resources: (1) drug–target interactions, (2) drug side effects, (3) toxicogenomics, and (4) protein–protein interactions and biological pathways.

Application of Biomarkers in Postmarketing

If the drug is approved, additional postmarket or long after the drug approval (or Phase IV) studies may be required to ensure the product's safety in the general population. All approved human medicines are monitored by passive surveillance to determine adverse events and deviations in product quality. Serious and rare adverse effects of drugs are often observed only after marketing of the drug, as premarketing clinical trials are limited in the number of patients being studied. Information obtained postmarketing has resulted in recent labeling changes (e.g., carbamazepine [CBZ], warfarin).

The usefulness of a biomarker may also be discovered in studies performed in the Phase IV or during usual therapy. Adverse drug reactions (ADRs) are a major issue for clinical practice and include a wide variety of clinical toxic drug reactions. The term adverse reaction usually excludes nontherapeutic overdosage (i.e., accidental drug exposure) or lack of efficacy. According to the axiom of Paracelsus, all compounds are toxic at high doses and all are safe at very low doses (Borzelleca, 2000). Toxic and adverse effects of drugs may be classified as pharmacological, pathological, or genotoxic and their incidence and seriousness are related, at least over some range, to the concentration of the toxic chemical in the body. Many chemicals are not toxic themselves but are activated by transformation into toxic metabolites. The toxic response is then dependent on the balance of the rate at which the toxic metabolites are produced and destroyed.

Severe ADRs are often classified into two groups. The *first group* is dose-dependent and predictable on the basis of the drug's known pharmacological actions of the therapeutic drug (examples include bleeding induced by oral anticoagulants [i.e., warfarin], hypoglycemia induced by diabetic drugs, leukopenia induced by cytotoxic anticancer drugs, or convulsions produced by local anesthetics). These may occur within therapeutic dose ranges and those that are undesirable in a given therapeutic situation and often represent an exaggeration of the known primary and/or secondary pharmacology of the drug (i.e., side effects) or may occur with doses above the therapeutic range for a particular patient (i.e., overdosage toxicity). The phenotypes of the *second group* are not explained by the mode of action. These reactions are idiosyncratic, are unpredictable from the pharmacological action of the drug, and are not necessarily dose-dependent. This second group is responsible of nearly 10%–15% of the all ADRs, particularly idiosyncratic reactions, which include, for instance, severe cutaneous disorders, such as Stevens–Johnson syndrome (SJS) or toxic epidermal necrolysis (TEN), and injury to the liver caused by different drugs.

Genetic variants that cause susceptibility to a drug reaction loom large. The identification of such variants is expected to improve the management of patient care by determining which patients should avoid a specific drug and which patients should take a modified dose of the drug. Genes that are currently known to be associated with ADRs can be classified mainly into three categories: (1) drug-metabolizing enzymes, (2) drug transporters, and (3) human lymphocyte antigens (HLAs). Genes in the first two categories influence the PK/PD of drugs, and poor clearance of drugs from the body can increase the concentration of the drug to a toxic level and thus result in ADRs. For example, genetic variants in the genes encoding thiopurine *S*-methyltransferase and uridine diphosphate glucuronosyltransferase 1A1 are known to increase the risk of myelotoxicity associated with treatment with azathioprine and irinotecan, respectively (Chung et al., 2004). For the third category, the HLA-B*1502 allele is associated with serious dermatologic reactions (e.g., TEN and SJS to the tricyclic antidepressant drug CBZ, an anticonvulsant). CBZ developed SJS/TEN; studies illustrated a strong association between CBZ-induced SJS and the presence of

the HLA-B*1502 allele, rendering this allele in a small patient from Taiwan a risk factor (i.e., a predictive biomarker) (Hung et al., 2006). For these drugs are recommended that the relevant genetic tests be performed before the drug is prescribed. Another example of pharmacogenomics and drug toxicity is with statins. A strong association has been described between myopathy and two tightly linked variants in the *SLCO1B1* gene in patients consuming simvastatin (Pasanen et al., 2006), as well as polymorphisms in some solute transporter genes associated with altered hepatic uptake of pravastatin, indicating that genetic variations in *SLCO1B1* might affect the variability of outcomes in patients treated with statins. A variant of *SLCO1B1* was found in a patient with pravastatin-induced myopathy (Morimoto et al., 2004). Warfarin is another example, in which a significant proportion of variation in the PK/PD between patients influences the anticoagulant response from a fixed dose. Variability has been linked to the genetic variants of CYP2C9 and VKORC1 (Schwarz et al., 2008).

The various circumstances of drug toxicity can be summarized as follows: (1) *toxicity on target* (or mechanism-based) toxicity (i.e., toxicity due to interaction of the drug with the same target that produces the desired pharmacological response); (2) *hypersensitivity and immune responses* (e.g., allergic responses); (3) *off-target toxicity* (i.e., the drug is not specific in its interactions; binding to an alternate target is the cause of toxicity). One example is the terfenadine, which binds to H_1 receptor, eliciting the desirable antihistaminic response and to the hERG channel, causing arrhythmias; (4) *bioactivation* (i.e., some drugs are converted to reactive metabolites); and (5) *idiosyncratic reactions* (Guencherich, 2011).

The context of idiosyncratic reactions is individual and they are usually rare $(1/10^3-1/10^4)$. At least five theories have been proposed to explain these reactions: The *first theory* involves polymorphisms or rare alleles of metabolism enzymes. The concept is that sensitivity is due to lack of (or too much) metabolism of a drug, including a lack of detoxication (e.g., having ultrarapid metabolizers in the P450 2D6 group) and also being deficient in a glutathione (GSH) transferase or other enzymes to detoxify the medicinal product, occurring in approximately 1% of Caucasian population. The *second theory* is the hapten formation. Some individuals show more activation of a drug to yield a hapten and the variation in the immune systems of individuals will dictate that only a few will show this response (Uetrecht, 2007). The *third theory* is sometimes referred to as the inflammagen model (Ganey et al., 2004). It is theorized that the bioactivation and other events occur in many people and that inflammation (or other predisposing episodes) render only some individual more sensitive. The *fourth*

theory is the danger hypothesis. Injured tissue produces danger signals (e.g., lipid oxidation products, cytokines) that evoke a toxic response, not the drug or its metabolites. The *fifth theory* is the pharmacological intervention model (Gerber and Pichler, 2004). In this model, drugs elicit immunological responses by reversible binding to protein (i.e., without covalent binding). One basis for this model is the formation of reactive metabolites.

Among ADRs, hepatotoxicity and nephrotoxicity are two major reasons that drugs are withdrawn postmarket in part because of the failure of animal safety studies to translate to human safety of a new chemical entity. Thus, there is need for new efficient biomarkers that can translate effectively. Additionally, personalized medicine biomarkers can be used to predict whether that individual will respond favorably or adversely to a drug or medical therapy. Metabolomics can play a role in providing translational biomarkers for organ injury and for predicting a susceptible subset of the population that should avoid specific drugs. Metabolomics refers to "the measurement of the metabolite pool that exists within a cell under a particular set of conditions" (Fiehn, 2002), and metabonomics describes "the quantitative measurement of the dynamic multiparametric metabolic response of living systems to pathophysiological stimuli or genetic modification" (Nicholson et al., 1999). Metabolomics and metabonomics are metabolic profiling methods that offer the opportunity to identify biomarkers or patterns of biomarker changes related to drug toxicity in biofluid samples, such as urine and blood, which can be collected with relative ease. Moreover, it is possible by measuring the gene expression patterns before and after compound treatment to study interactions between structure and activity of the whole genome and adverse biological effects with exogenous stressors (Aardema and MacGregor, 2002). Genes that consistently exhibit increased or decreased expression during these toxic responses in model systems serve as biomarkers to predict potential adverse preclinical outcomes. The overall aim of toxicogenomics analysis is the identification of the mode of action by which a compound induces a toxic/adverse effect (Edwards and Preston, 2008). In addition to the identification of characteristic molecular pathways, it has been reported that specific transcripts can be used as mechanistic or predictive biomarker for organ-specific toxic alterations (Zidek et al., 2007).

INTEGRATION AND USE OF SAFETY BIOMARKERS IN DRUG DEVELOPMENT

Safety biomarkers can be used to predict, detect, and monitor drug-induced toxicity during both preclinical studies and human trials. Unlike techniques for histopathology, blood and urine biomarkers are noninvasive

but remain quantifiable and of translational value. The recognition by both the pharmaceutical industry and regulatory agencies that toxicological biomarkers may have much to offer in helping to bring safe drugs to the market being a reality. Biomarker measurements reflect the time course of an injury and provide information on the molecular mechanisms of toxicity (Boekelheide and Schuppe-Koistinen, 2012). In addition, biomarker measurements support target validation and proof of target, mechanism, and efficacy, and they are being developed first in preclinical animal models of disease; the majority of biomarker research is done in clinical trials that test cancer drugs, which represent the single largest therapeutic class of drug in development. There are actually a number of guidelines and recommendations from regulatory agencies on validation of bioanalytical methods, in particular for measuring drugs or metabolites, as well as published guidance from the US Food and Drug Administration (FDA) and European Medicines Agency (EMA) dedicated to genomic biomarker assays.

Biomarkers have been used in clinical diagnosis and drug development for decades to measure physiological parameters such as blood pressure, heart rate, body temperature, and urine color, as well as clinical chemistry parameters such as enzymes in blood and urine, serum creatinine levels, and urinary glucose. Examples are the appearance of glucose and albumin in urine with hyperglycemia as biomarkers of diabetes, and blood pressure and cholesterol reduction as biomarkers that have attained a status as surrogate endpoints for drug approval because they are clearly linked to mortality resulting from heart attack and stroke (Temple, 1999). Currently, biomarkers are being developed to identify patients at disease risk and to predict potential treatment responders, adverse event occurrences, and favorable clinical outcomes for many disease states, especially cancer.

Advances in molecular biology and analytical technologies have enabled the discovery of novel biomarkers that include individual genes, transcripts, proteins, and endogenous metabolites (including lipids) and their associated patterns of expression. The use of novel, but less well-established, pharmacodynamics biomarkers can further facilitation decision-making from discovery through preclinical development and into clinical trials, whereas rapid advances in genomics and proteomics have increased the discovery of new biomarkers and their value in drug development and treatment of disease. Other examples include the use of imaging patterns, electrical signals, and cell levels in body fluids to identify potential concerns (Boekelheide and Schuppe-Koistinen, 2012).

The effective integration of biomarkers into clinical development programs, with the objectives of enriching a responder population or identifying patients at risk for an adverse event, is essential; it may facilitate new medicinal product development and promote personalized medicine.

Application of Safety Biomarkers in Different Phases of Drug Development

During the discovery phase, there are several opportunities for in vivo toxicity assessment. Toxicological biomarkers are important in all phases of drug development, including discovery, preclinical assessment, clinical trials, and postmarket surveillance. During the toxicity studies, traditional biomarkers utilized for toxicity assessment, for instance, are physiological measures, clinical hematology and biochemical parameters, macroscopic and microscopic tissue assessment, and specific biomarkers of potential issues identified during target validation and through in vitro indicator assays, which can be estimated in the context of in vivo exposures. Additionally, there is an opportunity to assess the potential for unexpected compound-related toxicity in animal disease models, for which the systemic effects of a disease process may lead to aggravation of toxicity (Boelsterli, 2003).

Pathology, including all the aspects of anatomic (histopathology), clinical chemistry, and clinical pathology (hematology), is generally considered the single most significant portion of data to come out of systemic toxicity studies (particularly the repeat dose, with versions from 14 days to 2 years in duration). Anatomic pathology evaluations actually consist of three related sets of data (gross pathology observations, organ weights, and microscopic pathology) that are collected during termination of the study animals. At the end of the study, a number of tissues are collected during termination of all surviving animals (test and control). In toxicology, histopathology remains the "gold standard" for safety assessment during the preclinical phase of drug development, permitting researchers to identify the type, localization (i.e., target organ), and severity of organ lesions being a sensitive technique that conveys large amounts of information on the spatial and temporal relationship of toxicological processes. Organ weights and terminal body weights are recorded at study termination so that absolute and relative (to body weight) values can be statistically evaluated. The problem existing with histopathology as the only approach to evaluating tissue injury is that it is very costly in terms of animals and time and therefore interferes with the ability to extend drug screening. Bindhu et al. (2007) have provided a review of practices of how such organ weight information is evaluated and utilized in the overall evaluation of pathology and adverse effects. In general, with the exception of brain

weights, relative (to body weight) changes are considered more relevant to identifying target organ toxicities. The evaluation of the pathological changes induced in laboratory animals by new drugs represents the cornerstone of their safety assessment before they can be first tried in patients. This preliminary assessment, which is based largely on conventional histopathological techniques, represents a major contribution to the development of new treatments for both human and animal diseases. The basic model of the dosing laboratory with various dose of new drug for increasing periods of time, accompanied by careful clinical observations, biochemical and hematological monitoring, followed by histopathological examination of the tissue, remains essentially unaltered.

Histopathology has particular limitations as a gold standard in the translation of preclinical animal-based safety studies to the clinical testing of a new drug. Although pharmaceutical companies rely on a variety of biochemical, mechanistic, molecular, and physiological datasets in the development of a new drug, histopathological analysis of animal studies remains a key contributor to the decision about safety, despite the known limitations of these data (Olson et al., 2000). Histopathology analysis lacks the quantitative objectivity inherent in biomarkers; while biomarkers are measured with the evolving new technologies, histopathology remains at the discretion of individual pathologists. Other considerations are the impact of variability in histopathology methods on biomarker qualification. Burkhardt et al. (2011) pointed out in a study documented by four different pathologists who evaluated slides (blinded and nonblinded) the interpathologist variation as a source of variability to alter the biomarker interpretation. The pathologist is required not only to evaluate alterations to organs and tissues and any relationship that they might have to drug treatment but also to assess the likely relevance any treatment-related finding they might have for patients (Gad, 2009).

The role of biomarkers in the preclinical safety gives the lie to the assessment of indication of toxicity, the mechanism characterization of toxicity, and defining the maximum tolerated dose. It is pivotal to determine the relevance of biomarkers in each preclinical species: the correlation of safety markers with PK/PD data allows the refinement of drug formulation, administration, and dosing/schedule schemes.

TRADITIONAL INDICATOR FOR DRUG TOXICITY ASSESSMENT

Traditional indicators of target organ toxicity used in drug preclinical safety studies consist of a battery of clinical pathology parameters in blood and urine coupled

TABLE 38.1   Standard Clinical Pathology Measures in Fluids

Clinical Chemistry	Albumin, alkaline phosphatase, bilirubin, blood urea nitrogen, calcium phosphorus, chloride, creatinine, creatine kinase, gamma-glutamyltransferase, globulin, glucose, alanine aminotransferase, aspartate aminotransferase, lactate dehydrogenase, total bilirubin, total cholesterol, total protein, triglycerides, electrolytes (Na, K, Cl), glucose, bile acids, total CO_2.
Hematology	Red blood cell count, hemoglobin, hematocrit or packed cell volume, erythrocytic indices (mean corpuscular hemoglobin, mean corpuscular volume, mean corpuscular hemoglobin concentration, red cell distribution width), platelet count, mean platelet volume, prothrombin time, reticulocyte count, white cell count, white cell differential count, activated partial thromboplastin time.
Urinalysis	Color, clarity, volume, specific gravity or osmolality, pH, bilirubin, urobilinogen, glucose, occult blood, phosphorus, total protein, electrolytes (Na, K, Cl), nitrites, ketones, creatinine, microscopic sediment.

with histopathological examination of altered tissues. Table 38.1 lists the clinical pathology parameters often measured in multidose toxicity studies.

Several analytes and enzymes are used to assess the integrity and the function of organs (Lanning, 2006). However, it should be highlighted that changes in clinical pathology parameters must be interpreted in the context of understanding of pathophysiology and the known effects of the drugs tested. Some of these enzymes and analytes are briefly described in the following sections.

Alkaline Phosphatase

Alkaline phosphatase (AP) is composed of several isoenzymes that can hydrolyze organic phosphatase ester bonds in an alkaline medium, giving rise to an organic radical and inorganic phosphate. These isoenzymes are present in practically all tissues of the body, especially at or in the cell membranes; there are specific forms of AP in liver, bone, intestine, placenta, and kidney. However, the predominant forms present in normal serum are the liver and bone forms. In addition, normal young growing animals have serum AP activities up to three times higher than those in normal mature animals (Stockham and Scott, 2002). In addition, during pregnancy, serum AP levels rise two- to fourfold by the ninth month and return to normal by 21 days postpartum. It appears that the AP is associated with lipid transport in the intestine and liver and calcification in the bone. AP increases markedly in diseases that impair bile formation (cholestasis) and to a lesser extent in hepatocellular disease. The three major causes of high serum AP

activity are induction of hepatic AP (i.e., intrahepatic or posthepatic cholestasis), induction of hepatic AP release (i.e., iatrogenic corticosteroids, phenobarbital, hyperadrenocorticism), and increase of osteoblastic activity (i.e., fractures).

Creatine Kinase

Creatine kinase (CK) is a leakage enzyme, and increased serum values occur with reversible and irreversible damage; high serum CK values are indicative of active or recent muscle injury or damage.

Aminotransferases

These enzymes, including alanine aminotransferase (ALT) and aspartate aminotransferase (AST), are blood indicators of hepatocyte damage, which have been used for decades in preclinical studies and for clinical monitoring of adverse effects. ALT is reliable for routine screening for liver injury or disease, whereas AST is present in skeletal muscle and heart and most commonly associated with their damage. AST is relatively nonspecific, but high levels indicate liver cell injury. These enzymes leak out of the hepatocyte cytosol when the plasma membrane permeability is altered. The magnitude of ALT increases in liver damage or disease is greater than that of AST. Serum aminotransferases and AP are common indicators of hepatocellular and hepatobiliary injury, respectively.

AST is not only found in the liver but also in the muscle. Therefore, in case of a compound suspected to create lesions of the muscle, other enzymes such as sorbitol dehydrogenase (SDH) (liver-specific) and CK (muscle and brain) could be used to differentiate the source(s) of AST. SDH is quite sensitive but is fairly unstable, so samples should be processed as quickly as possible.

Lactate Dehydrogenase

Lactate dehydrogenase (LDH) is a hydrogen transfer enzyme that is found in the cytoplasm of most of the cells of the body. LDH, commonly included in routine analysis, is insensitive as an indicator of hepatocellular injury. The peak of the increase in serum LDH values is usually observed within 48–72 h and tissue levels of LDH are about 500 times greater than normal serum levels. Causes of increased serum LDHs include muscle damage or necrosis, hemolysis, liver disease, renal tubular necrosis, pyelonephritis, and malignant neoplasia.

Bilirubin

Bilirubin is the yellow breakdown product of normal heme catabolism and is measured to assess liver damage. Hyperbilirubinemia results from increased bilirubin production, decreased liver uptake, or conjugation or decreases biliary excretion; it is often seen prior to increases in serum total bilirubin. Typically, increased total bilirubinemia is accompanied by enhanced Alanine aminotransferase (ALP) (Stockham and Scott, 2002). It is known that (1) increases in serum total bilirubin may be due to increased hemoglobin destruction (i.e., hemolytic hyperbilirubinemia) or liver damage (i.e., obstructive hyperbilirubinemia) and (2) increased serum total bilirubin is an early indicator of cholestasis or hepatopathy. Serum bilirubin may not be a particularly sensitive index of liver dysfunction or disease prognosis.

Creatinine and Blood Urea Nitrogen

Serum creatinine can provide similar information to blood urea nitrogen (BUN) in renal disease or postrenal obstruction or leakage. It is freely filtered through the glomerulus; however, small amounts are reabsorbed by renal tubules and secreted by the proximal tubules. Creatinine also estimates blood filtering capacity of kidney, as BUN does, but is more specific than BUN. Creatinine levels are also increased by reduced renal perfusion. Creatinine clearance may also be measured and is considered to be an accurate index of glomerular filtration rate (GFR) but BUN estimates blood filtering capacity of the kidneys (i.e., it is significantly elevated until kidney function is reduced 60%–75%). Serum creatinine and BUN are commonly used markers of the renal clearance of nitrogenous waste and thus of the kidney function, whereas creatinine serum levels are modulated by muscle mass, age, dehydration status, and extrarenal clearance (gut). The FDA (2008) accepted BUN and serum creatinine in rat kidney safety assessment studies that use histopathology as the gold standard.

A significant proportion of creatinine (up to 25% in healthy human) is secreted by the tubuli into urine and is not filtrated by the glomeruli. Furthermore, serum creatinine and urea levels are influenced by nonrenal sources (protein supplementation) and other adverse effects, including changes in protein synthesis and catabolic states resulting from lesions of the muscle. Urea is the primary end product of protein catabolism in most species and is freely filtered at the glomerulus, but it is equally freely diffusible out of the tubule, and a highly variable but significant amount (40%–70%) reenters the extracellular fluid (and ultimately the plasma). The rate of urea production does not constantly increase with a high-protein diet and with enhanced tissue breakdown due to hemorrhage, trauma, or glucocorticoid therapy; in addition, a chronic or an abruptly absent adequate food supply or intake increases BUN

(Urbschat et al., 2011). In comparison, a low-protein diet and/or advanced liver disease can lower the BUN without change in GFR, despite an already existing reduction in GFR (Proulx et al., 2005). The extent of urea reabsorption is in general in inverse proportion to tubular flow rates.

Plasma Proteins

The proteins as α- and β-proteins, albumin, and clotting factors (but not γ-globulin) are synthesized in the liver. Albumin is the most abundant protein in blood plasma (comprises about half of the blood serum protein) and is the major determinant of plasma oncotic pressure and transports numerous substances; its serum concentration is determined by (1) the relative rates of its synthesis and degradation or loss, (2) its distribution between the intra- and extravascular beds, and (3) the plasma volume. Albumin detects tubular injury and is most commonly used because it is the highest level protein in urine. Albumin is also the protein most likely to be found at increased levels early with a variety of renal disorders, in particular with glomerular injury, although it is not a specific marker for any one site. Normally, serum total protein concentration is in direct proportion to the serum albumin concentration. The size and negative electric charge of albumin exclude it from excretion in the glomerulus. These serum proteins and some others increase nonspecifically in response to tissue injury (e.g., inflammation) with the release of cytokines.

Total protein alterations are generally associated with decreased production (liver) or increased loss (kidney). Total protein (a classical biomarker for the glomerular filtration membrane) is the ensemble of all protein species measured together. Large and strongly charged proteins are not filtered by the glomerulus, but the small proteins go free through the glomerular barrier and become reabsorbed by the proximal tubular. Proteins appeared in the urine result from damaged nephrons. In urine, the abnormally high excretion of proteins is called proteinuria and has been highlighted in the literature as (1) a clinical prognostic marker, (2) a preclinical and clinical diagnostic marker to detect acute kidney injury (AKI), and (3) a factor predicting progressive loss of renal function in the context of a variety of diseases (Chesney et al., 1981; Diamond and Yoburn, 1982; Herget-Rosenthal et al., 2004a,b; Polkinghorne, 2006; Richmond et al., 1982). However, in the setting of early AKI, proteinuria does function as a suitable biomarker. This is strengthened by several aspects: classical AKI is not accompanied by proteinuria/albuminuria; therefore, proteinuria would not be a marker in the course of recovering from AKI (Urbschat et al., 2011). Alterations of the glomerular filtration barrier, such as damage of the glomerular podocytes, lead to leakage of plasma proteins into the ultrafiltrate (Schmid et al., 2003).

The normal glomerular filtrate contains 10 mg protein/L, but only approximately 1% is normally present in the urine because of the strong reabsorption capacity of the proximal tubule. If this reabsorption reaches a saturation point due to excessive glomerular damage/leakage with an often observed associated "poisoning" of the proximal tubules or if the tubular protein reabsorption complex is directly damaged by toxic agents, proteinuria can be observed despite normal GFRs (Guder and Hofmann, 1992).

A number of recent publications highlight the diagnostic power of total protein for AKI induced by nephrotoxicants, such as cisplatin, thalidomide, pamidronate, aminoglycosides, ifosfamide, doxorubicin, or nonsteroidal antiinflammatory drugs (Benoehr et al., 2005; Desikan et al., 2002; Guo and Nzerue, 2002; Koerbin et al., 2001; Zomas et al., 2000).

Total Protein

This is a classical biomarker for the glomerular filtration membrane measured in the urine. Alterations of the glomerular filtration barrier, such as the damage to the glomerular podocytes, result in leakage of plasma proteins into the ultrafiltrate. If the reabsorption of proteins reaches a saturation point due to excessive glomerular damage/leakage with an often observed associated "poisoning" of the proximal tubules or if the tubular protein reabsorption complex is directly damaged by toxic agents, proteinuria can be observed despite normal GFRs (Guder and Hofmann, 1992). Total protein is used in the AKI diagnostic for a known number of nephrotoxicant drugs such as cisplatin, thalidomide, pamidronate, aminoglycosides, ifosfamide, doxorubicin, or nonsteroidal antiinflammatory drugs.

Gamma-Glutamyltranspeptidase

Gamma-glutamyltransferase (GGT) is present in the liver, pancreas, and kidney. GGT is elevated in cholestasis, and the liver levels of this microsomal enzyme are increased in response to microsomal enzyme induction. Likewise, anticonvulsant drugs have been shown to elevate the GGT and AP activities in preclinical species and humans in the absence of histological evidence of hepatic injury (Mendis et al., 1993).

Hydroxybutyrate Dehydrogenase

Hydroxybutyrate dehydrogenase (HBDH) is a cardiac biochemical marker. The patient's high level of HBDH indicates myocardial infarction.

TABLE 38.2 Existing Biomarkers of Clinical Pathology

Biomarkers	Use	Limitations
Serum creatinine[a]	To detect kidney toxicity in preclinical and clinical studies; routine clinical care	Sensitivity and specificity: Poor sensitivity and specificity for detection of renal injury. Limitation for estimating glomerular filtration rate. Insensitive for detection of histological injury in preclinical toxicity studies and humans.
Blood urea nitrogen[a]	To measure renal function	Poor sensitivity and specificity for detection of renal injury. Limited ability to monitor drug toxicity in humans.
Urinalysis	To identify a renal toxicant	Relatively primitive and the reliability of the results correspond with the methods employed.

[a]Not very sensitive or specific to detect acute kidney injury because of the fact that they are affected by many renal and extrarenal factors.

Lactate Dehydrogenase

Lactate dehydrogenase (LDH) is a hydrogen transfer enzyme that is found in the cytoplasm of most of the cells of the body. The peak of the increase in serum LDH values is usually observed within 48–72 h. Causes of increased serum LDH comprise muscle and liver damage, renal tubular necrosis, pyelonephritis, and malignant neoplasia; this enzyme is not very specific unless isozymes are evaluated.

Sodium, Potassium, and Chloride

These ions are measured to assess the electrolyte status. Electrolyte gain or loss can occur in the gastrointestinal tract (e.g., dietary intake, loss of saliva, gut stasis, diarrhea, vomiting), kidney (e.g., lack of antidiuretic hormone, excess or lack of aldosterone, tubular disease), lung (e.g., hyperventilation, febrile episodes), and skin (e.g., sweat, febrile episodes). Sodium is the major cation of extracellular fluid and is essential in the maintenance of water distribution and osmotic pressure. In acute renal failure, the fractional excretion of sodium is the most accurate screening test to differentiate between prerenal and intrarenal disease origin (e.g., a value below 1% suggests prerenal disease) (Urbschat et al., 2011). Potassium is the major intracellular cation and is the critical ion in maintaining ionic gradient for neural impulse transmission. Chloride is the major extracellular anion and is regulated passively by gradients derived from active sodium transport across cell membranes; like sodium, chloride is involved in water distribution, osmotic pressure, and anion–cation balance in the extracellular fluid compartment. The serum chloride concentration is directly proportional to the sodium concentration.

Urinalysis

The analysis of urine should be performed in any toxicological study, particularly in rodents when the test material is suspected to be a renal toxicant. The urinalysis provides a unique opportunity to selectively and noninvasively sample a single target organ by examination of its end product. The results, which should be interpreted along with histopathology results, can be effective in determining whether the kidney is functioning properly or if its capacity has been overcome. As a minimum, the general appearance, specific gravity, acidity, protein, glucose, ketones, bilirubin, urobilinogen, and cellular content/morphology (microscopic) should be measured. The urine volume, combined with assessment of urine concentration (specific gravity or osmolality), can serve as an index to renal function. The uses and limitations of some existing biomarkers of clinical pathology are listed in Table 38.2.

BIOMARKERS OF DRUG LIVER TOXICITY

Drug-induced adverse liver effects as drug-induced liver injury (DILI) are frequent events that appeared in nonclinical and/or clinical studies during the development of new drug entities. The detection of hepatotoxicity alerts is a continuous process covering all drug development phases, and the identification of a hepatotoxic potential in nonclinical studies has frequently resulted in delayed or discontinued development of drug candidates. DILI is the most common adverse event causing withdrawal of approved drugs and postmarketing regulatory decisions and is associated with significant mortality. Metabolic activation of drugs is an important mechanism in DILI.

To date, standard nonclinical toxicity studies remain the cornerstone of the prediction of hepatotoxicity in humans. However, new approaches and the refinement of existing methods are necessary to improve prediction of DILI in humans. Various promising investigative approaches are currently being evaluated for potential screening purposes or use on a case-by-case basis, following hepatotoxicity alerts in standard nonclinical toxicity studies. Furthermore, a number of industry/academic/regulatory consortia are assessing the utility

of new approaches. These consortia are among others operating under the Innovative Medicines Initiative (IMI) and the C-path and International Life Sciences Institute (ILSI)/Health and Environmental Sciences Institute (HESI) institutes. HESI qualified two biomarkers of drug-induced nephrotoxicity in rats, urinary clusterin and renal papillary antigen 1 (RPA-1), with FDA. RPA-1 was qualified by FDA for voluntary use in detecting acute drug-induced renal tubule alterations, particularly in the collecting duct, in male rats when used in conjunction with traditional clinical chemistry markers and histopathology in Good Laboratory Practice (GLP) toxicology studies for drugs for which there is previous preclinical evidence of drug-induced nephrotoxicity or where it is likely given the experience with other members of the pharmacologic class.

The liver is the primary responsible organ for drug metabolism using phase I and phase II and thus is exposed to drugs and metabolites rapidly after gastrointestinal absorption. Many liver cytochrome P450 enzymes can be either activated or suppressed by bioactive nutritional components or other drugs and these interactions can affect the drug metabolism and clearance from the liver. Hence, metabolic status may be a significant element in determining whether a toxic reaction occurs in the liver and if so, the capability of the patient to overcome the insult. The metabolism, which is intended to inactivate xenobiotics, can also lead to the formation of toxic, reactive metabolites, which can impair cellular functions. Reactive metabolites can bind to macromolecules and different structures within the cell, leading to loss of protein function, perturbation of lipid metabolism, DNA damage, and oxidative stress and for that several biomarkers have been proposed (Fig. 38.1). In addition, other

consequences of xenobiotic hepatotoxicity are known, such as inhibition of hepatic transporters, inflammatory processes, bile duct hyperplasia, and hepatic tumors. Selective serum markers of apoptosis, necrosis, and inflammation would have benefit for differentiating the fundamental mechanisms of DILI.

The gold standards used to monitor hepatotoxicity are the serum liver transaminase enzymes ALT and AST. Changes in the ALT serum levels indicate hepatocyte necrosis with high sensitivity and fairly good specificity. The specificity and sensibility of ALT and AST are limited as there is a lack of correlation of liver enzyme changes and the observable histopathological damage. Therefore, the increases of serum ALT levels are not often correlated with liver histomorphologic alteration.

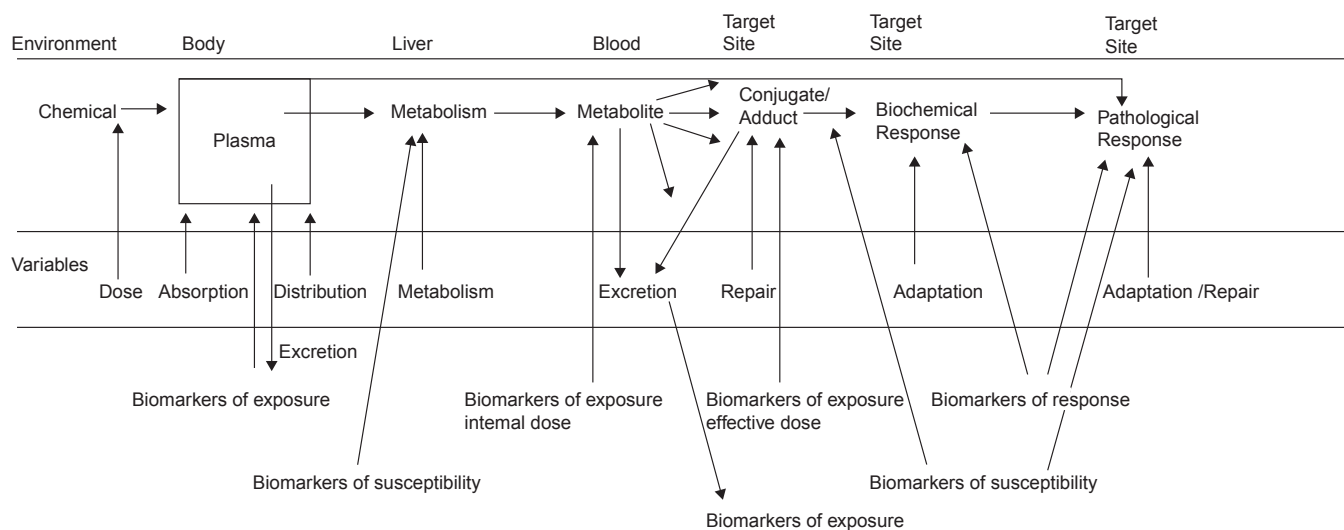
Some candidate drugs may cause isolated adverse liver effects in humans that are not predicted from nonclinical studies. This type of DILI is termed *idiosyncratic*. The mechanism of human idiosyncratic liver effects appears to include an interaction of genetic and nongenetic factors that are not reproduced in standard nonclinical toxicity studies (Ulrich, 2007; Walgren et al., 2005). Retrospective analysis of nonclinical data has provided no evidence that idiosyncratic drug-induced hepatotoxicity in humans could have been predicted from nonclinical toxicity data (Kaplowitz, 2005; Ong et al., 2007; Peters, 2005). Given the current understanding that idiosyncratic drug reactions are rare, human-specific, and most often dose-independent events, it should be emphasized that an improved prediction of idiosyncratic hepatotoxicity may not be achievable on the basis of nonclinical toxicity data. It is conceivable that improved detection and prediction of idiosyncratic DILI may be achieved in the future by new predictive biomarkers and/or in vitro and/or


FIGURE 38.1   The biomarker paradigm for metabolism of drugs.

in vivo models, which are currently not available and/or validated. Approaches of individual companies and international collaborative research initiatives aiming at incorporating promising innovative tests into the regulatory requirements are continuing (Evans et al., 2004).

Biomarker for Monitoring Liver Injury

The best characteristics of hepatic damage biomarkers include organ specificity for liver, strong correlation with well-defined hepatic histomorphologic changes, outperformance of or added information to ALT and/or AST values, adaptation of screening assays to high-throughput modalities that are commercially available, and sample accessibility by noninvasive procedures such as blood collection (Ozer et al., 2008). Preclinical assays currently include some combination of serum ALT, AST, AP, GGT, SDH, total bilirubin, and bile acids among others.

ALT is a biomarker for hepatocyte injury, but its blood level can increase for a variety of reasons; thus, its value alone is not a reliable biomarker for liver injury. On that basis, the pharmaceutical industry and regulatory agencies have invested much effort toward discovering novel biomarkers that are organ-specific and benefit both preclinical and clinical studies.

It is known that blood-borne mRNA species were elevated at low doses of hepatotoxicants that did not cause changes in the classical biomarkers of liver injury, such as ALT and AST. Moreover, at higher doses, the mRNA species were elevated earlier than the classical biomarkers (Mendrick, 2011).

Alanine Aminotransferase and Its Two Isoforms

Alanine aminotransferase (ALT) is the clinical chemistry gold standard for detection of liver injury or hepatotoxic effects. Although the overall clinical utility of serum ALT measurements is exceptional, it does not always correlate well with preclinical histomorphologic data. Damaged hepatocytes release their contents including ALT and AST into the extracellular space. The ratio of serum AST to ALT can be used to differentiate liver damage from other organ damage (Ozer et al., 2008). ALT levels are greater than AST levels in certain types of chronic liver disease, for example, in hepatitis.

Two forms of ALT have been identified, ALT1 and ALT2, encoded by separate genes. In normal human tissue, high expression of ALT1 was found in liver, skeletal muscle, and kidney and low levels in heart muscle and not detectable in pancreas. High ALT2 activity was detected in heart and skeletal muscle, whereas no ALT2 expression was found in liver or kidney (Lindblom et al., 2007). As with the liver, the traditional markers of AST and CK lack both specificity and sensibility.

Humans express ALT1 and ALT2 and these two forms of the enzyme share approximately 70% identity (Yang et al., 2002). The cellular and tissue distribution of the different ALT proteins has not been characterized in humans, and their relative contribution to serum is unknown. As a result of immunoassay, it is possible to distinguish human ALT1 and ALT2.

Glutamate Dehydrogenase

Glutamate dehydrogenase (GLDH) activity is present in mitochondria and has a role in oxidative deamination of glutamate. Because it is an inducible enzyme, the utility of GLDH as a marker of liver cell necrosis has been questioned in humans during excessive alcohol intake. GLDH may appear in blood without appreciable evidence of hepatic necrosis either by cytoplasmic enzyme synthesis or mitochondrial material within released cytoplasmic membrane blebs (Solter, 2005). GLDH activity increases with hepatocellular damage as does the ALT. Moreover, unlike transaminases, GLDH activity is not inhibited by compounds that interfere with pyridoxal-5′-phosphate, such as isoniazid and lead (O'Brien et al., 2002). Serum GLDH activity is more liver-specific than transaminases and is not substantially affected by skeletal muscle damage.

Serum F Protein

Serum F protein is a 44-kDa protein that is produced in large amounts in liver and small quantities in kidney and is present at low serum concentrations in normal humans. The serum F protein was identified as 4-hydroxyphenylpyruvate dioxygenase, which is a key enzyme in tyrosine catabolism (Neve et al., 2003). The serum F protein concentration was a more sensitive and specific marker of liver damage than conventional liver function tests (AST, ALP, GGT activities) and showed a close correlation with the histological assessment of liver damage (Foster et al., 1989). Serum F protein can be measured by radioimmunoassay in a variety of human diseases and showed elevations in the serum of patients with hepatocellular damage (Foster et al., 1989). Serum F protein in patients taking CBZ and phenytoin as monotherapeutics, in patients receiving multiple drugs, and in patients taking sodium valproate were slightly elevated being an indicator of hepatocellular dysfunction associated with anticonvulsant therapy. Evidence indicates that serum F protein is not influenced by enzyme induction (Callaghan et al., 1994).

Arginase-I

Arginase is a hydrolase that catalyzes the catabolism of arginine to urea and ornithine. Cytosolic mitochondrial

isozyme arginase-I is highly liver-specific, almost exclusively a periportal liver enzyme, making it a candidate biomarker for liver toxicity. The activity of arginase-I in serum is considered to be an exact test of liver function. However, the activity of arginase-II, localized in perivenous hepatocytes, is increased in human cirrhotic liver while arginase-I is decreased. It has been suggested that such changes in both the expression and activity of the two arginase isozymes in cirrhotic liver compared with control tissue may allow compensation of ammonia detoxification in various zones of hepatic acinus in cirrhotic livers (Chrzanowska et al., 2009).

In humans, liver graft function after transplantation is dependent on ischemia-reperfusion injury, toxicity of drugs (i.e., immunosuppressive agents and antimicrobials), and transplant rejection. Arginase I has been evaluated as a more specific test of liver function compared with traditional serum markers for this model situation. Serum arginase I reaches the maximum concentration 1 day after liver transplantation and showed powerful and significant correlation with serum AST and ALT activities (Ashamiss et al., 2004).

New Biomarkers for Monitoring Liver Injury

A number of promising biomarkers for liver injury with better sensitivity and specificity have been proposed, as described in the following sections:

Alpha-Glutathione S-transferase

Glutathione S-transferases (GSTs) are inducible phase II detoxification enzymes, and their action reduces drug toxicity and facilitates urinary excretion of metabolites. GST catalyzes the conjugation of GSH with reactive metabolites formed during phase I metabolism. There are four isozymes of GST (alpha, pi, mu, and theta), which are expressed in human and other mammals. The alpha-glutathione S-transferase (α-GST) class consists of two subunits (dimer) and is expressed in human hepatocytes where it accounts for approximately 5% of the soluble protein (Coles and Kadlubar, 2005). The diagnostic use of α-GST (detects necrosis in centrolobular region) to assess acute hepatotoxicity has been compared with serum aminotransferases. Unlike aminotransferases, which are principally found in the periportal hepatocytes, α-GST is also uniformly distributed throughout the centrilobular region of the liver. α-GST has a good correlation between its level and liver histopathological endpoints and rapidly decreases to baseline levels after cessation of the drug causing the injury (Higuchi et al., 2001). α-GST expression is confined to liver and kidney; however, renal injury does not cause increased serum but increased urine levels.

The human α-GST polymorphisms could modulate serum α-GST levels, so the lack of α-GST elevation with drug toxicant treatment might indicate an individual with polymorphism(s) in α-GST. The most frequently found polymorphism in human GST-α is in hGSTA1*B, which correlates with reduced liver expression levels as the SP1 promoter element is mutated (Coles et al., 2001). Its frequency is high (40% in Caucasians, 35% in Africans, and 15% in Asians), and therefore this polymorphism could have high impact on the values obtained in human clinical trials (Coles and Kadlubar, 2005). Changes in α-GST have to be determined relative to predose levels. α-GST was not qualified by FDA because it was found to either increase or decrease depending on the location of the renal injury, which might confound data interpretation.

Gamma-Glutamyl Transpeptidase

Gamma-glutamyl transpeptidase (GGT) activity is localized in liver, kidney, and pancreas tissues. The highest GGT concentration is in the kidney and pancreas followed by the liver. GGT has multiple functions including catalytic transfer of γ-glutamyl groups to amino acids and short peptides, and hydrolysis of GSH to a gamma-glutamyl moiety and cysteinylglycine in GSH and GSH conjugate catabolism (Csanaky and Gregus, 2005). GGT activity in the serum is a marker of hepatobiliary injury, especially cholestasis and biliary effects, although it is not only expressed in liver but also in kidney, pancreas, and bile ducts. This enzyme might be affected in severe ADRs.

Sorbitol Dehydrogenase

Sorbitol dehydrogenase (SDH) catalyzes the reversible oxidation-reduction of sorbitol, fructose, and NADH. It is widely distributed in tissues throughout the body and is primarily found in the cytoplasm and mitochondria of liver, kidney, and seminal vesicles. SDH is a specific indicator of acute hepatocellular injury; this can be useful in rodents and of value in humans (Khayrollah et al., 1982). SDH can be considered as a liver toxicity biomarker that has functions across preclinical species and it performs comparably to other liver enzymatic activities.

Purine Nucleotide Phosphorylase

Purine nucleotide phosphorylase (PNP) is a key enzyme involved in the purine pathway located in the cytoplasm of different cell types (e.g., endothelial cells, Kupffer cells, and hepatocytes) and is a leakage marker released into hepatic sinusoids during necrosis. It reversibly catalyzes the phosphorolysis of nucleosides to their respective bases and corresponding 1-(deoxy)-ribose-phosphate. PNP is found in a number of tissues, particularly in liver, and to a lesser extent in heart and muscle (Marrer and Dieterle, 2010) and could be

modified in an ADR (Bantia et al., 1996). PNP detects hepatocyte necrosis.

Malate Dehydrogenase

Malate dehydrogenase (MDH) is involved in the Krebs cycle, catalyzing the reversible transformation of malate into oxaloacetate utilizing NAD^+. It is also a leakage marker released into the serum after tissue damage, being highly abundant in liver followed by heart, skeletal muscle, and brain. This enzyme is localized in the mitochondria (10%) and in the cytoplasm (90%) (Marrer and Dieterle, 2010). MDH activity has proven to be useful in staging liver diseases and is increased in cirrhotic patients (Misra et al., 1991).

Paraoxonase-1

Paraoxonase-1 (PON-1) is a high-density lipoprotein-associated esterase, which is involved in metabolism/detoxification of organophosphates (e.g., diazoxon and paraoxon) in the liver and protects low-density lipoproteins (LDL) from oxidative modification. PON-1 is reduced in serum in response to injury. PON-1 detects liver function marker. Reduced PON-1 levels in serum are a consequence of reduced PON-1 synthesis and secretion in response to an injured liver (Ferré et al., 2002). Studies indicate that plasma PON activity in humans exhibits a polymorphic distribution, with individuals showing a trimodal pattern with high, intermediate, or low PON activity. Gene frequencies for high or low metabolizers have also been shown to vary among groups of different ethnic or geographical origins. The molecular basis of the polymorphism has been associated with several mutations (Brophy et al., 2001). In a

given population, mutations in PON-1 lead to variations in plasma PON-1 activity up to 40-fold and differences in PON-1 protein levels up to 13-fold are also present within a single PON1 genotype (Furlong et al., 2002). Because of polymorphisms, the utility of PON-1 activity appears to be greater for preclinical evaluation of hepatotoxicity compared to use in the clinic.

Biomarkers in Acetaminophen Hepatotoxicity

Acetaminophen is the most widely used and popular over-the-counter analgesic and antipyretic drugs in the world, which is safe when taken at therapeutic doses but produced hepatotoxicity and kidney damage following overdose. Many studies indicate that oxidative stress is involved in the various toxicities associated with acetaminophen (Wang et al., 2017). Acetaminophen contributes to around 50% of cases of all of drug-related acute liver failure in adults both in the United States and United Kingdom (UK), results in more than 200 deaths/year in the UK alone, and is a component in 40% of the 80,000 poisoning presentations to UK hospitals (Ostapowicz et al., 2002). An overall scheme of drug toxicity includes many aspects, some of which are related to metabolism. The hepatotoxicity of acetaminophen is initiated by N-acetyl-p-benzoquinone imine (NAPQI), a reactive metabolite formed by cytochrome P450-mediated (P450 2E1) process, which first depletes GSH and then covalently binds to cellular proteins (Fig. 38.2). The reactive iminoquinone product reacts with mitochondrial proteins and produces mitochondrial injury and reactive oxygen species (ROS), and the latter, in turn, activates the cytoplasmic signal
FIGURE 38.2   Metabolism of acetaminophen.

transduction pathway. Covalent binding has been studied in hepatotoxicity as a result of drug activated to reactive products. The degree of covalent binding is higher for hepatotoxic drugs than for nonhepatotoxic drugs; nevertheless, the variation in covalent binding is considerable for both these drug categories (Guengerich, 2011). GSH and taurine are sulfur-containing antioxidants that can reduce or prevent acetaminophen-induced drug toxicity by deactivating NAPQI, the toxic metabolite of acetaminophen. It was shown that urinary levels of creatine were increased on day 1 or day 2 in five high-dose liver toxicity studies and the taurine concentration in urine was increased in three of five liver toxicity studies, while GSH, S-adenosylmethionine was found to be reduced in four of five liver toxicity studies (Schnackenberg et al., 2009).

The comparison of toxicity of acetaminophen with its metaisomer, 3-hydroxyacetanilide, with respect to levels of total covalent binding both in vitro and in vivo, has also been studied (Roberts et al., 1990). However, different reactive intermediates are produced from acetaminophen and the metaisomer, an iminoquinone and orthoquinone, respectively. The early events lead to mitochondrial dysfunction with ROS and peroxynitrite formation (Jaeschke et al., 2003). Mitochondrial stress has since developed in terms of being a major aspect of drug toxicity, so some of the evidence suggests a combination of the drug (or drug metabolite) promoting oxidative stress (a "direct" effect) and alteration of signal transduction systems resulting in further loss of mitochondrial function (an "indirect" effect). It appeared that acetaminophen generated more mitochondrial binding and the metacongener more cytosolic binding (Jones et al., 2010).

The cellular events that link drug metabolism to clinical outcome are poorly understood. Selective serum markers of apoptosis, necrosis, and inflammation would be of benefit for differentiating the underlying mechanisms of DILI. Necrosis is the final and ultimate form of cell death. However, it has been suggested that intracellular events following acetaminophen metabolic activation can cause hepatocyte apoptosis. Hepatocyte apoptosis, necrosis, and innate immune activation have been defined as features of the toxicological response associated with the hepatotoxin acetaminophen. Circulating biomarkers that represent the different mechanistic aspects of acetaminophen hepatotoxicity may have utility in the clinical situation to provide information regarding the mechanism of acute liver failure.

The circulating miRNAs represent a class of liver-specific blood-based biomarkers during clinical acetaminophen hepatotoxicity (Starkey Lewis et al., 2011). Moreover, high mobility group box 1 protein (HMGB1) and keratin-18 (K18) have been reported as circulating

mechanistic indicators of cell death balance in clinical acetaminophen hepatotoxicity (Craig et al., 2011; Antoine et al., 2012). Hypoacetylated HMGB1 (necrosis indicator), caspase-cleaved K18 (apoptosis indicator), and full-length K18 (necrosis indicator) present in serum showed strong correlation with the histological time course of cell death and was more sensitive than ALT. The hyperacetylated form of HMGB1 (inflammatory indicator) in serum indicated that hepatotoxicity was associated with an inflammatory response. The use of a combined molecular, proteomic, and histological approach to investigate the differing circulating forms of HMGB1 and K18 as potential serum-based proteins could define the multidimensional mechanistic aspects of the dynamics between apoptosis, necrosis, and inflammation during DILI (Antoine et al., 2009). Liquid chromatography-tandem mass_Spectrometry (LC/MS/MS), histological, and proteomic evaluation could be used for differentiating the circulating molecular forms of HMGB1 and K18.

High Mobility Group Protein B1

HMGB1 is a nuclear-binding protein that has proinflammatory activity and targets Toll-like receptors and the receptor for advanced glycation end products on target cells (Hori et al., 1995; Park et al., 2004). It is released in a hyperacetylated form with the involvement of distinct lysine residues from activated innate immune cells (Bonaldi et al., 2003) and passively in a hypoacetylated form by necrotic cells, while it is known not to be released by apoptotic or secondary necrotic cells (Scaffidi et al., 2002).

Caspase-Cleaved K18

Caspase-cleaved K18 is an early event in structural rearrangement during apoptosis. Full-length K18 released passively during necrotic cell death and fragmented K18 generated during apoptosis can be released into the blood and accumulate over time. Serum quantification of caspase-cleaved and full-length K18, which can represent markers of apoptosis and necrosis, has been used during pharmacodynamics of chemotherapeutic drug monitoring in patients and animal models (Cumming et al., 2008).

HMGB1 is passively released by cells undergoing necrosis and is actively secreted as an inflammatory mediator by monocytes and macrophages. Immunoassays directed toward the recognition of caspase-cleaved K18 (cK18; apoptosis) and full length K18 (FL-K18; necrosis) have been reported in clinical studies as biomarkers for the therapeutic drug monitoring of chemotherapeutic agents (Cummings et al., 2007) and for the quantification of hepatocyte cell death mode during liver disorders such as nonalcoholic steatohepatitis (Wieckowska et al., 2006).

Glutathione S-Transferase Alpha

The biomarker glutathione S-transferase alpha (GST-α) has been used in patients with self-administered acetaminophen overdose. In these situations, elevated serum GST-α levels were observed, as well as elevated serum F protein levels. GST-α, serum F protein, and ALT activity all showed elevations postadmission, which was consistent with liver biopsies indicating necrosis (Beckett et al., 1989).

Malate Dehydrogenase

Malate dehydrogenase (MDH) activity is one biochemical index of acetaminophen liver injury that coincided with histological evidence of necrosis (Zieve et al., 1985). The MDH activity increases in a manner correlated with morphological changes after administration of thioacetamide, diethylnitrosamine, and diethanolamine (Korsrud et al., 1972). MDH detects hepatocyte necrosis.

Cytochrome c

Cytochrome c is another potential mitochondrial marker of drug-induced injury which has been shown to reach peak elevations in serum along with ALT and AST by acetaminophen.

Biomarkers for Drug-Induced Liver Injury in Tuberculosis—Human Immunodeficiency Virus—Infected Patients

In patients with pulmonary tuberculosis, a significant improvement in oxidative stress and suppression of inflammatory response has been reported after the initial 2-month therapy. However, it has been shown that even after 6 months of successful chemotherapy, pulmonary tuberculosis is still associated with increased levels of circulating lipid peroxides and low plasma concentration of antioxidants. Before chemotherapy, mycobacteria induce ROS production by activating both mononuclear and polymorphonuclear phagocytes. Tuberculosis is, therefore, characterized by poor antioxidants defense that exposes the host to oxidative tissue damage.

The potentially hepatotoxic antituberculosis drugs from the first-line regimen are isoniazid, rifampicin, and pyrazinamide. The conditions that increase the risk of antituberculosis drug-induced hepatitis can be summarized as the following: malnutrition, excessive alcohol intake, aging, chronic hepatic diseases including viral infections (e.g., HIV/AIDS), female sex, ethnicity (Asians), concurrent administration of enzyme inducers, and inadequate compliance (McIlleron et al., 2007).

It has been described that tuberculosis is the most common opportunistic fatal infection in HIV-infected patients. Concomitant HIV and tuberculosis treatment is recommended in patients with low CD4 cell counts. The concurrent treatment with antiretroviral and antituberculosis drugs is complicated because of ADRs; in particular it exacerbates risk for DILI, and overlapping toxicity between drugs used to treat HIV and tuberculosis could also complicate the management. Although rifampicin and efavirenz are key drugs used for concomitant tuberculosis and HIV therapy, data on the concomitant use—related liver injury and biomarkers are limited, particularly from sub-Saharan Africa, a region highly affected by HIV/AIDS and tuberculosis, as is much of the remainder of the continent. In general, drugs used to treat HIV and tuberculosis infections are known to induce drug-metabolizing enzymes and transporter proteins. Induction might also lead to increased production of harmful reactive intermediates and ROS. There is high incidence of antitubercular and antiretroviral DILI in Ethiopian patients. Patient variability in systemic efavirenz exposure and pharmacogenetic variations in NAT2, CYP2B6, and ABCB1 genes determine susceptibility to DILI in tuberculosis—HIV co-infected patients. Close monitoring of plasma efavirenz level and liver enzymes during early therapy and/or genotyping practice in HIV clinics are recommended for early identification of patients at risk of DILI (Yimer et al., 2011).

BIOMARKER OF DRUG-INDUCED KIDNEY TOXICITY

Urine color, clarity, and volume, as well as specific gravity or osmolality, an index of urine concentration, and renal clearance measurements, are all useful marker guides to detect renal injury in experimental animals and humans (Sharratt and Frazer, 1963). Microscopic examination of urine sediment was introduced, in combination with the previous biomarkers, to look for cells, casts, crystals, and bacteria. The advent of dipstick tests for protein, glucose, ketones, hemoglobin, and bilirubin in urine also enabled rapid qualitative measurement. Two known functional serum biomarkers, serum creatinine and BUN, are commonly used to detect kidney toxicity in preclinical and clinical studies, as well as in routine clinical care. Both, however, have severe limitations relating to sensitivity and specificity.

The most efficient way to prevent or attenuate nephrotoxicity is to have sensitive and specific biomarkers. These biomarkers should be able to sensitively predict toxicity in preclinical models and clinical situations so that they can be used to efficiently guide drug developers to modify or discard the potential therapeutics and replace them with variants that affect the same target without the toxicity. However, it is important to recognize that safety concerns must always be incorporated into a general "risk—benefit" analysis and that toxicity of a drug does not necessarily mean that it

should not be developed or approved. Some examples of nephrotoxic drugs that have provided a very high therapeutic benefit are the aminoglycoside antimicrobials, the cancer drug cisplatin, and the antiviral tenofovir. Drugs that compete with creatinine for renal transport pathways, in particular cimetidine, trimethoprim, and salicylates, will decrease the secretion component and elevate baseline plasma levels in the absence of a reduction in GFR. The enzyme used as a biomarker of nephron injury, β-galactosidase, is elevated following some glomerular toxicants before proteinuria is evident (Price, 1982).

The discovery of electrophoresis for the separation of proteins (i.e., small molecular weight urinary proteins) as markers of renal injury (e.g., β2-microglobulin and retinol-binding protein) has been very important. This was later on supplemented with analysis of enzymes and proteins in urine, such as LDH and AP. A number of known marketed drugs induce kidney injury, with the main mechanisms of nephrotoxicity being the following: vasoconstriction, altered intraglomerular hemodynamics, direct tubular cell toxicity, interstitial nephritis, crystal deposition, thrombotic microangiopathy, and osmotic nephrosis (Schetz et al., 2005).

Several alternatives to serum creatinine and BUN have been proposed in response to the urgent need for biomarkers that predict human nephrotoxicity in preclinical studies, allow more timely diagnosis of AKI in humans, and ideally localize the injury to a specific nephron site. Nowadays, there are new kidney safety biomarkers to detect AKI, such as kidney function biomarkers (serum cystatin C, detects GFR), de novo expression biomarkers (KIM-1 (urinary), detects proximal tubular injury and regeneration, neutrophil gelatinase–associated lipocalin (NGAL) (urine, serum), detects proximal tubular injury), leakage markers (NAG), or functional biomarkers for the glomerular filtration membrane (total protein) and tubular reabsorption processes (β2-microglobulin). Among the most important biomarkers are KIM-1, β2-macroglobulin and total protein (urinary) (detects glomerular injury and tubular reabsorption complex), urinary clusterin (detects tubular injury, with similar performance and characteristics to Kim-1), albumin (detects tubular injury), trefoil factor 3 (TFF3; detects tubular injury), and urinary cystatin C (detects glomerular injury with subsequent impairment of tubular reabsorption, with similar performance and characteristics to those of urinary β2-microglobulin) (Marrer and Dieterle, 2010).

Urinary kidney injury markers include molecule-1 (KIM-1), NGAL, interleukin-18 (IL-18), cystatin C, clusterin, fatty acid–binding protein liver type, and osteopontin. These biomarkers not only have the potential to both transform the way to detect and quantify nephrotoxicity and prevent the development and entry into the market of nephrotoxic drugs but also allow the continued development of potentially useful drugs that, without the help of biomarkers, would be erroneously believed to be toxic on the basis of a particular preclinical model. It is important to consider that biomarkers for one type of kidney toxicity may not be as useful in another, so a good biomarker for injury may not reliably indicate delayed repair; a biomarker that detects inflammation effectively may not be as sensitive as in detecting early proximal tubule toxicity in the absence of inflammation. A biomarker of injury might not detect a functional defect, such as is observed in Fanconi syndrome or nephrogenic diabetes insipidus, and a biomarker useful in an animal model may or may not be useful in the same way in humans. Another issue is whether panels of biomarkers will be more informative than a single biomarker. At first, this might seem logical because different biomarkers might be more sensitive or specific for different forms of injury. Nevertheless, if multiple biomarkers are used to detect a similar form of injury, an adjudication process will be necessary if the biomarkers suggest different outcomes.

Urinary β2-Microglobulin

Urinary β2-microglobulin is used to monitor tubular reabsorption. It has been shown that impairment of the tubular uptake causes increased excreted urinary β2-microglobulin levels. Two mechanisms have been identified that are involved in this impairment. Firstly, glomerular alterations, damages, and/or diseases allow higher molecular weight proteins to pass through the filtration membrane, causing a high protein load in the tubuli. As a consequence, proteins such as albumin compete for common transport mechanisms, decreasing the tubular uptake of β2-microglobulin and increasing the excretion into urine (Thielemans et al., 1994). Secondly, the tubular reabsorption complex is directly affected by treatment with drugs or different tubular diseases. Increases of urinary β2-microglobulin in the context of nephrotoxicity have been described in HIV patients treated with tenofovir disoproxil fumarate and other antiretroviral agents, patients with aminoglycoside treatments, cisplatin treatment regimens, and gold treatment (sodium aurothiomalate) for rheumatoid arthritis.

BIOMARKERS OF DRUG-INDUCED VASCULAR INJURY

Drug-induced vascular injury (DIVI) is a major concern not only preclinically but also clinically because of a total lack of diagnostic markers and gaps in fundamental science of pathogenesis, mechanism of injury, and development of vascular lesions. Clinical

development of novel therapies can often be a danger when DIVI is observed in preclinical toxicity studies. DIVI is a vascular injury that develops acutely in response to drug administration and progresses to vascular inflammation. It is a common finding in preclinical toxicity studies involving vasoactive drugs that alter blood pressure and heart rate such as minoxidil, hydralazine, or milrinone. For these drugs, the decision to proceed from preclinical safety to clinical development was made based on measuring heart rate and blood pressure as surrogate markers in clinical trials. However, these two clinical endpoints are not significantly perturbed with other known DIVI drugs such as endothelin receptor antagonists. The observation that drugs can cause DIVI without hemodynamic changes has led the regulatory agencies to require new DIVI biomarkers for use in the clinical setting and stoppage of drug development by pharmaceutical companies when there is pathological evidence of DIVI in preclinical studies (Louden and Morgan, 2001).

DIVI as the previously defined preclinical type of lesions has not been clearly documented in the clinic. This introduces difficulties in the translational development of biomarkers, as it is unclear how biomarkers, which correlate with histopathology-confirmed preclinical vascular injury, can be clinically qualified. Nevertheless, investigational work has led to a few promising biomarkers, which still have to overcome a number of limitations.

Biomarkers for Monitoring Drug-Induced Vascular Injury

Traditionally, the regulatory authorities and pharmaceutical companies manage the potential risk of drug-induced vascular toxicity as the occurrence correlated with decreases in blood pressure, concomitant reflex tachycardia, and increases in coronary blood flow. By contrast, recent experiences with endothelin receptor antagonists suggest that vascular injury is not always associated with intense hypotension and marked reflex tachycardia. Localized vasodilatation, inability of the vasculature to maintain tone, and alterations in regional blood flow dynamics all play a key role in the pathogenesis of this vascular lesion (Brott et al., 2005). Hemodynamic parameters such as heart rate and mean arterial blood pressure are not satisfactory clinical surrogates for managing the potential risk of drug-induced vascular toxicity. Identification of biochemical diagnostic biomarkers with preclinical and clinical utility would be of value.

The first promising biomarker investigated preclinically and clinically is von Willebrand factor (vWF) and the vWF propeptide (vWFpp). vWF is a glycoprotein, synthesized by endothelial cells and megakaryocytes and released into the circulation, being a marker of endothelial cell injury. vWF is released on vascular damage and is transiently increased in plasma prior to morphological evidence of damage in dogs and rats treated with vascular toxicants, such as fenoldopam or potassium channel openers (Newsholme et al., 2000). The C-Path Institute's Predictive Safety Testing Consortium (PSTC) currently investigates the preclinical and clinical utility of this exploratory biomarker, as well as of vWFpp, to monitor DIVI. Thus far, a good correlation has been found between the amplitude of the transient change of vWF and the severity of progress of the lesions, but a time disconnect (early transient increase followed by return to baseline values despite lesions progression) puts in question the predictability, reliability, and general clinical applicability of circulation vWF as a diagnostic marker to monitor progressive vascular injury. The possible explanation for this "only" transient release is the trapping of a significant amount of the released vWF in the vessel wall and surrounding tissues. Therefore, plasma vWF probably represents an underestimation of the actual amount released from the damaged endothelial cells, especially for later time points. Circulating plasma vWF could still be a good marker of endothelial cell perturbation prior to morphological changes, but this excludes its use for monitoring the progression of lesions (Brott et al., 2005).

Another promising biomarker of vascular injury is more specific to endothelial and smooth muscle cell injury: caveolin-1 (Cav-1), the major structure protein of caveolae. Caveolae (little caves) were first described as flask-shaped plasma membrane invagination capable of transporting molecules across the endothelial barrier. They are located on the surface of endothelial cells and smooth muscle cells and contain both adenylyl cyclase and nitric oxide synthases (NOS). The caveolin family comprises at least three genes that are expressed heterogeneously in different cell types. Interestingly, adenylyl cyclase and NOS are co-localized with and functionally regulated by Cav-1, being a good biomarker of DIVI. Cav-1 has been reported to be a potential biomarker of vascular injury caused by certain vasodilator drugs (Brott et al., 2005).

Data suggest that Cav-1 is highly expressed in normal blood vessels but there is a decrease of Cav-1 expression specifically at the site of vascular damage, pointing to a possible release of Cav-1 from vessel walls into blood. Treatment of cancer cells with cytotoxic (antineoplastic) agents usually increases caveolin expression (Belanger et al., 2003). The C-Path Institute's PSTC currently investigates the preclinical and clinical utility of this exploratory biomarker, as well as of vWFpp to monitor DIVI (PSTC, 2008).

Vascular biomarkers and cytokines related with atherosclerosis in regularly treated and attack-free familial Mediterranean fever patients have been described. In a study where the examinations were performed during attack-free period, all patients received colchicine treatment, a first-line treatment agent, for disease control and for preventing and arresting renal amyloidosis; the antiinflammatory effect of colchicine is multifaceted and is mainly based on its antimitotic and antichemotactic activity on granulocytes and it reduces vascular injury parameters. IL-17 was significantly higher in familial Mediterranean fever patients, and the markers related to endothelial injury, including asymmetric dimethylarginine, osteoprotegerin, and thrombomodulin, were significantly downregulated (Pamuk et al., 2013). Colchicine treatment may have a negative effect (in favor of maintaining vascular homeostasis) on asymmetric dimethylarginine concentrations.

BIOMARKERS OF DRUG-INDUCED CARDIAC INJURY

Coronary artery disease and acute myocardial infarction (AMI) are the leading causes of death in developed and developing countries. Biomarkers of injury to the heart have only been developed in more recent times. The myocytes are the major cell in the heart, and the heart's purpose is to pump blood. Because myocytes essentially cannot be regenerated, if heart cells die, then cardiac function has a high probability of being impaired. When the cell dies, the proteins inside the cell will be released, with proteins in the cytoplasm leaving the cell more rapidly than the ones in membranes or fixed cell elements. The most sensitive markers should be those in the highest abundance in the cell, and as the major function of the heart is contraction, the proteins involved in contraction and producing energy to support it should be good candidates for biomarkers of cardiac injury, which could be detected in blood. One also has to consider the means by which markers can reach the blood stream. As occlusion of blood flow is the primary cause of myocardial infarction, most of the proteins reach the blood via the lymphatics, where they can be prone to degradation, leading to delayed appearance in the blood (Rosalki et al., 2004).

Monoclonal Antibodies

The discovery of monoclonal antibodies (Kohler and Milstein, 2005) revolutionized diagnostics for human diseases, including myocardial infarction with the development of a monoclonal antibody reactive only with CK-MB isoenzyme. This led to a quantitative test. The old gold standards myoglobin and CK-MB served as first-line cardiotoxicity markers, despite limited specificity and short serum half-life, until the recent addition of the cardiac troponins T (cTn-I and cTn-T), qualified and more specific biomarkers of cardiac injury (Rosalki et al., 2004).

Troponins

Troponin (TN) is a component of the heart muscle and its release is indicative of early events in heart tissue degeneration, necrosis, and myocyte damage and it is an obvious candidate biomarker. In humans, cardiac TNs, myocardial-specific structural proteins, are the preferred markers as the cornerstone for the diagnosis of myocardial infarction, and increased cardiac TN is defined as a measurement greater than the 99th percentile of an appropriate reference group. TN, however, offers far more than just improved diagnostic sensitivity and specificity (NTP, 2006). Several groups have demonstrated a powerful relationship between the increase in TN and the risk of mortality in patients presenting with a non—ST elevation acute coronary syndrome, i.e., without classical changes on the electrocardiogram consistent with an acute injury pattern. There are two specific types of TN, TnT and TnI. TN-T and QT prolongation have been used as biomarkers to evaluate potential for cardiac electrophysiology toxicities and prognosis after heart attack.

Cardiac TNs I and T have high sensitivity and specificity for damage to the heart muscle. Emergency patients with chest pain are systematically tested for elevated cardiac TNs levels to confirm a presumption of myocardial infarct. In AMI, TN levels rise as early as 3.5 h after the onset of chest pain. TNs are not only markers for myocardial infarction but also markers of heart muscle damage (i.e., detects necrosis of heart muscle) related to multiple causes, such as severe tachycardia, inflammatory conditions (myopericarditis), and different cardiomyopathies. Being leakage markers, elevations of TNs are only seen when necrosis of the heart muscle has occurred similarly to CK-MB and myoglobin. But in contrast to these two markers, TNs feature a longer half-life, increasing the window of detection after the primary insult. Cardiac TNs have low baseline levels supporting a sensitive detection. For example, increased cTn-I and cTn-T levels were found in rats just 2 h after administration of the cardiotoxicant isoprenaline (Bertinchant et al., 2000).

TNs are also used in nonclinical drug development studies in rats and dogs for three different context of uses (COUs): (1) when there is a "previous indication of cardiac structural damage with a particular drug" states that "cardiac troponin testing can help estimate a lowest toxic dose or a highest non-toxic dose to help choose doses for human testing," (2) when "there is

known cardiac structural damage with a particular pharmacologic class of a drug and histopathologic analyses do not reveal structural damage" states that "circulating cardiac troponins may be used to support or refute the inference of low cardiotoxic potential," (3) when "unexpected cardiac structural toxicity is found in a nonclinical study" states that the "retroactive ('reflex') examination of serum or plasma from that study for cardiac troponins can be used to help determine an NOAEL or LOAEL." This retroactive study may then support utilization of this biomarker in future safety testing (FDA, 2017).

B-type Natriuretic Protein

B-type natriuretic protein (BNP) is a peptide hormone released from cardiomyocytes during ventricular stress. BNP is transcribed within the ventricular myocardium and has compensatory diuretic activity during heart failure. The synthesis of BNP occurs through a preprohormone—preproBNP—cleaved into proBNP. Once produced in myocardial cells, proBNP is in turn cleaved into an N-terminal fragment NT-proBNP and BNP fragment, which are logically secreted in a 1:1 ratio. Because BNP is primarily synthesized and secreted by myocytes, in ventricular myocardium, in proportion to the end diastolic pressure and ventricular volume/stretch, the measurement of plasma BNP concentration was introduced to the clinical laboratory as a test to identify cardiac failure (i.e., congestive heart failure) and related cardiac indications. The amino terminal cleavage equivalent (NT-proBNP) is now progressively replacing BNP, thanks to a better stability and the availability of more sensitive and robust assays (Rehman and Januzzi, 2008). Plasma BNP is found at considerable concentrations, and its clearance is mediated by endopeptidases leading to a half-life of about 5−10 min (Pemberton et al., 2000).

BNP is regarded as a cardiac-specific hormone, reflecting mechanical stress on the myocardium (Kramer and Milting, 2011). BNP is typically elevated when pathological findings are noted and thus was recommended as a biomarker to evaluate myocardial pressure and volume overload and is considered a strong "negative predictor," as a low value means volume parameters are normal. Increased BNP concentrations are an independent predictor of mortality in patients presenting with acute coronary syndromes. The group did not know whether an abnormal BNP level would constitute an adverse response. Although BNP protein assays based on serum samples are available for humans, in rodents the assay requires RNA extraction from the heart, which limits measurements at necropsy (NTP, 2006).

The prognostic utility of natriuretic peptides has been explored particularly in ischemic heart disease and conditions leading to right ventricular dysfunction. The limiting factor is the specificity of serum NT-proBNP related to its clearance only through the kidney, rendering kidney disease a cofactor.

Circulating Micro-RNAs

In AMI patients, earlier biomarker of the relative delay release time of troponin are demanded to reduce mortality by AMI. Recent studies have found that circulating micro-RNAs (miRNAs) are closely linked to myocardial injury and currently are emerging as sensitive biomarkers in plasma and serum. The increased levels of circulating miRNAs after, and parallel the extent of myocardial damage are estimated by cardiac troponin. More than 200 miRNAs exist in the heart; miR-1, miR-133, miR-208, miR-499, and other miRNAs are expressed in heart (Li et al., 2012). For details on miRNAs as biomarkers of cardiovascular toxicity and diseases, see Chapter 12 in this book.

The Heart Breakout Group recommended the routine inclusion of three biomarkers in the National Toxicology Program (NTP) subchronic studies: TN, α2-macroglobulin in the rat, and BNP in conjunction with ultrasound. All of these biomarkers are considered indicative of a disease process rather than predictive.

BIOMARKERS OF DRUG-INDUCED BRAIN INJURY

Neurological diseases create difficulties in both diagnosis and in the ability to objectively monitor responses to treatment, as few body fluid biomarkers exist and direct sampling of the brain is rarely advised. Thus, diagnosis of some diseases and brain injuries utilizes subjective clinical assessment. Signs of treatment effectiveness can take months and in many cases are based solely on subjective patient feedback. Thus, the possible utilization of genomics applied to peripheral blood cells in this area would fulfill a great clinical need. Much remains to be done in terms of reproducing the gene signatures in new biological samples, demonstrating, for example, disease exclusivity, before their usefulness can be ascertained.

One goal of personalized medicine is to improve the prediction of an individual patient's response to therapy. A pilot study examined valproic acid (VPA) or carbamazepine (CBZ) treatment in children with epilepsy using whole blood genomic expression, where epileptic patients could be distinguished as with and without CBZ treatment (Tang et al., 2004). It was found that gene expression patterns could discriminate between patients who were and were not responding to VPA treatment. There was little overlap between the

VPA and CBZ signatures, suggesting that there are drug-specific responses that can be detected. If such biomarker patterns can be replicated in new studies, they would be very useful for personalized medicine.

Translational biomarkers of mood disorders have also been identified (Le-Niculescu et al., 2008), studying the gene expression differences in whole blood samples between patients with bipolar disorder and in whole blood samples from mice models of bipolar disease. These authors correlated these results with previously published data from their laboratory on gene expression changes in the brains of mice in these models (Ogden et al., 2004) and data reported on gene expression levels in human postmortem brain from individuals with mood disorders; genetic links to this disorder were found. They selected the top 10 genes that could identify patients with high and low moods. Moreover, there have been biomarkers identified for the diagnosis of hallucinations (gene panel of seven) and for delusions (gene panel of 31) in psychotic patients; some overlap was found in the biomarkers for hallucinations, delusions, and mood state, but it was found that biomarkers for mood state tended to be regulated in the opposite direction than were seen in psychotic patients.

Another approach is to evaluate the individual patient before drug exposure to ascertain susceptibility to drug-induced adverse events. A study was performed in patients recruited in a clinical trial for an Alzheimer's drug, in which the transcriptome of peripheral blood mononuclear cells was examined prior to drug treatment. Two biomarker panels were recognized: one set that identified those individuals susceptible to an adverse event and a second panel that could predict efficacy of the drug (O'Toole et al., 2005).

Studies have discovered that the expression of miRNA may provide a new tool in detecting neurological disease, ADRs, and renal allograft rejection. A recent study examined the miRNA levels in the brain and in the blood of rats subjected to stroke (ischemic or hemorrhagic) and chemically induced seizures and reported unique miRNA patterns for each condition, with a correlation between the brain and blood patterns. The miRNAs most affected were miR-298, miR-155, and miR-362-3p (Liu et al., 2010). Another neurological condition, multiple sclerosis, was also taken into consideration for the miRNAs, and so not reduced blood levels of miR-17 and miR-20a were found in these patients. To perform this experiment, T cell knock-in and knockout models were used in vitro to determine the genes regulated by these miRNA species and they were found to be T-cell activation genes; these same genes were expressed at higher levels in the blood of patients with multiple sclerosis (Cox et al., 2010). In conclusion, the data suggests that these miRNA may be useful biomarkers.

BIOMARKERS IN DRUG SAFETY EVALUATION

Importance of Understanding Specific Mechanisms of Toxicity in Drug Development

Modern high-throughput technologies for transcripts, proteins, and endogenous metabolites offer a major opportunity to systematically identify sensitive and specific blood and urine safety biomarkers that could serve as an index of damage specific to each of the important tissues and organs. Today, it is technically feasible to identify tissue-specific markers through the use of these—omics technologies by integrating and correlating toxicology data. These changes in gene, protein, and metabolite expression are consistent, sensitive, and early and provide the molecular basis of drug-induced injuries. The genomic-derived candidate markers can then be localized to organs using in situ hybridization (ISH) and immunohistochemistry (IHC) for their proteins. The concerns at the transcript level are reflected on the protein level and thereafter secreted into body fluids where they can be quantified (Dix et al., 2007).

A greater understanding of the molecular basis of toxicity and its influence on disease and disease progression can play a major role in drug development outcomes. In the early phase of research, biomarkers support the mechanistic characterization of toxicity, show an early indication of toxicity, and help define the maximal tolerated dose. Biomarkers can be used in early or late drug development for enrichment of patient populations to increase the odds of detecting a phenotypic or clinical efficacy signal. For example, data from early clinical trials that enroll patients with poor metabolizer genotypes in early phases of clinical trials to evaluate dose—concentration—response relationships in patients with different genotypes can inform the study design of latter-phase clinical studies. In latter stages of development, stratification approaches might be employed for looking at response in subgroups of patients.

Safety biomarkers can also play an important role in deciding if candidate drugs are transferred from the preclinical to the clinical phase in the case where traditional clinical markers would not detect early-onset organ toxicity. If a pharmaceutical company can clearly show in preclinical studies that the novel biomarkers can be used to detect early toxicity, to monitor onset and reversibility, and to manage any potential adverse effect of a new drug with significant therapeutic potential, a clinical implementation strategy with these biomarkers can enable a clinical development program on a case-by-case basis (PSTC, 2008).

Biomarkers in Drug Safety Evaluation

The Biomarkers Definitions Working Group (BDWG) of the National Institute of Health (NIH) defined a biomarker as "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes or pharmacological responses to a therapeutic intervention." To maintain definitional integrity, it has been agreed that the term *validation* will refer to the technical characterization and documentation of method performance, and the term *qualification* will refer to the evidentiary process of linking a biomarker with specific biological processes and clinical endpoints (BDWG, 2001). A molecular biomarker is defined as a specific subset of small molecule (metabolite) or large molecule (protein or DNA) biomarkers that may be discovered using genomic technology, as opposed to clinical biomarkers arising from imaging technology (Lewin and Weiner, 2004).

Molecular profiling (the application of genomic, transcriptomic, proteomic, and metabolomics technologies to the development of in vivo molecular biomarker) of a patient's phenotype utilizes molecular biomarkers of the genome, transcriptome, proteome, and metabolome to provide a molecular basis for the normal or healthy patient phenotype in a particular environment and thereby provides many opportunities for improving the choice of therapy and the prediction of drug response and disease pathology (Koch, 2004). Alteration of molecular biomarker in the diseased state compared with the normal state (characterized by the normal molecular phenotype) provides a molecular characterization of the disease phenotype, which is utilized in the diagnosis.

Biomarkers are considered to be parameters of injury or toxicity to help diagnose or monitor disease, but the biomarkers present in blood and urine give no information on the variability or range of response from individual cells or areas within a tissue. Biomarkers that represent highly sensitive and specific indicators of disease pathways have been used as substitutes for outcomes in clinical trials when evidence indicates that they predict clinical risk or benefit. In consequence, useful biomarkers can be quantitated and should provide information about normal or pathobiological states (Lock and Bonventre, 2008). The most reliable way to assess the clinical impact of a therapeutic intervention is through its effect on well-defined clinical endpoints (e.g., survival, myocardial infarction, stroke). A clinical endpoint is also a characteristic or variable that reflects how a patient feels or functions or how long a patient survives (Frank and Hargreaves, 2003).

Certain biomarkers have been used as substitutes for clinical endpoints (i.e., the most credible characteristic used in the assessment of the benefits and risks of a therapeutic intervention in randomized clinical trials) as a basis for drug approval. The term *surrogate endpoint* is defined as a biomarker that is intended to substitute for a clinical endpoint. A surrogate endpoint is expected to predict clinical benefit (or harm or lack of benefit or harm) based on epidemiologic data.

A conceptual paradigm has been developed to show the relationship of a biomarker to a clinical endpoint and the application of the biomarker as surrogate endpoint in the evaluation of therapeutic interventions (BDWG, 2001) (Fig. 38.1). The model also shows that biomarkers can be useful in the assessment of safety, as well as efficacy (MacGregor et al., 1995; Santella, 1997). Some biomarkers (e.g., blood pressure) may have dual functions in assessing efficacy (i.e., benefit) and safety (i.e., risk). Characterization of a biomarker as a surrogate endpoint requires it to be "reasonably likely, based on epidemiologic, therapeutic, pathophysiologic or other evidence, to predict clinical benefit" as indicated in the Food and Drug Modernization Act of 1997. The utility of a biomarker as a surrogate endpoint (i.e., a biomarker that is intended to substitute for a clinical endpoint) requires demonstration of its accuracy (the correlation of the measure with the clinical endpoint) and precision (the reproducibility of the measure) (Fig. 38.3).

Biomarkers have been used in drug development and treatment monitoring for a long time and quantitatively measure perturbations to the system anywhere in the causal path between drug administration and clinical effect.

Likewise, the concept of bridging biomarkers of toxicity would include not only those biomarkers that span use during in-life studies in preclinical species and also in humans but also in vitro or ex vivo study results used as surrogate biomarkers that accurately "predict" a toxic outcome in preclinical studies and/or humans (early-phase clinical trial to establish the "proof of concept") or to establish in vitro—in vivo correlations. On the other hand, there is wide consensus in the scientific community that biomarkers are and will be of utility as estimating tools in improving risk assessment of drugs. For the assessment of nephrotoxicity in vitro, different test systems are available, such as isolated perfused kidneys, cut slices, and isolated fragments and cells (glomeruli and tubules), which are relatively close to the in vivo situation, although the isolation and cultivation is complex and the time of cultivation and treatment is hardy restricting (Fuchs and Hewitt, 2011).

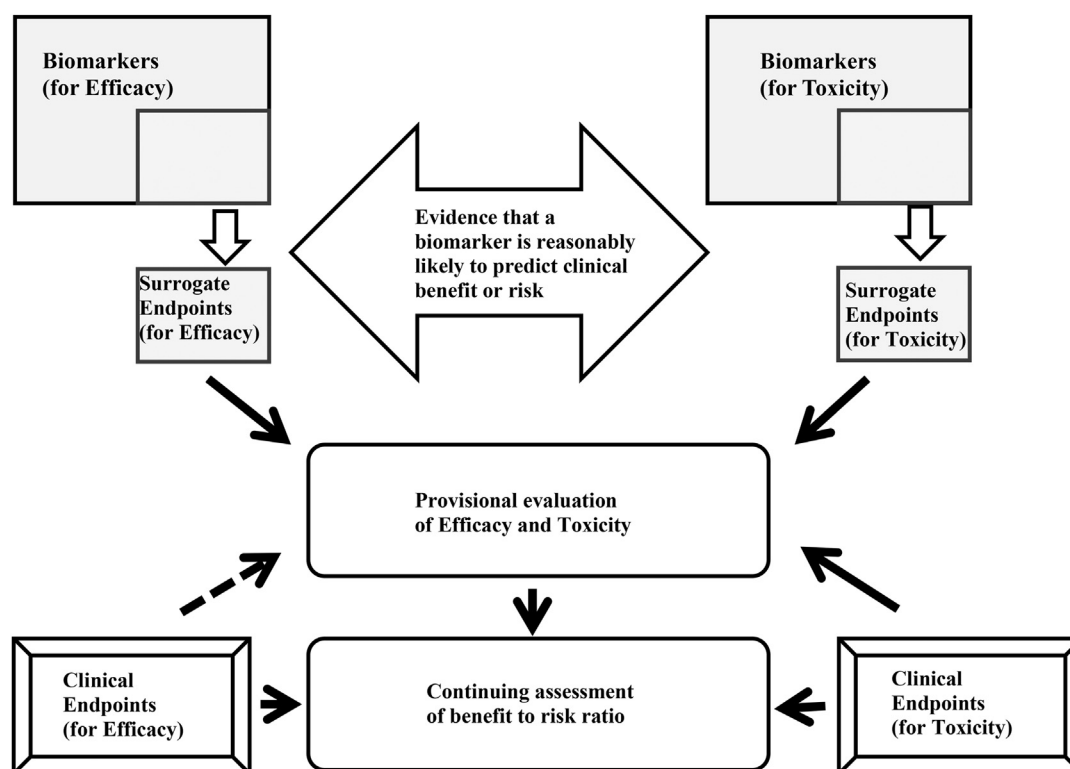
The essential need for a public process biomarker validation is addressed by the European Commission that started development of the IMI draft (IMI, 2005) and the process defined by the recommendations from the European Centre for the Validation of Alternative Methods (ECVAM), which include the development of in vitro models employing cells and tissues from rats


FIGURE 38.3   The biomarker paradigm for drug development (BDWG, 2001).

and mice, so that the in vitro and in vivo data can be compared and the possibility for extrapolating in vitro results to the in vivo situation in man can be determined. IMI (2005) defined desirable characteristics for a biomarker of drug safety assessment: (1) specific for certain types of injury; (2) indicates injury in a variety of experimental species and humans; (3) can be used to bridge across nonclinical/preclinical studies to clinical and surveillance types of studies; (4) more effective at indicating injury than any other biomarker currently used; (5) used instead of classic biomarkers, not in addition; (6) can be easily measured (in real time) even at a later stage (measurement is not strongly time dependent); (7) more reproducible and sensitive than the original toxicity endpoint it would replace; and (8) reduces the number of individuals tested (animals or humans). These IMI definitions are closely reflected in the work of the PSTC of the Critical Path (C-Path) Institute.

Following BDWG (2001), biomarkers have many other important applications in disease detection and monitoring of health status. These applications include the following: (1) as a diagnostic tool for the identification of those patients with a disease or abnormal condition (e.g., elevated blood glucose concentration for the diagnosis of diabetes mellitus); (2) as a tool for staging of disease (e.g., measurements of carcinoembryonic antigen-125 for various cancers) or classification of the extent of disease (e.g., prostate-specific antigen [PSA]

concentration in blood used in cancer detection) to reflect extent of tumor growth and metastasis and α-fetoprotein (AFM) for hepatocellular carcinoma; PSA and AFM have never been formally validated or tested in prospective trials; (3) as an indicator of disease prognosis (e.g., anatomic measurement of tumor shrinkage of certain cancers); and (4) for prediction and monitoring of clinical response to an intervention (e.g., blood cholesterol concentrations for determination of the risk of heart disease).

Safety Biomarkers for Preclinical and/or Clinical Perspectives

Kidney

To date, AKI, also referred to as "acute renal failure," is associated to a high mortality rate of up to 80% (Han and Bonventre, 2004). It has been highlighted that nephrotoxicity contributes to 8%–60% of all cases of AKI, with the mechanisms of nephrotoxicity involving vasoconstriction, altered intraglomerular hemodynamics, direct tubular cell toxicity, interstitial nephritis, crystal deposition, thrombotic microangiopathy, and osmotic nephrosis (Schetz et al., 2005).

The traditional tests to determine kidney toxicity, such as BUN and serum creatinine, are functional markers (i.e., constant production by the body and a clearance via the kidney) and are not optimal for early

detection or localization of kidney damage, being significantly upregulated when up to two-third of the nephron's function has already been lost. Determination of the creatinine clearance measurement is accomplished by measurement of creatinine in blood and in 24 h collection urine. Creatinine, a muscle-derived by-product of creatine metabolism, has several significant advantages as a plasma marker of GFR over urea: it is synthesized and delivered to the plasma at a fairly consistent rate. Serum creatinine, as reference parameter for kidney function, must be regarded with caution because of the following features: (1) serum creatinine concentrations can vary widely within age, gender, muscle mass, muscle metabolism, overall body weight, nutrition situation, and hydration status; (2) serum creatinine concentrations may not change until a significant amount of kidney function has already been lost, meaning that renal injury is already present or occurs before serum creatinine is elevated; (3) at lower rates of glomerular filtration, the amount of tubular secretion of creatinine results in overestimation of renal function (the latter capacity of the kidneys to excrete creatinine is hardly predictable for the individual; it also depends on some medication interfering with tubular creatinine transport); (4) during acute changes in glomerular filtration, serum creatinine does not accurately describe kidney function until a steady-state equilibrium has been reached, which may require several days (Nguyen and Devarajan, 2008). In the short run, BUN and serum creatinine showed poor sensitivity and specificity for detection of renal injury (Star, 1998). Serum creatinine and GFR estimation can only be used in patients with stable or chronically altered kidney dysfunction. For that reason, efforts have been done to find out new urinary biomarker.

Kidney Injury Molecule-1

Kidney injury molecule-1 (KIM-1) is a type 1 trans-membrane protein containing a 6-cystein immunoglobulin-like domain and a mucin domain that is not detectable in normal kidney, tissue, or urine. KIM-1 is a biomarker because transmembrane protein is expressed by tubule epithelial cells in response to injury. KIM-1 is sensitive and specific, has no interferences with pathologies unrelated to kidney, and is highly stable in urine. It exhibits homology to a monkey gene, hepatitis A virus cell receptor 1 (HAVcr-1), and therefore is sometimes referred to as HAVcr-1. KIM-1 mRNA and protein are expressed at a very low level in normal kidney and increase dramatically in injured kidney, particularly in differentiated proximal tubule cells in human and rodent kidney after AKI, ischemia, drug-induced nephrotoxicity, renal cell carcinoma, tubule-interstitial fibrosis, and inflammation; acute and chronic kidney disease all induce KIM-1 gene and protein expressions.

β2-Microglobulin

Urinary β2-microglobulin is a single polypeptide chain of 12 kDa, which is readily filtered by the glomeruli and almost completely reabsorbed and metabolized by the tubuli; therefore, it is used to monitoring tubular reabsorption. Only 0.3% of the β2-microglobulin filtered by the glomeruli is normally excreted into urine. It has been shown that impairment of the tubular uptake causes increased excreted urinary β2-microglobulin concentration levels, up to several hundred-folds. Two identified mechanisms have been involved in this impairment. Firstly, glomerular alterations, damages, and/or diseases allow higher molecular weight proteins to pass through the filtration membrane, causing a high protein load in the tubuli. Consequently, proteins such as albumin compete for common transport mechanisms, decreasing the tubular uptake of β2-microglobulin and increasing the excretion into urine (Thielemans et al., 1994). Secondly, the tubular reabsorption complex is directly impacted by treatment with drugs or different tubular diseases. Increases of urinary β2-microglobulin in the context of nephrotoxicity have been described in more than 200 peer-reviewed publications, such as HIV patients treated with tenofovir disoproxil fumarate and other antiretroviral agents (Gatanaga et al., 2006), patients with aminoglycoside treatments (Schentag and Plaut, 1980), cisplatin treatment regimens (Tirelli et al., 1985), and gold treatment (sodium aurothiomalate) for rheumatoid arthritis (Latt et al., 1981), to name a few examples. In human urine, α-1 and β2-microglobulins are commonly used, due to their relative instability in acid or contaminated urine; in particular, α-1 microglobulin is present in fairly high abundance in normal urine, shows robust elevation with tubular disease, and is slightly more stable to degradation than β2-microglobulin, making it the preferred marker of tubular malfunction in human bioassays (Marchewka et al., 2001; Price, 2002).

Cystatin C

Serum cystatin C is a low molecular protein with a molecular weight of ∼13 kDa. Cystatin C is a 120 amino acid nonglycosylated basic cysteine protease inhibitor widely expressed by all nucleated cells in the body. Urinary cystatin C detects glomerular injury with subsequent impairment of tubular reabsorption, aw well as with similar performance and characteristics as urinary β2-microglobulin. Cystatin C is directly and freely filtered by the glomerulus, is reabsorbed completely, is not secreted by the tubule, and is considered an ideal marker for GFR. Urinary excretion of the low molecular weight protein cystatin C, which is an endogenous

marker of renal dysfunction, correlates with the severity of acute tubular damage. The blood levels of cystatin C are not significantly affected by age, gender, race, or overall muscle mass. It is a marker for the estimation of glomerular function (e.g., in cachectic patients or early AKI, where serum creatinine could underestimate the true renal function) (Urbschat et al., 2011). Cystatin C assay has been compared with serum creatinine measurements in human beings, which is identical in sensitivity. Cystatin C assays are all antibody-based and used against human cystatin C but have antigenic cross-reactivity across species.

Clusterin

Clusterin is involved in cell adhesion, membrane recycling, tissue remodeling, cell cycle regulation apoptosis, and DNA repair. Clusterin is overexpressed in human renal diseases, in particular in renal ischemia, unilateral urethral obstruction, or in response to various nephrotoxins. Urinary clusterin detects tubular injury, with similar performance and characteristics to KIM-1.

Trefoil Factor 3

Trefoil factor 3 (TFF3) a new promising kidney biomarker, detects tubular injury for acute drug-induced renal toxicity (EMEA, 2008).

Overall, the novel biomarkers were more sensitive and specific for kidney injury when compared with BUN and creatinine. Novel and existing biomarkers such as KIM-1, albumin, clusterin, and TFF3 were approved by FDA for use as biomarkers of drug-induced acute kidney tubule alterations in GLP rat studies used to support clinical trials. Total protein, β2 microglobulin, and cystatin C were approved by FDA for use as biomarkers of drug-induced acute glomerular alterations, damage, and/or impairment of kidney tubular reabsorption in GLP rat studies used to support clinical trials (Sauer and Porter, 2018.

Other Kidney Biomarkers

Several protein biomarkers have been assayed as noninvasive indicators of kidney injury.

Lipocalin-2

Lipocalin-2, also referred to as NGAL, is a small 25 kDa secreted protein (belongs to lipocalin family) bound to gelatinases from neutrophils and epithelial cells, including those of the proximal tubule. It is expressed and secreted in kidney epithelial cells only during inflammation as cell protection mechanism, especially in damaged proximal tubuli to induce reepithelialization. mRNA and protein levels are extremely rapidly increased within 3 h of renal ischemic injury in animals and humans. NGAL was found to be a useful early predictor in contrast to KIM-1. A possible issue with NGAL is its specificity; this marker is induced in serum by bacterial infections, chronic obstructive pulmonary disease, and liver injury (Xu and Venge, 2000). Urinary and plasma NGAL have also been proven to predict contrast-induced AKI with a high diagnostic power just 2 h after contrast administration (Bachorzewska-Gajewska et al., 2007; Hirsch et al., 2007) and, similarly, to IL-18, increased NGAL levels in urine collected the day after kidney transplantation could predict recipients with subsequent delayed graft function and who needed dialysis (Parikh et al., 2006). NGAL was identified as one of the fastest upregulated genes in the early phase of the postischemic mouse kidney (Supavekin et al., 2003) being detected in the very first urine sample within 2 h following ischemia and displaying increased levels correlating with the duration of ischemia. NGAL was found to be a useful early predictor of AKI, with urine or plasma/serum NGAL levels functioning as well. Additionally, NGAL level had prognostic value for clinical endpoints, such as initiation of dialysis and mortality (Haase et al., 2009).

N-Acetyl-β-ᴅ-Glucosaminidase

N-Acetyl-β-ᴅ-glucosaminidase (NAG) is a lysosomal enzyme of 140 kDa with two isoforms (A and B) predominantly found in proximal tubules cells so that increased activity of this enzyme in the urine suggests tubular injury to cells and thus can serve as a specific urinary marker for the tubular cells. Because of its high molecular weight, NAG is not filtered by glomeruli and its excretion into urine correlates with increased tubular lysosomal activity, tubular cell injury (leakage), and indirectly with increased proteinuria being a leakage marker. NAG has been used for long time as a marker because of its localization in the proximal tubules. In the course of kidney diseases, AKI, and treatment with nephrotoxic compounds, urinary NAG levels remain persistently elevated before rises of serum creatinine and BUN (Price, 1992). The increase in urinary NAG activity indicates damage to tubular cells, although it can also reflect increased lysosomal activity without cellular damage (Liangos et al., 2007). However, the use of NAG remains limited because its urinary excretion is also elevated in glomerular diseases (e.g., diabetic nephropathy) (Marchewka et al., 2001).

Interleukin-18

Interleukin-18 (IL-18) is a proinflammatory cytokine that belongs to the IL-1 superfamily and is produced by macrophages and other cells. Apart from its physiological role, IL-18 is also able to induce severe inflammatory reactions, which suggests its role in certain

inflammatory disorders. IL-18 is constitutively expressed in the intercalated cell of the late distal convoluted tubule, the connecting tubule, and the collecting duct of the healthy human kidney. Moreover, these cells contain three major components required for the release of the active proinflammatory cytokine IL-18, namely pro-IL-18, P2X7, and the intracellular cysteine protease caspase-1, which converts the preform of IL-18 to its active form, which then exits the cell and may enter the urine, for example, in AKI. Furthermore, urinary IL-18 was significantly upregulated prior to the increase in serum creatinine in patients with acute respiratory distress syndrome who developed AKI, predicting mortality at the time of mechanical ventilation (Parikh et al., 2006). Plasma IL-18 levels are known to be increased in various pathophysiological states, such as inflammatory arthritis, inflammatory bowel diseases, systemic lupus erythematosus, psoriasis, hepatitis, and multiple sclerosis. Thus, although this cytokine seems to be a candidate biomarker in the setting of AKI, its proinflammatory properties and its upregulation in inflammatory disease may limit its application in terms of sensitivity and specificity.

Matrix Metalloproteinase-9

Matrix metalloproteinase-9 (MMP-9) is elevated in postischemic kidney tissue in an animal model. Although it has not been evaluated as a urinary biomarker for AKI, it seems to be an early predictive urinary biomarker of ischemia AKI in children and adult patients after cardiac surgery (Han et al., 2008). These authors examine (1) the utility of urinary biomarkers MMM-9, NAG, and KIM-1 (singly or in combination) for detection of AKI in a cross-sectional study in adults and (2) the temporal expression pattern of urinary biomarkers before the development of AKI in a prospective case—control study in children.

Netrin-1

Netrin-1, a laminin-related neuronal guidance molecule, is highly expressed and excreted in the urine after AKI in animals. Urinary netrin-1 excretion was increased dramatically in 13 patients with AKI, whereas no changes were detected in 6 healthy volunteer urine samples. Therefore, urinary netrin-1 might be a promising early upregulated biomarker for detection of renal injury (Reeves et al., 2008).

Monocyte Chemotactic Peptide-1

Monocyte chemotactic peptide-1 (MCP-1) is a potent chemokine originated by renal cells and acting as mediator in acute ischemic and toxic kidney injury. In the mouse model, MCP-1 protein and its mRNA increased in intrarenal injury more than those of NGAL. In prerenal and postrenal injury, NGAL and MCP-1 gene expressions increased in a comparable way. In patients with AKI, MPC-1 and mRNA levels are increased in urine without overlap in the absolute urine. On that basis, MPC-1 might be a biomarker of AKI, possibly giving complementary information to the NGAL analysis (Munshi et al., 2011).

Liver

The liver is a complex organ with interdependent metabolic, excretory, and defense functions. The liver is the primary organ for drug metabolism and thus is exposed to drugs and metabolites rapidly after gastrointestinal absorption. The gold standards used preclinically and clinically to monitor hepatotoxicity are the liver enzymes ALT and AST measured in blood. Changes in the ALT serum levels point to hepatocyte necrosis with high sensitivity and fairly good specificity. Unfortunately, too high sensitivity is not an advantage here. Often serum ALT levels increase in the absence of histomorphologic alteration in the liver. This emphasizes the potential for other sources of serum ALT activity. Nevertheless, ALT is still more liver-specific, as it is found in highest concentrations in the cytosol of hepatocytes, whereas AST serum activity is also found in blood cells, skeletal muscle, and heart besides of hepatocytes (Hunt et al., 2007). As a result, increased levels of transaminases may be caused by liver-independent processes such as muscle injury, cardiac events, changes of body mass, blood-related pathologies, or pancreatitis.

Heart

The discovery of monoclonal antibodies (Kohler and Milstein, 1975) revolutionized diagnostics for human diseases, including myocardial infarction with the development of a monoclonal antibody reactive only with CK-MB isoenzyme. This led to a quantitative test. A search for more specific markers of cardiac injury focused on the cTn1 and cTnT, which are currently used (Rosalki et al., 2004; FDA, 2012).

The Heart Breakout Group recommended the routine inclusion of three biomarkers in NTP subchronic studies: TN, α_2-macroglobulin in the rat, and BNP in conjunction with ultrasound. All of these biomarkers are considered indicative of a disease process rather than predictive.

α_2-Macroglobulin

α_2-Macroglobulin in the rat, analogous to human C-reactive protein (CRP), was recommended even though this marker is not cardiac-specific because the investigators felt it was important to have an indication of systemic inflammation. α_2-Macroglobulin was suggested as a way to address potential effects on the vasculature.

Like BNP, α_2-macroglobulin is considered to be a "negative" predictor such that a normal value indicates the absence of systemic inflammation and absence of vascular injury. An elevated α_2-macroglobulin would probably be associated with vascular injury, including inflammation (NTP, 2006).

Ultrasound

Ultrasound can be used to identify an adverse effect. Ultrasound is noninvasive technique that requires a live animal and has been recommended for suspected cardiotoxicants (NTP, 2006).

Others Novel Biomarkers

Other novel biochemical plasma biomarkers described for terminal heart failure patients, which might predict an advanced mortality risk or even recovery, are described in the following sections.

C-Reactive Protein

C-reactive protein (CRP) is an acute-phase reactant and has been recommended as a predictive biochemical biomarker for risk of coronary disease. CRP is not a specific biomarker of inflammation and correlates very poorly with extent of atherosclerosis throughout angiography (biomarker of risk). CRP contributes to risk assessment independently of serum cholesterol measures and in particular is consistent with histopathology findings of active inflammatory cells in plaque (Albert et al., 2001). Other inflammatory biomarkers, such as lipoprotein-associated phospholipase A_2, secretory type II phospholipase A_2, oxidized LDL, myeloperoxidase, and growth differentiation factor, are under investigation.

Galectin-3

Galectin-3 (also known as Mac-2, CBP-35, or LBP) is a β-galactoside-binding protein with a preference for lactose and N-acetyllactosamine (Ochieng et al., 2004). There are a number of cell types that express galectin-3 such as neutrophils, macrophages, and mast cells, and lung, stomach, colon, uterus, and ovary cells (Kim et al., 2007). Myocardial galectin-3 was found to be increased in those rats, which progressed to heart failure (Sharma et al., 2004), and therefore is used as a biomarker for prediction of mortality in severe heart failure even under mechanical circulatory support (Kramer and Milting, 2011).

Matrix Metalloproteinases

Matrix metalloproteinases (MMPs) constitute a group of zinc- and calcium-dependent endopeptidases, which are also involved in pathomechanisms of cardiovascular, inflammatory, and oncological diseases (Manicone and McGuire, 2008). More than 20 MMPs have been described, with MMP-2 (gelatinase A) and MMP-9 (gelatinase B) being the most relevant MMPs in cardiovascular disease. The proteolytic activity of MMP-2 and MMP-9 is regulated by cleavage of the propeptide and through inhibition of the active enzyme by endogenous inhibitors of MMPs (tissue inhibitors of metalloproteinases [TIMP] or α_2-macroglobulins) (Clark et al., 2008).

Tissue Inhibitors of Metalloproteinases

The tissue inhibitors of metalloproteinases (TIMP) family is comprised of four members. TIMPs bind MMPs in a stoichiometric 1:1 ratio and thereby block access of substrates to the catalytic domain of the endopeptidases. TIMP-1, TIMP-2, and TIMP-4 are secreted proteins, whereas TIMP-3, as a membrane bound TIMP, is restricted to the extracellular matrix. In the context of secreted biomarkers in heart failure, TIMP-1 and TIMP-4 are the most frequently discussed TIMP family members. The highest TIMP-1 levels have been found in ischemic cardiomyopathy.

Lung

The NTP sponsored a workshop to identified additional biomarkers of lung disease and lipid metabolism (i.e., metabolic syndrome), which could be assessed routinely in NTP subchronic toxicology studies (NTP, 2006).

In pulmonology, one of the biomarkers used is the partial pressure of oxygen (acute lung injury and acute respiratory distress syndrome are defined by the difference between the alveolar and arterial concentration of oxygen). This biomarker reflects the critical life-sustaining function of the organ (delivery of oxygen to the circulation to support aerobic metabolism) (Waikar et al., 2009). Additionally, the Lung Breakout Group considered and discussed a variety of potential approaches for collecting biomarkers ranging from lavage fluid analysis, respiratory function, enhanced tissue pathology, and imaging to gene analysis and proteomics. Of these, the Lung Breakout Group felt three assays would be most useful for the NTP: (1) bronchoalveolar lavage analysis, especially appropriate for obtaining cell counts and differentials. Molecular biomarkers that can be obtained through lavage analysis are, for example, chemokines, cytokines, antioxidants, and albumin, among others, but the Breakout Group did not make specific recommendations. Instead, they recommended the NTP select a panel of markers to evaluate processes such as immunity (innate and acquired) and inflammation; (2) histopathology markers, reflecting lung injury, inflammation, apoptosis, repair, and other events either early or late in the disease process. The Breakout Group

suggested the trichrome and Periodic acid—Schiff stains and Ki67 protein for cell proliferation, conducting immune histochemistry for proteins assessed in bronchoalveolar lavage analysis; and (3) gene expression analysis. The Breakout Group recommended that the NTP explore the use of gene expression analysis not as a routine measure, but on a more limited basis.

Lipid/Carbohydrate Metabolism

The three highest priority biomarkers identified by the lipid/carbohydrate metabolism Breakout Group were serum cholesterol/triglycerides, insulin, and GSH. Liver histological analysis was recommended to separate microvesicular and macrovesicular fatty changes to distinguish different pathological processes. Moreover, insulin was recommended because it is considered a better marker of insulin resistance than glucose, but it was suggested to consider the measure of glucose bound to hemoglobin in red blood cells (hemoglobin A1C or HbA1C) or fructosamine. Regarding metabolic disorders, the GSH measurement was recommended as a marker of whole body oxidative stress. Other biomarkers proposed were sterol regulatory element binding proteins in the liver (if histochemical techniques can be developed) indicating early events in cholesterol (SREBP 2) and fatty acid (SREBP 1) synthesis and liver triglycerides. The measures of inflammation (i.e., tumor necrosis factor alpha and IL-6) could be useful as a routine measurement or in special studies, even though changes are not specific to perturbations in lipid and carbohydrate metabolism.

Central Nervous System

It is now stated that a triplet of cerebrospinal fluid (CSF) biomarker (total tau, phosphorylated-tau, and the 42 amino acid fragment of amyloid beta [Aβ]) reflect core neuropathological features of Alzheimer's disease (AD) and contribute diagnostically relevant information if measured in a proper manner. The cause of AD, a serious neurodegenerative disease, is currently unknown but pathological, genetic, and nonclinical evidence suggests that Aβ peptides and specifically the highly amyloidogenic isoform Aβ42 (with 42 residues) are involved in the pathogenesis of AD. CSF biomarker signature based on a low Aβ1-42 and a high T-tau and/or positron emission tomography (PET)-amyloid imaging positive/negative can be useful to identify patients with clinical diagnosis of mild to moderate AD who are at increased risk to have an underlying AD neuropathology for the purposes of enriching a clinical trial population.

The EMA (2011a) published a positive qualification opinion capacitating the use of low CSF Aβ42 and high CSF tau as enrichment tools for clinical studies of amyloid-targeted therapies in predementia AD. There were two purposes of that qualification. The first purpose was to seek a broadened use of CSF biomarkers as tools to enrich clinical trials in AD dementia patients (mild to moderately severe) with neuropathology most likely to benefit from treatment with amyloid-modulating therapies. The second purpose was to support qualification of PET-amyloid imaging as a second biomarker to be used as an enrichment tool in clinical studies of amyloid-targeted therapies in patients with predementia AD and in patients with mild to moderately severe AD. In patients with minimal cognitive impairment (MCI), a positive CSF biomarker signature based on a low Aβ1-42 and a high T-tau is predictive of evolution to AD dementia type. ELISA methods to measure this CSF biomarker's signature are commercially available but the process of measurement is also complex. The CSF biomarker signature based on a low Aβ1-42 and a high-tau qualifies for identifying MCI patients as close as possible to the prodromal stage of AD, as defined by the Dubois criteria (Dubois et al., 2005).

There are several types of biomarkers relevant for central nervous system diseases drug development. There are five primary types of biomarkers relevant to AD drug development: (1) Brain imaging: *Structure* (magnetic resonance imaging (MRI); diffusion tensor imaging: white matter tracts, cortical thickness mapping); *function* (fluorodeoxyglucose PET); functional MRI; MRI arterial spin labeling; single-photon emission computed tomography (SPECT) of cerebral blood flow; dopamine transporter SPECT; *molecular and chemical constituents* (amyloid PET, MR spectroscopy); (2) electrophysiologic measures: electroencephalography, evoked potentials; (3) plasma, serum, and CSF (amyloid-related measures [Aβ40, Aβ42, other Aβ species]; inflammatory markers [cytokines]; oxidation markers [isoprostanes]; other serum and CSF measures; amyloid synthesis/clearance with stable isotope-labeled kinetics); (4) "omics" platforms with microarray and spectroscopic determination of multiple gene, protein, lipid, metabolite, or other measures combined with advanced informatics required to interpret the study results; and (5) genetics (disease-related [e.g., apolipoprotein genotype]; pharmacogenetics [e.g., CYP enzyme genotypes]) (Cummings et al., 2013). The biomarker IL-18 has also been found to increase the AD-associated Aβ production in human neuron cells.

Genetic and Genomic Biomarkers

Genetic biomarkers (i.e., genetic variation) for drug efficacy and adverse effects have traditionally been derived from two sources: (1) genetic variation in the target on which the drug acts and (2) variation in enzymes that metabolize the drug. The genetic constitution

can influence an individual's sensitivity toward exogenous substances, drugs in particular. Biomarkers that predict risk for disease can identify patients who will have a greater than average benefit from therapy. This creates a new opportunity to enrich clinical trials with patients who are likely to have more events and to achieve earlier drug approval. Markers that predict risk of cardiovascular, thrombotic, and liver diseases may also identify a subset of individuals at substantially elevated risk for adverse drug effects (White et al., 2006).

In principle, identifying genetic risk factors for severe ADRs, particularly idiosyncratic reactions (i.e., severe cutaneous disorders and DILI caused by several drugs), could significantly decrease the incidence rate of ADRs and improve the process of drug development. The genetic basis of ADRs can be categorized into two groups. The first group involves genes that drive pharmacological mechanism (drug targets, drug metabolizing enzymes, and drug transporters (Nakamura, 2008)). The second category involves the immune system; one important molecule for ADRs associated with immune reactions is the HLA, which plays a key role in initiation of immune responses and killing target cells by presenting antigens to the T-cell receptor (Rudolph et al., 2006).

The HLA gene region codes for three classical class I (HLA-A, HLA-B, and HLA-C) and three class II (HLA-DR, HLA-DP, and HLA-DQ) antigens. Class I antigens are recognized by cytotoxic $CD8^+$ T cells and class II by $CD4^+$ T cells. Of the highly polymorphic HLA genes, HLA-B is the most polymorphic with over 800 variants reported in the human genome (Horton et al., 2004). HLA genes within each class encode structurally similar but distinct HLA proteins that bind and present HLA-type–specific antigenic peptides to T-cell receptors (Horton et al., 2004; Rudolph et al., 2006). HLA disease associations that are related to genes with immunological and inflammatory functions have been identified in many autoimmune and inflammatory conditions. Among these idiosyncratic ADRs, the usefulness of abacavir HLA-genetic biomarker (HLA-B*5701) (i.e., induced hypersensitivity reaction in HIV-infected patients) has been confirmed in Caucasians from several prospective studies, such as the PREDICT-1 study (Mallal et al., 2008). This finding has been successfully applied in clinical practice, and a prescreening for HLA-B*5701 before treatment with abacavir has shown a reduction in the occurrence of abacavir-associated hypersensitivity reactions. The association of CBZ-induced SJS/TEN and an HLA-genetic biomarker (HLA-B*1502) in Han Chinese is extremely high compared with other drugs (Chung et al., 2004). Therefore, HLA-B*1502 screening is recommended for CBZ in clinical practice by the US FDA, and HLA-B*5701 screening is recommended for abacavir by the US FDA and EMA. Before treatment with CBZ or abacavir, HLA analysis should be performed to exclude HLA-B*1502 or HLA-B*5701 unless the patient is from a population that shows extremely low frequency of these HLA types. Such exclusion of patients from treatment with causative drugs would markedly reduce the possibility of severe ADRs and prevent overestimation of severe cutaneous ADRs that could otherwise result in excessive discontinuation of treatment (Hung et al., 2006).

Other biomarkers of drug toxicity of genetic variation in human are dihydropyrimidine dehydrogenase, thiopurine methyltransferase, CYP2C19, the *bcr-abl* translocation, Factor V Leiden, and APOE4 (White et al., 2006).

Classic examples of genomic biomarkers (i.e., genetic variation) for drug efficacy include genetic variation in the drug target (including its expression level) and drug-metabolizing enzymes. There are numerous metabolic biomarker tests that are on the market as FDA-approved or laboratory-developed tests. Recent US FDA approvals of tests for cytochrome P-450, CYP2D6 and CYP2C19, and uridine diphosphate glucuronosyltransferase (UGT)1A1 have given regulatory endorsement to biomarkers that can improve drug safety by identifying individuals at risk for drug toxicity. The test results are indicative of whether the patient is an ultrarapid, extensive, intermediate, or poor metabolizer of a drug that is substrate for CYP2D6 or CYP2C19. This type of genotyping knowledge may assist the treating clinician in selecting the right dose for a given patient to achieve target systemic drug exposure. UGT1A1 genotype information is of the utility in the treatment use of irinotecan, a drug used to treat colon cancer and small cell lung cancer.

Oncotype DX predicts the risk of women with node-negative, estrogen receptor–positive (ER^+) breast cancer of experiencing cancer recurrence 10 year following diagnosis and also predicts the extent of benefit with chemotherapy. A similar test is the MammaPrint approved by the FDA. Genetic tests recently approved by the FDA are tests for the polymorphisms in two enzymes, CYP2C9 and VKORC1, for determining an optimal starting dose for warfarin therapy.

Biomarker Validation and Qualification

Most safety biomarkers have been used in safety assessment for many years without being formally qualified, and many of them show deficiencies with respect to sensitivity, specificity, and predictive value (Boekelheide and Schuppe-Koistinen, 2012). With that in mind, during development of biomarkers, the following steps should be followed: (1) identification, (2) preclinical qualification, and (3) clinical qualification and diagnose use (Marrer and Dieterle, 2010). These are described in more detail in the following sections.

Identification of Safety Biomarkers

Preclinical screens of histopathology and informative biomarkers are essential in transitioning new drugs into human testing. For this to take place, the peripheral biomarkers must reflect histopathological changes or events. The safety biomarker study should be oriented toward identification biomarkers that have the greatest measured peripherally in body fluids (i.e., serum, plasma, and urine) when beginning the investigations of toxicity.

At present, identification of the biomarkers needs toxicogenomics, which implies the integration and correlation of data from toxicology studies. Toxicogenomics relates to substance-induced changes of the transcriptome to identify cellular and subcellular mechanisms. Perturbation of the expression profile of specific genes leads to pathological outcomes. Taking the examples of nephrotoxic drugs, a number of genes such as clusterin, NGAL, and KIM-1 are strongly and coherently deregulated in the kidney and correlate well with histopathologically confirmed lesions in the tubules (Marrer and Dieterle, 2010). The genomic-derived candidates can then be localized in the organ of interest by ISH and IHC for its protein.

The perturbation at the mRNA level of a perfect safety biomarker candidate is reflected in its protein level and subsequent secretion into periphery. A protein modulated by toxicity can be identified by proteomics (measured total cellular protein and determine the posttranslational modification and fate of proteins) in the tissue or peripheral fluids. Data from proteins can be more relevant that the information from genomic analysis, due to the fact that the changes in mRNA levels do not necessarily correlate with changes in protein expression.

Once this identification of protein biomarker candidates is done, it is followed by the development of immunoassays for routine determinations as to which methods need validation in terms of specificity, selectivity, accuracy, precision, sensitivity, robustness, linearity and parallelism, and dynamic range (using a definition of an upper and lower limit of detection and quantification). Traditional methods used to characterize and quantify biomarkers from preclinical and clinical studies are chromatography and mass spectrometry.

Preclinical Qualification

The regulatory agencies have initiated the creation of various consortia that are working toward the identification and characterization of exploratory biomarkers to qualify them for a specific use. Currently, collaborations exist between pharmaceutical companies, regulatory agencies (US FDA and EMA), and academia for qualifying biomarkers, providing a model that investigates and identifies reliable safety markers for preclinical applications. An example of such a collaboration was initiated by the Nephrotoxicity Working Group of the PSTC, which was created as part of the FDA's C-Path Initiative in 2007. PSTC was initially established with the primary aim of qualifying novel nonclinical safety biomarkers for use in nonclinical safety assessment studies to support drug development. As discussed elsewhere, most novel safety biomarkers being evaluated by PSTC have been correlated with histopathological changes in target organs and are designed to substitute for histopathological evaluation in its absence (Dieterle et al., 2010). The PSTC nonclinical qualification strategy is to use specific prototypical organ toxicants in rats, dogs, and nonhuman primates to define correlations between novel biomarker response and histopathological changes. Currently, the primary target organs of interest for PSTC are the liver, kidney, testis, pancreas, heart, skeletal muscle, and vascular system. Regulatory qualification is the formal regulatory endorsement or acceptance of a drug development tool for a specific COU.

Qualification of novel nonclinical biomarkers for use in animal models provides a regulatory endorsed tool to assess the safety and efficacy of new drugs prior to clinical development with the next step being translation of the preclinical biomarker to a qualified clinical biomarker (Sauer and Porter, 2018).

Renal biomarkers have been divided into clinical application of tubular markers and glomerular markers. Other groups are presently involved in qualifying biomarkers to detect hepatotoxicity, vascular injury, nongenotoxic carcinogens, and myopathy. Thus, each group is dealing with qualification of a biomarker within a certain context. A marker may be useful in one clinical setting—for example, patients in an intensive care unit or patients with sepsis or after cardiac surgery—but not in another. The very best biomarkers will be useful in many situations (Lock and Bonventre, 2008).

Many biomarker candidates have failed to show sufficient specificity and sensitivity for clinical use, although other promising candidates have emerged recently. In the Nephrotoxicity Working Group of the PSTC, performance of each new biomarker versus the accepted standards of BUN and serum creatinine is evaluated by comparison of the area under the curve (AUC) of the receiver operating characteristic (ROC) analysis for each new biomarker with the similar data obtained for BUN and creatinine. ROC curves provide a comprehensive and visually attractive way to summarize the accuracy of predictions. Each point on the curve represents the true-positive rate and false-positive rate associated with a particular test value. ROC curves have been generated both from data merged from all positive

histopathology scores as a benchmark for renal injury for all studies by study site, as histopathology is widely regarded as the "gold standard" for animal studies, and for data from subset ranges of these scores. AUC provides a useful metric to compare different tests (indicator variables). While an AUC value close to 1 indicates an excellent diagnostic test, a curve that lies close to the diagonal (AUC = 0.5) has no information content and thus no diagnostic practicability. Finally, in confirmatory studies, the best cut-off value is determined for each biomarker based on the best ratio between sensitivity and specificity.

The Nephrotoxicity Working Group of PSTC selected 23 urinary biomarkers and evaluated the utility of most promising biomarkers in several rat models of kidney injury, which were performed under GLP regulations. A first set of new nephrotoxicity biomarkers is currently being evaluated in rats using known nephrotoxicants (e.g., gentamicin, cisplatin). These biomarkers reflect toxicity in different anatomical regions of the kidney and are intended to provide earlier warning signs of drug-induced toxicity. Seven renal safety biomarkers (KIM-1, albumin, total protein, β2-microglobulin, cystatin C, clusterin, and TFF3) were qualified for limited use in nonclinical and clinical drug development following submission of drug toxicity studies and analyses of biomarker performance for the US FDA and EMA by PSTC Nephrotoxicity Working Group. The ROC curves have been performed for the complete KIM-1 and albumin data and also for the complete KIM-1, clusterin, total protein, β-2 microglobulin, and cystatin data. The FDA and the EMA, respectively, have concluded that seven urinary biomarkers of kidney injury submitted by the C-Path Institute of PSTC are considered qualified for particular uses in regulatory decision-making. The first four can be included as biomarkers of drug-induced acute kidney tubular alterations in GLP rat studies to support clinical trials, whereas the last three can be included as biomarkers for acute glomerular alteration/damage and/or impairment of kidney tubular reabsorption (Dieterle et al., 2010). The current gold standard biomarkers, serum creatinine and BUN, are insensitive and appear only in advanced stages of kidney injury (Waikar et al., 2009).

A number of accessible protein biomarkers, with a high probability of success in diagnosing nephrotoxicity in rats and monkeys, are available as exploratory biomarkers. These include (in addition to the widely known biomarkers such as urinary albumin, urinary total protein, urinary β2-microglobulin) the Kim-1, clusterin, and urinary cystatin C, TFF3, as well as changes in the differential expression of other genes included in a toxicogenomic signature for nephrotoxicity. These seven kidney biomarkers correlate to either tubular histomorphologic alterations or to glomerulopathy with functional tubular involvement and "add information" to serum creatinine and BUN.

To support the use of biomarkers for translational contexts to allow the translation of a drug into human studies, which caused renal injury in preclinical GLP studies, the clinical data were accompanied by peer-reviewed experts supporting their clinical utility. As a result, the EMA and FDA concluded that (1) in the context of nonclinical drug development, the seven urinary kidney biomarkers submitted were considered acceptable for the detection of acute drug-induced nephrotoxicity, either tubular or glomerular with associated tubular involvement. They provide additional and complementary information to BUN and serum creatinine to correlate with histopathological alterations considered to be the gold standard. Additional data on the correlation between the biomarkers and the evolution and reversibility of AKI and information on species-specificity are needed. In addition, further knowledge on species-specificity is required. However, it was recognized that KIM-1, β-2 microglobulin, and total protein are considered acceptable for preclinical context. (2) In the context of clinical drug development, it was recognized that it is worthwhile to further explore, in early clinical trials, the potential of KIM-1, albumin, total protein, β2-microglobulin, urinary clusterin, urinary TFF3, and urinary cystatin C as clinical biomarkers for acute drug-induced kidney (DIKI) injury.

Until further data are available to correlate these biomarkers with the evolution of the nephrotoxic alterations and their reversibility, their general use for monitoring nephrotoxicity in the clinical setting cannot be qualified. The use of these renal biomarkers in clinical trials is to be considered on a case-by-case basis to gather further data to qualify their usefulness in monitoring drug-induced renal toxicity in man.

The regular qualification of biomarkers is actually supported by a formal biomarker qualification process, which was established by the EMA (formerly EMEA) (scientific advice procedures) in the course of this formal biomarker submission. The EMA issued a draft guidance document for pharmacogenetics in 2005 (EMEA, 2005). The EMA and FDA guidelines for voluntary genomic data submission, both the documents, contribute to minimize risks of creating inadvertent obstacles to the use of genomic technology. The EMA issued other documents related with pharmacogenomic biomarkers as well (EMA, 2007; EMA, 2011a; b).

Clinical Qualification and Diagnostic Use

The clinical qualification of safety biomarkers for wide contexts of use is faced with additional challenges compared with preclinical qualifications. In addition to

the absence of histopathology evaluation as gold standard, the many challenges include clinical endpoints that are often nonperfect gold standards, less-controlled heterogeneous populations with sometimes underlying chronic diseases and co-medications, low incidences rates of drug-induced toxicities in clinical studies, ethical concerns, logistic challenges, and many more (Marrer and Dieterle, 2010). In addition to the PSTC consortium, to help define the operational approach for the qualification of safety biomarkers, the European IMI Strategic Research Agenda issued a draft by the European Commission (IMI, 2005) safer and faster evidence-based translation consortium (SAFE-T), which has established a generic qualification strategy for new translational safety biomarkers (TSBMs) that will allow early identification, assessment, and management of drug-induced injuries throughout the research and development process. The SAFE-T consortium is a public—private partnership comprising 20 participants from the pharmaceutical industry, small to medium enterprises, academic institutions, and clinical units of excellence with representatives from the EMA and FDA as external observers and advisor.

The clinical studies in SAFE-T are to be conducted by applying all relevant national and European Union (EU) legislation and regulations. The collection, use, and retention of blood samples will be compliant with Directive 95/46/EC of the European Parliament and of the Council of October 24, 1995, on the protection of individuals with regard to the processing of personal data and on the free movement of such data (OJ L 281, 23.11.95). The Charter of Fundamental Rights of the EU dedicates certain political, social, and economic rights for EU citizens and residents into EU law (drafted by the European Convention and solemnly proclaimed on December 7, 2000, by the European Parliament, the Council of Ministers, and the European Commission; its then legal status was uncertain and it did not have full legal effect until the entry into force of the Treaty of Lisbon on December 1, 2009), and Directive 2001/20/EC of the European Parliament and of the Council of April 4, 2001, on the approximation of the laws, regulations, and administrative provisions of the member states relating to the implementation of good clinical practice in the conduct of clinical trials on medicinal products for human use (OJ L 121, 1.5.2001).

The SAFE-T consortium proposes a generic qualification strategy for TSBMs, outlining proposals on how to generate sufficient preclinical and clinical evidence to qualify new TSBM for regulatory decision-making in defined contexts. The experience gained during the course of the SAFE-T project for three organ toxicities will be integrated into improvements for this initial generic approach. Each work program

DIKI, DILI, and DIVI will follow the general qualification plan of a two-stage program of studies: initial exploratory followed by confirmatory studies. The biomarker profile for DILI is considered exploratory preclinical and clinical and for DIVI, exploratory (Matheis et al., 2011).

As stated previously, most safety biomarkers in use today have not been formally qualified. There is no systematic scientific qualification strategy in place allowing for the accumulation of sufficient clinical and biological evidence for the acceptance of biomarkers independent of a specific drug. Regulatory agencies have established submission procedures for the regulatory review and endorsement of biomarker qualification, but they have not yet defined the scientific standards and approaches needed. The SAFE-T consortium has proposed principles of a research plan to develop biomarkers for regulatory decision-making in specific circumstances (Matheis et al., 2011) (see Fig. 38.4). This type of endorsement is known as "regulatory qualification"; that is, the formal regulatory endorsement or acceptance of a drug development tool for a specific COU.

The first submission of kidney safety biomarkers by the PSTC (Dieterle et al., 2010) also opened the door to a new framework of fit-for-purpose qualification of biomarkers instead of having an absolute "all or nothing" qualification. With more data and evidence, the limited context can be extended. This principle has been referred to as an "incremental," "progressive," or "rolling" qualification. Thus, the SAFE-T consortium proposes broad principles of a research plan including assay method validation and biomarker qualification to develop biomarkers for regulatory decision-making in specific contexts. While clinical diseases have a long history, systematic efforts to discover and validate markers of adverse exposure to or effects of exogenous chemical agents (i.e., toxicological biomarkers) are generally more recent. Most safety biomarkers have been used in safety assessment for decades without being formally qualified, and many of them show significant deficiencies regarding sensitivity, specificity, and predictive value. They provide little molecular understanding of the mechanisms of toxicity and their deficiencies contribute to safety-related drug attrition and withdrawals (Kola and Landis, 2004).

Translational Safety Biomarker

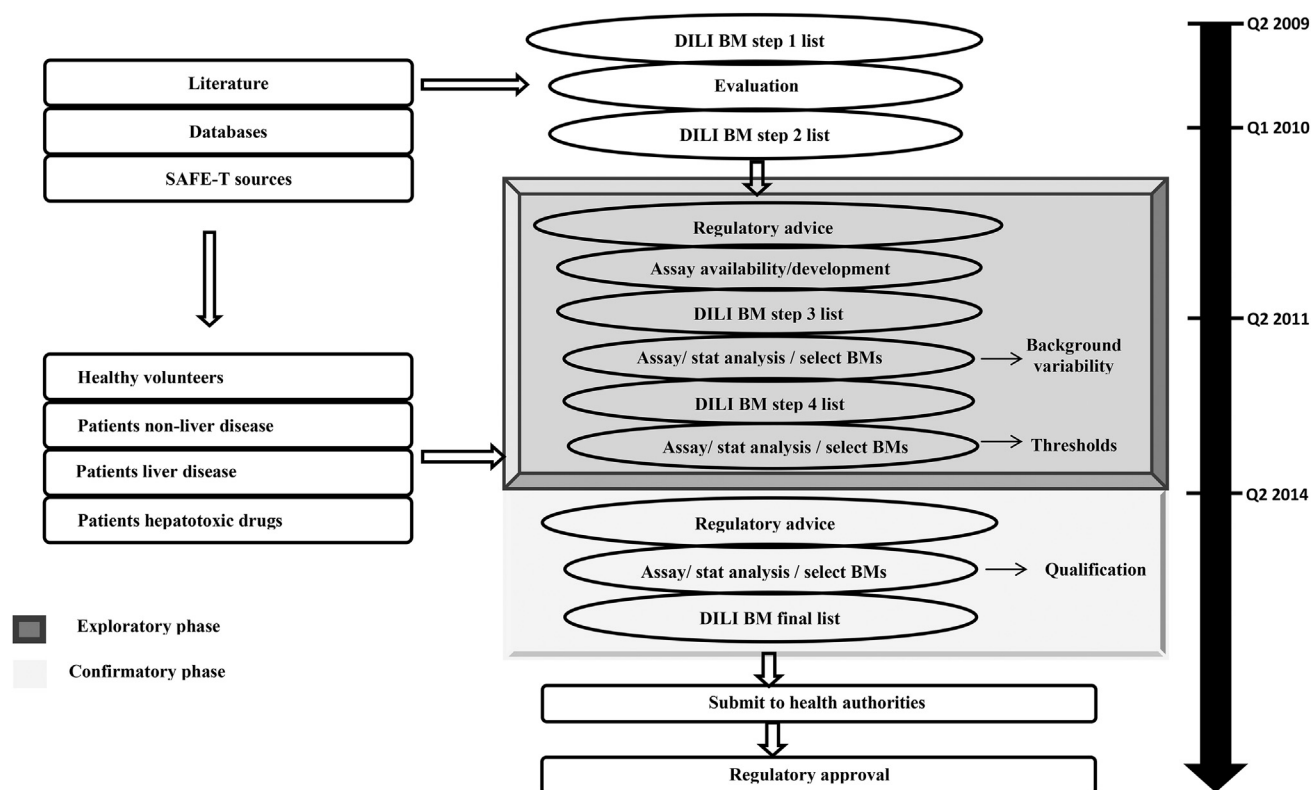
Translational research is the research process that investigates and translates nonclinical research results into clinical applications and tests their safety and efficacy in a Phase 1 clinical trial. Traditionally, nonclinical drug toxicity can be investigated using cellular tests, cell culture, and tissue culture models to explore


FIGURE 38.4   Biomarker qualification process proposed by safer and faster evidence-based translation (SAFE-T) consortium.

molecular, cellular, tissue, and even organ effects in vitro. Moreover, animal models provide needed information at the organism level. The future of preclinical biomarker qualification describes the translational role that preclinical biomarkers play in the qualification process for clinical biomarkers. One characteristic of the safety biomarkers is that it is noninvasive and translates between species. Biomarkers may have their greatest value in early efficacy and safety evaluations such as in vitro studies in tissue samples, in vivo studies in animal models, and early-phase clinical trials to establish "proof of concept." To improve these outcomes, a systemic and dynamic understanding of physiological and pathophysiological processes is needed, along with expanded application of translational biomarkers for drug efficacy and tissue and organ injury. TSBMs can predict, detect, and monitor drug-induced toxicity during human trials for testing drugs and are needed to assess whether toxicities observed in laboratory animal studies are relevant to humans at therapeutic doses.

In the case of studies in experimental animals, the biomarker must also be the one that is relevant to humans. The most valuable biomarkers are those that can be used in animals and humans. These "translational biomarkers" can be rigorously studied in animals, thereby establishing well-defined relationships between biomarker levels and tissue histopathology. One of the most notable challenges in assessing drug toxicity in humans is that we do not have tools capable of predicting toxicity across species borders (Bonventre et al., 2010). The dependence of preclinical screening on histopathology and weakly informative biomarkers causes considerable delays and inefficiency in transitioning new drugs into human testing. Therefore, delays confirmation of the safety and effectiveness of new therapies is needed (Warnock and Peck, 2010). In humans the transitional biomarkers are of particular interest, as they can be used to monitor safety and efficacy in clinical trials, in particular when the capacity to obtain tissue is severely restricted for performing histopathology. For example, liver biopsies are performed by percutaneous or transvenous routes and they have limitations on the procedure and relative contraindications.

One example of the importance of translation research is translational neuroscience, which provides a framework for advancing development of new therapies for AD patients. This translational neuroscience includes new preclinical models that may better predict human efficacy and safety, leading to improved clinical trial designs and outcomes that will accelerate drug

development and the use of biomarkers for more rapidly providing information regarding the effects of drugs on the underlying disease biology. The NIH is responding to the crisis in drug development by funding translational research. The formation of the National Center for Advancing Translational Science (NCATS) is one milestone in reorganizing the NIH to orient more toward public—private partnerships and product development (Collins, 2011). NCATS has resources to support drug discovery and advance promising compounds through preclinical development, including assay development and high-throughput screening, synthesis, formulation, pharmacokinetics, toxicology, medicinal chemistry, molecular libraries probe production, genomics, interference RNA, tissue chips for drug screening, and technologies for identifying and validating drug targets.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Unexpected drug toxicity is still a major reason for pharmaceutical companies withdrawing drugs from the marketplace. Among ADRs, hepatotoxicity and nephrotoxicity are two major causes for drugs being withdrawn postmarket, in part because of the failure of animal safety studies to translate to human safety of a new chemical entity. Two examples of high risk for drug adverse reactions are the acetaminophen hepatotoxicity and the high incidence of antitubercular and antiretroviral DILI (McIlleron et al., 2007). In both clinical situations, biomarkers hold much interest. In the first condition, the circulating miRNAs represent a class of liver specific blood-based biomarkers during clinical acetaminophen hepatotoxicity. In the second condition, the pharmacogenetic variations in genes determine susceptibility to DILI in tuberculosis/HIV coinfected patients. Other important drug adverse reactions are related to vessels and heart, as well as brain injuries. Pharmaceutical industries and regulatory agencies expect that new and better safety biomarkers will play an important role in improving key aspects of the drug development process, as well as shortening the time-consuming process and reducing the cost. Thus, there is a need for new efficient biomarkers with enough sensitivity and specificity to translate effectively from the preclinical phase to clinical phase. One characteristic of the biomarkers is that they can be noninvasive and can translate between species. The TSBMs can predict, detect, and monitor drug-induced toxicity during human trials for testing drugs and are needed to assess whether toxicities observed in laboratory animal studies are relevant to humans at therapeutic doses. The most valuable biomarkers are those that can be used in animals and humans. The safety biomarkers to be used in safety assessment should be formally qualified and validated and are important in all phases of drug development, including discovery, preclinical assessment, clinical trials, and postmarket surveillance. Biomarkers from blood and urine could replace traditional histopathological evaluation to determine adverse responses in several organs, tissues, and systems such as kidney, liver, heart, vascular vessels, lung, central nervous system, and lipid/carbohydrate metabolism. New technologies and molecular approaches, including molecular profiling and molecular pathology with rapid detection of urine and blood as a complement to the classical toolbox, promise a future of further discoveries and improvements in the safety biomarker field and for the first time have been accepted by the regulatory agencies. There are high demands for ideal properties and roles of biomarkers in several pathological conditions. Biomarkers should be organ-specific in addition to having rapid execution and being inexpensive, noninvasive, reliable, and capable of an early detection. Personalized medicine biomarkers can be of utility to predict whether an individual will respond adversely to drug therapy. For some drugs, it is recommended to use genetic tests before the drug is prescribed. Studies of disease could discover biomarkers that can also be used to identify drug-induced injury (in particular, liver, kidney, vessels, heart, and brain injuries). To optimize clinical utility of biomarkers, body fluids are preferred over direct tissue sampling. The possible utilization of genomics applied to peripheral blood cells in the area of disease and brain injuries would fulfill a great medical clinical need. Much remains to be done in terms of reproducing the gene signatures in new biological samples, demonstrating, for example, disease exclusivity, before their usefulness can be discerned. Studies have discovered that the expression of miRNA may provide a new tool in detecting ADRs.

Risk Assessment, Regulation, and the Role of Biomarkers for the Evaluation of Dietary Ingredients Present in Dietary Supplements

Sandra A. James-Yi[1], Corey J. Hilmas[2], Daniel S. Fabricant[3]

[1]Associate Principle Scientist, Product Safety/Nutritional Toxicology, Mary Kay Inc., Addison, Texas, United States; [2]Senior Vice President of Scientific and Regulatory Affairs, Natural Products Association, Washington D.C., United States; [3]President and CEO, Natural Products Association, Washington D.C., United States

INTRODUCTION

Dietary supplements in the United States are an FDA-regulated commodity used by an increasing number of individuals on a daily basis. This topic brings up a wide range of opinions from both supplement users and nonusers alike, in regard to regulation, safety, and efficacy. There are reports in the literature suggesting that the use of certain dietary supplement products and ingredients, specifically, those with a known or predictable pharmacological activity (nutraceuticals), have the potential for adverse events even if a preemptive risk assessment is performed prior to market distribution. Despite the long-held standing that a particular dietary ingredient is "safe" due to a substantial history of traditional use, information and research substantiating present-day usage and form may be lacking.

There are considerable drivers in the marketplace that contribute to or potentially compound risk. These include a public perception that these products are inherently safe because they are advertized as "all-natural"; have a history of traditional use but in a different form or manufactured by a different process; and are sold to the consumer as a capsule or tablet, similar to prescription drugs they would get from a medical professional, and thus deemed to have undergone the same process, scrutiny, and guidance as pharmaceuticals prior to release in the marketplace or there may be the belief that they have passed regulatory standards for product safety or efficacy, by a regulatory body such as FDA. In addition, because of the passage of time between the original use of a supplement and present day suggested use, and the evolution of modern-day medicine, there is a significant loss of historical knowledge and familiarity with many products, their nutritive value, and recommended usages within the traditional medical community.

Because of customer demand, many health-care practitioners are becoming more familiar with many of the dietary supplements on the market. The industry has grown at such a rapid pace that all of the products and combination products that are available to the average consumer may be difficult for medical practitioners and the general public to follow. Inherent in the science of nutrition is the difficulty in developing and performing robust studies. The scale with which products are coming onto the market makes this even more of a challenge for health-care professionals, industry, government regulators, and consumers alike. Communication is essential between health-care practitioners and their patients with respect to what is known about individual and combination dietary supplement products and the applicable cautions that need to be tailored to an individual's specific needs.

A contributing factor to the risk associated with the use of dietary supplements is consumer misinformation or lack of education for their intended use. Consumers of supplements often "self-prescribe" over-the-counter dietary supplements based on information from web-based public domains, bloggers, media outlets, word-of-mouth within their communities, manufacturers, and distributors of products.

The goal of this chapter is to review the process of assessing risk associated with the use of dietary supplements; the role that biomarkers play in the risk assessment and identification of hazards associated with the use of dietary supplements by different populations of users; and how science informs FDA regulatory decisions with respect to FDA's regulatory tools for application to dietary supplements. Although not exhaustive, listed below are factors to take into consideration when evaluating comprehensive safety profiles for dietary supplements as part of the process of risk assessment and hazard identification. Although the goal of this chapter is to address the biomarkers of physiological and biochemical changes corresponding with or directly caused by dietary supplements and ingredients with pharmacological activity (nutraceuticals) or toxicity, this subject is immense and incorporates all of the chapters in this text as they apply to biomarkers of multiple organ system functions. Dietary supplements are commonly mixtures and many times they are derived from the extrapolation of botanicals used in traditional or folk medicine for modern-day applications. As such they will have multiple target sites for activity that cannot be easily condensed into a simple algorithm. Factors that need to be considered by toxicologists in performing risk assessments for these products include but are not limited to the following:

- **Inappropriate application of the known pharmacology** of an ingredient or supplement for uses that differ from their traditional or historical applications. For example, ephedra has an extensive history of use for treatment of clinical symptoms associated with respiratory disease. Its traditional use was never intended to be for weight loss. Thus, the known pharmacology of the ingredient, especially safety and efficacy, was not applicable to products marketed or intended to be used for weight loss.
- **Changes in the duration of use** of a dietary supplement from the traditional posology of acute or intermittent usage in folk medicine to an intended current usage of prolonged, continuous, or chronic usage, typical of nutritional supplementation to an individual's diet.
- **Changes in dose** causing a larger, possibly excessive dose to be administered to achieve some particular result(s). Maximum levels of product, close to the tolerable upper limit for administration, may be delivered to consumers to make sure that a product on a store shelf has a labeled amount of constituent ingredients at the time of purchase and use. Some products that may have a short shelf-life of active constituent(s) have resulted in industry maximizing

the amount per serving for dosing, based on tolerable, upper limits for a reasonable expectation of safe use rather than the minimal amount used to effect as is practiced within the pharmaceutical industry.
- **Changes in processing** that are significantly different from traditional or well-established methods. Herbs that historically have been consumed in one specific form, or in a particular cultural tradition for use, may now be processed or manufactured differently for the mass market. An example would be a botanical supplement that historically used a particular part of the plant for the basis of a tea preparation in folk medicine, may now be extracted with an organic solvent to extract and concentrate a specific, physiologically active component of the same plant. This significantly changes the chemical profile being delivered to consumers. The inherent synergist or antagonistic activity of constituents in the original tea may be gone and the resulting, concentrated extract may have an inherently different activity, posology, and risk assessment for a reasonable expectation for safe use within the general population for its intended use.
- **Concurrent use** of dietary supplements by consumers taken in conjunction with pharmaceuticals, especially drugs with a narrow therapeutic index. The medicinal drugs and supplements may have similar mechanistic actions or pathways of metabolism. Health-care professionals and the general population may not be educated adequately to think of dietary supplements contributing to potential problems with this type of polypharmacy. The concurrent use of multiple dietary supplements or herbal medicines with additive, synergistic, potentiating, or antagonistic pharmacological and toxicological activity can have serious consequences in individuals being treated for other medical conditions.

As science-based professionals, there needs to be a heightened level of communication between regulatory, academia, industry, and health-care professions, with the goal of identifying patterns of hazard or risk associated with the use of dietary supplements. The consumer rightfully assumes and expects that all stakeholders interested in dietary supplement safety have done due diligence prior to a product reaching the market. A reasonable expectation of product safety standards must align with the precautionary principle used by toxicologists involved in providing risk assessments to prevent potential harm in a very dynamic, demanding, lucrative, and growing marketplace.

OVERVIEW OF REGULATION OF DIETARY SUPPLEMENTS IN THE UNITED STATES

Federal Food, Drug, and Cosmetic Act

Dietary supplements are governed by four major sections of the Federal Food, Drug, and Cosmetic Act (Federal FD&C Act).

- Sec. 201 [21 U.S.C. 321] DEFINITIONS (ff)
- Sec. 402 [21 U.S.C. 342] ADULTERATED FOOD (f) and (g)
- Sec. 403 [21 U.S.C. 343] MISBRANDED FOOD
- Sec. 413 [21 U.S.C. 350b] NEW DIETARY INGREDIENTS

Dietary supplements are regulated under the Federal FD&C Act (the Act), as amended by the Dietary Supplement Health and Education Act (DSHEA) of 1994, and under the Fair Packaging and Labeling Act. DSHEA established a framework for regulating the safety of dietary supplements. This gave regulatory authority to the FDA to take action if there are product safety concerns (Hobson, 2009). Implementing regulations for certain provisions of DSHEA can be found in Title 21 of the Code of Federal Regulations (21 CFR). The term *dietary supplement* as defined in section 201(ff) of the Federal FD&C Act (the Act) is a product (other than tobacco) intended to supplement the diet that contains one or more of certain dietary ingredients, such as a vitamin, mineral, herb, other botanicals, amino acid, or dietary substance for use by man to supplement the diet by increasing the total dietary intake, of a concentrate, metabolite, constituent, extract, or combination of the preceding ingredients. Section 201(ff) of the Act further limits the term *dietary supplement* to mean products that are intended for ingestion in a form described in section 411(c)(1)(B)(i) of the Act (tablet, capsule, powder, softgel, gelcap, or liquid), which are not represented as conventional food, or as the sole item of a meal or of the diet, and that are specifically labeled as dietary supplements. According to 201(ff), "[e]xcept for purposes of section 201(g), a dietary supplement shall be deemed to be a food within the meaning of this Act." Based on case law, dietary supplements are not only regulated as food but must also be ingested, where "ingestion" means to take into the stomach and gastrointestinal tract by the oral route of administration having first passed through the mouth.

The term *dietary supplement* does not include products that are approved drugs, certified antibiotics, licensed biologics, or products that are authorized for investigation as a new drug, antibiotic, or biologic (and for which substantial clinical investigations have been instituted and for which the existence of such investigations

have been made public), unless the product was marketed as a dietary supplement or as a food before it was approved as a drug, antibiotic, or biologic, or, in the case of investigational products, before the public disclosure of such investigations.

Dietary supplements may not contain dietary ingredients that present a significant or unreasonable risk of illness or injury as set forth in section 402(f) of the Act, or that may render the supplement injurious to health (see section 402(a)(1) of the Act).

Under section 413 of the Act, a manufacturer of a dietary supplement that is or that contains a new dietary ingredient (NDI) (an ingredient that was not marketed in the United States before October 15, 1994) must submit to FDA, at least 75 days before marketing, information substantiating the manufacturer's conclusions that use of the dietary supplement will be expected to be reasonably safe for its intended use. Alternatively, a manufacturer of a dietary supplement that is or contains an NDI may petition FDA to issue an order prescribing the conditions under which such a dietary supplement will be expected to be reasonably safe. Nevertheless, it is still the responsibility of the manufacturer to ensure that a dietary ingredient used in a dietary supplement is safe for its intended use.

It is important to remember that there is no authoritative "list" of substances that were marketed in the United States as ingredients in dietary supplements or foods before October 15, 1994. Therefore, the manufacturer must determine if an ingredient may be a "new dietary ingredient" under the Act for which a notification is required. If a manufacturer does not have a basis to conclude that a notification is not required, and they introduce a product containing the ingredient into interstate commerce, they do so at the risk that it may be considered adulterated as a matter of law. In the absence of evidence that a dietary ingredient does not require a notification to be submitted for it, manufacturers may wish to make the required notification to avoid uncertainty. In the September 23, 1997 Federal Register, FDA published a final rule promulgating a procedural regulation in 21 CFR 190.6 for making the required notification.

DSHEA was followed by the Dietary Supplement and Nonprescription Drug Consumer Protection Act (Public Law 109—462), which was signed into law on December 22, 2006 and became effective on December 22, 2007. This law amended the Federal FD&C Act with respect to reporting of serious adverse events related to dietary supplements and nonprescription drugs. The law has four major provisions: requiring (1) the collection of all adverse event reports by manufacturers, distributors, and retailers of dietary supplements; (2) the reporting of serious adverse event reports to the FDA; (3) firms to maintain records of reports of all adverse events from use of the dietary supplement(s) such that FDA

is allowed to audit those records; and (4) that dietary supplement labels provide information to facilitate the reporting of serious adverse events associated with their use by consumers.

Lastly, Public Law P.L. 111−353, the FDA Food Safety Modernization Act, was signed into law on January 4, 2011. The major elements of the law include: prevention-based controls, inspection, and compliance to hold industry accountable; greater tools for increased food safety; mandatory recall authority for all food products; and enhanced partnerships among food safety agencies.

Regulatory Challenges

There is no requirement for the manufacturer of a dietary supplement to provide FDA with evidence of a product's efficacy. The manufacturer also need not provide FDA with evidence of ingredient safety prior to marketing, unless the product contains an NDI that has not been part of the food supply as an article used for food or is an article of food that has been modified in a form that is constitutionally, chemically altered.

FDA's Division of Dietary Supplement Program is tasked with the challenge of regulating a progressively expanding portfolio of dietary ingredients and finished products that are marketed as dietary supplements for a wide array of uses. When DSHEA amended the act in 1994, there were approximately 4000 products on the market; as of a 2009 Nielsen market survey, FDA estimated that there were 85,000 products on the market and this number is continuing to grow globally. With such growth the agency has encountered a number of unforeseen challenges. For example, FDA has found that dietary supplements marketed for sexual enhancement, weight loss, body building, and "calming" influences, can contain active pharmaceutical ingredients, analog of approved drugs, and other compounds, such as anabolic steroids, that do not qualify as dietary ingredients. Finding and testing these supplements for hidden, undeclared ingredients and removing those products from the market are a top priority for the Agency.

FDA's regulation of dietary supplements is particularly challenging given the seemingly endless volume of products that potentially transgress current regulations and the painstaking and costly process required by the government agency in proving that a violation exists. FDA continues to see dietary supplements marketed with ingredients that have been banned (i.e., ephedrine alkaloids and kratom) as well as dietary ingredients for which a notification to support the reasonable expectation of safety as an NDI was never submitted or containing an active ingredient that is undeclared on the labeling.

After identifying one of numerous potentially violative products, FDA is responsible for analyzing the ingredients of a product to determine whether a specific product is not in compliance. FDA conducts the laboratory analysis to prove the presence or absence of a product's ingredients that may compromise its safety. Even if the labeling of a particular dietary supplement identifies an ingredient suspected to render the product violative, the process requiring confirmation of a violation must be instituted, which is rigorous, extremely time-consuming, and expensive. When an ingredient that may render a product violative is adequately identified, FDA must then determine whether the ingredient is a dietary ingredient through an extensive search of the available scientific literature. Once it is determined whether the ingredient is a dietary ingredient, an examination of the product's other ingredients, labeling, and other promotional material is required to determine its proper regulatory status (e.g., unapproved new drug or an adulterated dietary supplement, i.e., nondeclared NDI).

Dietary Ingredient Safety

The Federal FD&C Act (the Act) prohibits the distribution of adulterated foods in interstate commerce. Under section 402(f)(1)(A) of the Act (21 U.S.C. 342(f)(1)(A)), a food is considered adulterated if it is a dietary supplement containing a dietary ingredient that presents a significant or unreasonable risk of illness or injury under the conditions of use recommended or suggested on the labeling, or if there are no stated conditions of use suggested or recommended in the labeling, under conditions of ordinary use. FDA bears the burden of establishing that the product presents a significant or unreasonable risk. Because dietary supplements are presumed to be safe, FDA's evaluation of whether a dietary supplement presents a significant or unreasonable risk generally takes place after the product is already on the market, with the exception of products that contain certain NDIs. Whether there is suspicion of a banned ingredient, concern over combinations of dietary ingredients, or safety concerns over an NDI, the use of biomarkers is crucial in determining whether dietary ingredients are adulterated. Although this list is not all-inclusive, Table 39.1 highlights several dietary ingredients of concern; the biomarkers that should be analyzed in the ingredient for quality control and may represent a component for possible risk and the known primary target organ systems associated with exposure causing clinical symptoms associated with the adverse event that is known to occur after ingestion. In the case of NDIs, manufacturers must demonstrate

TABLE 39.1 Dietary Ingredients of Concern, Their Biomarkers of Toxicity, and Target Organs Affected as a Result of Their Chronic Consumption in Dietary Supplements

Ingredient of Concern in a Dietary Supplement	Biomarker of Toxicity: Toxicant/Toxin, Drug, Metabolite	Target Organ System
Aristolochia spp. *and Asarum* spp.	Aristolochic acid	Renal/Urinary tract, liver
Blue-green algae	Microcystin	Hepatic
Bovine Source	Prohibited cattle material (21 CFR 189.5)	Central Nervous System
Butterbur (*Petasites hybridus*) root	Pyrrolizidine alkaloids	Hepatic, Cardiovascular
Comfrey (*Symphytum officinale* L)	Pyrrolizidine alkaloids	Hepatic, Cardiovascular
DMAA (1,3—dimethylamylamine)	1,3-Dimethylamylamine	Cardiovascular, Respiratory, Central and Peripheral Nervous system, Gastrointestinal
Ephedra	Ephedrine alkaloids	Cardiovascular, Central, and Peripheral Nervous System
Hydroxycut (previous formulation)	Unknown	Cardiovascular, Hepatic, Central Nervous System, Skeletal Muscle (Rhabdomyolysis), Renal
Kava (*Piper methysticum*)	Unknown	Hepatic
Lichen (*Usnea*)	Usnic acid	Hepatic
Kratom (*Mitragyna speciosa*)	Mitragynine, 7-hydroxymitragynine	Central Nervous and Respiratory System Depression
Rauwolfia	Reserpine	Central and Peripheral Nervous System, Cardiovascular
Red yeast rice	Lovastatin	Skeletal muscle toxicity, cardiovascular
Silver (listed as colloidal, ionic, native, alginate, protein, etc.)	Silver: Consumer advisory—risk of argyria at levels greater than RfD: 5 μg/kg BW/day	Dermal, Ophthalmologic (Note: All organ systems can be noticeably affected)
Desiccated thyroid glandulars	Thyroid hormone (9 CFR 310.15)	All organ systems

the process by which particular biomarkers of toxicity are absent within the process of notification to the FDA for an NDI.

As part of the process of determining tolerance and safe usage of a dietary supplement, a risk assessment is performed by a qualified toxicologist experienced in nutritional product safety. Because so little information and independent, peer-reviewed research is available for many of the products coming on to the market, the toxicologist responsible for the risk assessment needs to be armed with an extensive knowledge base and resources for the interpretation of a broad range of credible, scientific, primary, peer-reviewed data, including but not limited to in vitro, in vivo, and molecular studies as well as human clinical trials, case reports, and a myriad of other scientific and nonscientific, nutritional, historical, and environmental data to support the generation of safety profiles of dietary ingredient(s) for a reasonable expectation of tolerance and safety under the conditions of their intended use.

The Risk Assessment

In general, acceptable and recommended dietary daily intakes for the majority of vitamin and mineral exposures in the general population of healthy men, women, children, infants, and pregnant and/or lactating women have been well characterized. These guidelines are by no means static but are part of a dynamic process of characterization that continues to develop as methods of analyzing nutritional science, toxicology, and risk assessment develops among various subpopulations. For the purposes of this discussion on risk assessment, and the use of biomarkers of exposure and effect for the majority of newly marketed dietary supplements, the focus of this discussion will be on the role of biomarkers within the context of risk assessment of botanically derived dietary supplements.

Human populations are inherently outbred. The complexity of a "general" population and individual variation is currently being developed with customized tools and models provided by global genomics, epigenomics,

proteomics, metabolomics, and big data such as Read-Across (Berggren et al., 2015). A case in point is the investigation and discovery of the various functions and perturbations of the microbiome and the use of pre-biotics, probiotics, and synbiotics as dietary supplements. Biomarkers are objective measures of biochemical pathways, systemic organ function, internal and external perturbations of environmental markers, and chemical fingerprints of mixtures, plants and a multitude of other identifiers that may be present in natural or synthetic biological systems. Targeted research is just beginning to answer questions about the multisystemic, gender, environmental, cultural, and ancestral effects that nutrition and microbes contribute to a person's health.

A single, botanical, dietary ingredient (BDI) is a complex mixture of chemical compounds. Many of the products marketed as dietary supplements have multiple BDIs in formulations that have the potential for a multitude of additive, synergistic, potentiating, and/or antagonistic properties. In addition, constituents of these products are being grown, manufactured, and transported from vendors from all over the world. The ability to provide a reasonable expectation of safe use of these constituents by assessing quality, purity, stability, identity, and consistency of product, free from contamination or adulteration, under Good Manufacturing Practices, is vitally important for the protection of the consumer for the products intended use. Assessment of biomarkers and the chemical characterization or fingerprint of chemical constituents are vitally important to the process of public safety procedures and risk comparisons between BDIs. This is very important as new products come to market that may not be not in their natural state but in a chemical or physically modified form.

Although there is very little information or guidance specifically addressing the risk assessment of dietary supplements in the peer-reviewed literature, the nutritional toxicologist can follow the basic principles of risk assessment, weight of evidence, and the precautionary principle when assessing dietary supplements.

There are four basic components to risk assessment: *Hazard Identification, Hazard Characterization, Exposure potential, and Risk Characterization* (Boobis, 2007). The following is an overview of the steps that form this process for the evaluation of dietary supplements.

Hazard Identification

Hazard identification is performed to identify the range of possible intrinsic capabilities of a specific dietary supplement, its dietary ingredients (BDIs), and the characterized chemical constituents of the ingredients for the potential to cause harm. Because it is the responsibility of the manufacturer to ensure that a dietary ingredient used in a dietary supplement is safe for its intended use prior to distribution, industry must do due diligence to identify possible hazards that may be inherent to a BDI before it is exposed to the general population. It must also establish guidelines and biomarkers of botanicals for quality control. Hazard identification forms the basis for the development of the product label. This is a diagnostic challenge for botanically based products. Before a BDI product is introduced for development, there is usually some history of use. Important features associated with an investigation of a botanical are the region or country of origin; botanical nomenclature, plant genetic identification, and chemotype; original cultural purpose for use and dosing regimen; original methods of processing a BDI such as seasonal conditions for harvesting, part of plant used, processing, extraction methods, and storage. It is within this context for comparison that the risk characterization can be performed in relation to the suggested label usage under development for a specific BDI.

Because there is typically evidence of use of the BDI of interest or comparable products that have either recent or historical use, a comprehensive search of the literature for medical case reports of toxicity, clinical research, animal studies, in vitro analysis and any other pertinent mechanistic or molecular data of the BDI, or a specific chemical component of the BDI, is undertaken. Interpretation of the quality of data is highly dependent on the ability of the assessor(s) to have the experience to integrate the information to produce a toxicological narrative of risk. Experience with the principles of toxicological assessment, pathology, animal and human physiology and medicine, pharmacology, biochemistry, nutrition, and research study development and the principles of epidemiology and public health, all factor in to the creation of a robust risk assessment. In addition, it is very important to understand the origin of the data. Questions should be asked as to who owns the original study data? Who owns the laboratory or Contract Research Organization doing the study, the analysis, and the interpretation of the data? What was the initial incentive or purpose for the research project or clinical study? Was there a null hypothesis or a priori theoretical proposal or was there another motivation for conducting the study with expected outcomes and usage for the data?

Hazard Characterization

Hazard characterization is based on many components including but not limited to the results of cluster analysis and correlation of multiple biomarkers associated with human clinical studies, animal studies, molecular and mechanistic analysis, toxicokinetic and toxicodynamic information, clinical pathologic and histopathologic testing and documentation of adverse events occurring within

the context of various studies. Results are compared for consistency in physiological effect across studies of similar BDIs and their chemical components. There is a cumulative need for multiple tests to assess toxicity and predictive signatures (Waters and Merrick, 2009). Conservation along with corroboration of more than one functional pathway that merges within and between various animal physiological systems is necessary to establish health-based guidance values such as the upper limit of tolerance for various populations of consumers.

Negative outcome data are critical to identifying a lack of physiological changes that have the possibility of being associated with an adverse effect. Consistent with quality research, randomized, blinded, controlled studies utilizing credible, robust, and objective biomarkers associated with comprehensive baseline serum chemistries, physical examinations, health status of the population(s) tested, exposure data, ADME, and evaluation procedures for long-term chronic effects and reversibility are warranted. Many clinical studies associated with the use of BDI's tend to focus on the beneficial effects of a given product utilizing a wide variety of disparate, subjective outcomes. The studies tend to lack a standardized platform of objective, repeatable criteria for comparative analysis between studies. A standardized set of biomarkers indicating the presence or absence of adverse events is an integral function of robust clinical research studies and needs to be better established for research specifically relating to the use of BDI's. Typical of most past and current studies, if adverse effects are considered by the researcher to have not occurred, there will be a short statement of "No adverse events were recorded." This is insufficient. Procedural guidelines, a priori, for how the adverse events were collected, recorded, and the criteria for evaluation are critical to the interpretation of a study and a possible adverse incident. Did these events occur in more than one individual? Were they recurring? Were there variables associated with subpopulations including race, gender, and life-stage that will help in identifying individual variation in intake and sensitivity (Boobis, 2007)? Were they self-reported or were they conducted by trained personnel capable of obtaining objective assessment? This process is very fluid. As more information surrounding the use (and misuse) of BDIs in the public sector is garnered, epidemiological data for long- and short-term exposure outcomes and postmarketing data generated by academia, government and industry, in addition to the regulatory guidelines established by the FDA for adverse event reporting, will become critical for future product development and quality control.

Exposure Assessment

Risk is a function of hazard and exposure. Outside of acceptable or estimated daily intake for consumption of components of BDIs that may occur in a specific population's normal diet on a local basis, global sourcing and production of BDIs in dietary supplements carries significant challenges to manufacturers and distributers. Supply-chain exposure to contaminants in the field, residual solvents after manufacture, and contamination or economically motivated adulteration of product at various stages of production can occur. Close associations with suppliers and supply chain-management in conjunction with standard markers for the presence or absence of toxicants are key to decreasing exposure to contamination and subsequently, risk. As an example, the raw, unprocessed butterbur plant (*Petasites hybridus* L.) contains pyrrolizidine alkaloids (PAs), which have been associated with hepatobiliary veno-occlusive disease and neoplasia (Danesch and Rittinghausen, 2003; Sadler et al., 2007; Burrows and Tyrl, 2013). Butterbur has been used for hundreds of years as an analgesic and antiinflammatory remedy. Currently it is being used as adjunct support for more chronic conditions such as migraine headaches, allergic rhinitis, and asthma. The pharmacologically active substances are believed to be the sesquiterpene esters, petasin, and furanopetasin (Anderson et al., 2009; Chizzola et al., 2006). During processing PAs are removed. Standard, preemptive, operating procedures and specifications need to be in place for quality analysis and control indicating the absence of PAs at critical points of production prior to distribution to the consumer to assure its absence for chronic use that may result in more severe, debilitating, and life-threatening conditions.

Risk Characterization

Because of limited available data available on many dietary supplements, toxicologists find themselves quite often in the position of proving a negative, that the dietary supplement or ingredient under investigation will not be associated with any serious adverse events to support a reasonable expectation of safety. A conservative approach is always warranted in an environment where there may be competing objectives for production and release of a dietary supplement product to the market. Toxicologists, charged with completing a risk assessment on a NDI or supplement, will need to rely on the weight of evidence from known data in conjunction with the precautionary principle when evaluating product. In some cases it is quite possible and appropriate for the toxicologist to conclude that there is insufficient evidence to produce a tolerable upper limit or observable safe level for consumption of a dietary ingredient that would have a reasonable expectation of safety under the conditions of its intended use.

BIOMARKERS OF TOXICITY: DIETARY INGREDIENTS

Biomarkers Associated with the Presence of Banned Ingredients

Banned Dietary Ingredients Causing Neurostimulation—Ephedrine Alkaloids

Dietary ingredients are banned if they present an unreasonable risk of illness or injury. In the *Federal Register* of February 11, 2004 (69 FR 6788), FDA interpreted and applied the "unreasonable risk" standard in a final rule declaring dietary supplements containing ephedrine alkaloids to be adulterated because they present an unreasonable risk of illness or injury. As the rule explained, "unreasonable risk" implies a risk–benefit calculation that weighs a product's risks against its benefits under the conditions of use recommended or suggested in the product's labeling, or if the labeling is silent, under ordinary conditions of use. The Secretary of Health and Human Services also has authority under the statute to act where a product poses an "imminent hazard" to public health. The risk–benefit calculation is also true for multiple or combinations of dietary ingredients with common mechanisms and/or modes of action.

Ephedrine alkaloids are chemical stimulants that were originally found to naturally occur in some botanicals. In the 10 years prior to the published Ephedrine Final Rule of 2004, dietary supplements containing ephedrine alkaloids were labeled and marketed with claims for weight loss, energy, or enhancement of athletic performance. Today, FDA still encounters dietary supplement products containing ephedrine alkaloids in the form of raw botanicals imported from foreign suppliers intended for use in dietary supplements or destined for production of methamphetamine.

Ephedrine alkaloids are members of a large family of pharmacologically active compounds known as phenylethylamines or sympathomimetics. They include pseudoephedrine (a decongestant), phenylephrine (cold tablets, nasal sprays, and hemorrhoid treatment), phenylpropanolamine (PPA) (for treatment of urinary incontinence) and amphetamine-based products (for treatment of narcolepsy and attention deficit disorder). Their mechanism of action is due to the release of catecholamines (dopamine and norepinephrine) and serotonin. Primary effects associated with toxicity are due to the activation of both α- and β-adrenergic receptors causing serious adverse effects in primarily the central nervous and cardiovascular systems. Clinical symptoms that have been associated with toxicity due to phenylethylamines are hallucination, hyperactivity, agitation, tremors, seizures, sleep disorders, vasoconstriction, arrhythmias, hypertension, platelet aggregation, disseminated intravascular coagulopathy, hyperthermia, tachypnea, hyperinsulinemia, cardiovascular collapse, cerebrovascular hemorrhage/infarction, multiorgan failure, and death.

Ephedrine alkaloids are primarily derived from raw material and extracts from the plants *Ephedra sinica* Stapf, *Ephedra equisetina* Bunge, *Ephedra intermedia* var. *tibetica* Staph, and *Ephedra distachya* L. (the *Ephedras*) (Betz and Tab, 1995; World Health Organization, 1999). Other botanical sources found to contain ephedrine alkaloids include *Sida cordifolia* L. and *Pinellia ternate* (Thunb.) Makino (Ghosal et al., 1975; Oshio et al., 1978). Ma huang, *Ephedra*, Chinese *Ephedra*, and epitonin are several names used for the botanical sources. The plants were mostly found in desert regions of China and Mongolia and were the original source of ephedrine and pseudoephedrine prior to the early 1900s.

Other common names that have been used for the various plants that contain ephedrine alkaloids include sea grape, yellow horse, joint fir, popotillo, and country mallow. Although ephedrine is the primary alkaloid isolated from these plants, other closely related chemicals associated with these botanicals can also be used as biomarkers indicating contamination or adulteration of a dietary supplement. They include norephedrine, methylephedrine, norpseudoephedrine, and methylpseudoephedrine (Chen and Schmidt, 1930; Mahuang, 1987; Karch, 1996; Bruneton, 1995; Cui et al., 1991).

Banned Dietary Ingredients Causing Neurosuppression—Mitragyna speciosa (Kratom)

Mitragyna speciosa and extracts of its leaf are collectively referred to as kratom or by other synonyms and pseudonyms, including *Nauclea speciosa*, biak-biak, cratom, gratom, kakuam, katawn, kedemba, ketum, krathom, mambog, madat, maeng da, mitragynine extract, *Mitragyna javanica*, red vein/white vein, thang, ithang, and thom. *M. speciosa* or kratom is a botanical ingredient that would generally qualify as a dietary ingredient under section 201(ff) of the Federal FD&C Act (the Act) [U.S.C. 321(ff)]. The leaf and extracts are usually imported with a product code 54 as they are almost always intended as dietary supplements for ingestion. Kratom is obtained overseas from the dried leaves of a tree that grows most commonly in Thailand, Malaysia, Indonesia, Sumatra, Bali, and Vietnam. The whole leaf, crushed leaf, powder forms, and extracts are shipped directly to consumers for oral consumption or indirectly through US distributors in the United States.

Dry leaves of kratom are typically ingested as a tea or the dried leaves are crushed into smaller particulates for ingestion in foods that mask kratom's bitter taste. The powders, dry leaves, and crushed leaf forms can also be ingested by either directly placing them in blank capsules or wrapping them in bathroom tissue squares.

After kratom is placed in bathroom tissue, the tissue is twisted at both ends to contain the material, and then placed into the mouth and swallowed. This process is termed "parachuting." The raw botanical material is also incorporated into finished dietary supplements.

M. speciosa gained use among American consumers in the belief that it will relieve pain, anxiety, and depression and treat the symptoms of opioid addiction and for its euphoric properties for recreational use. It contains two potent alkaloids, mitragynine and 7-hydroxymitragynine. Both are biomarkers for *M. speciosa* toxicity. In low concentrations, these alkaloids produce euphoria, energy, and other stimulating effects. In higher concentrations, they are sedating and possess antinociceptive properties. Based on scientific research and modeling by the FDA, they have concluded that the compounds in Kratom have structural similarities with other opioid analgesics and exert effects on mu, delta (Thongpradichote et al., 1998), and kappa opioid receptors (Boyer et al., 2008; Dale et al., 2012), and they are now classified as opioids (FDA, 2018a).

There are safety concerns regarding the dietary ingredient kratom that support detaining this ingredient and legal enforcement against any dietary supplements known to contain kratom. These products are considered adulterated under section 402(f)(1)(B) of the Act (21 U.S.C. 342(f)(1)(B)). FDA's review of publicly available information regarding kratom concluded that there is not a reasonable assurance that the ingredient does not present a significant or unreasonable risk of injury to consumers.

The scientific literature has disclosed serious concerns regarding the toxicity of kratom in multiple organ systems. Consumption of kratom can lead to respiratory depression, nervousness, agitation, aggression, sleeplessness, hallucinations, delusions, tremors, loss of libido, constipation, skin hyperpigmentation, nausea, vomiting, addiction, and severe withdrawal signs and symptoms after refraining from use.

Detention and refusals of kratom imports do not rely on the provision in section 413 of the Act that deems a dietary supplement containing an NDI to be adulterated unless the manufacturer or distributor has filed an NDI notification with FDA at least 75 days before marketing (21 U.S.C. 350b).[1] Instead, kratom detentions and refusals rely on the adulteration standard in section 402(f)(1)(B) of the Act, which provides that a food is adulterated if it contains an NDI for which there is inadequate information to provide a reasonable assurance that any such ingredient does not present a significant

or unreasonable risk of illness or injury. In general, FDA would not be inclined to support the detention of bulk NDIs unless it had identified concrete safety concerns. Reports of addiction clinics dedicated to kratom abuse and emergency room visits for kratom intoxication have increased over the past 6 months. Kratom is an emerging issue of public health that should be taken seriously. From 2010 to 2015, calls to poison control centers have increased 10-fold (FDA, 2017) along with at least 36 deaths associated with its use (FDA, 2017). Based on this information the FDA has exercised its jurisdiction to seize imports and enforce voluntary destruction by companies that had imported kratom for the intent of distribution to consumers (FDA, 2017; 2018b).

Biomarkers Associated with the Presence of Endocrine Disruptors

Dessicated Thyroid Glandulars

Dietary supplements containing animal-derived, thyroid glandular tissue are currently marketed for weight loss, body building, nutritional support, and altering thyroid hormone levels. Marketing such a dietary supplement to explicitly or implicitly treat hypothyroidism, with respect to an individual's thyroid stimulating hormone (TSH) or thyroid hormone level, would be a disease claim as per Title 21 CFR 101.93(g). The public health issue for using such a product, even for weight loss, is the tendency for consumers to incorrectly self-medicate themselves to achieve weight loss by jumpstarting a perceived underactive thyroid.

Dietary supplements are considered food under the Federal FD&C Act (the Act). Animal-derived thyroid tissue is declared on many dietary supplement product labels as a dietary ingredient, but it is not. In contrast to FDA-approved thyroid-containing products, which are synthetic drugs approved for defined medical conditions, at consistently defined and approved concentrations and dosages of administration, desiccated thyroid supplements are primarily derived from the thyroid glands of slaughterhouse animals. The thyroid tissue that is ingested, even if it is cooked, or frozen prior to cooking, contains variable levels of the thyroid hormones, levothyroxine (T_4), and levothyronine (T_3). Both forms of thyroid hormone are active after ingestion and absorption into the general circulation with the potential of resulting in multisystemic effects (Table 39.2) that can result in the clinical syndrome known as thyrotoxicosis factitia (Bouchard, 2015).

---

[1] There is an exception to the notification requirement for dietary supplements that contain only dietary ingredients that have been present in the food supply as articles used for food without chemical alteration. 21 U.S.C. 350b(a)(1).

TABLE 39.2　Clinical Signs and Symptoms of Hyperthyroidism due to Consumption of Thyroid Glandular Ingredients Contained in Dietary Supplements (Bouchard, 2015)

Organ Systems Affected by Exogenous Thyroid Hormone Toxicity	Clinical Sign or Symptom
Ocular	Alterations in vision, photophobia, eye irritation, exophthalmos
Musculoskeletal system	Fatigue, muscle weakness, exertional intolerance, rhabdomyolysis, accelerated osteoporosis
Respiratory system	Dyspnea
Nervous system	Irritability, anxiety, behavioral changes, mental disturbance/psychosis, insomnia, eating disorders, tremor, paralysis, coma
Cardiovascular system	Palpitations, tachydysrhythmias (atrial fibrillation/flutter, extra systoles, high-output congestive heart failure), widened pulse pressure (elevated systolic, decreased diastolic), left ventricular hypertrophy, focal myocarditis, cardiac failure, pulmonary hypertension, angina pectoris, thromboembolism, myocardial infarction, stroke, sudden death
Gastrointestinal system	Gastrointestinal disturbance (nausea, vomiting, diarrhea)
Reproductive system	Impaired fertility and fetal development
Metabolic	Hyperthermia, heat intolerance, increased diaphoresis, weight loss, hypothyroidism
Dermal	Delayed palmar desquamation

Historically, ingestion of animal-derived thyroid gland has been used by for a variety of cosmetic and medical purposes. Ancient Egyptians used them as a beauty aid. Enlarged, goiterous necks were considered fashionable in women (Bouchard, 2015). Up until the 1950s thyroid hormone from animal tissue was used to treat conditions such as hypothyroidism (Bouchard, 2015). Currently, thyroid hormone derived from animal tissue is being marketed as an aid for weight loss and as a stimulant. Its use has been fraught with adverse events. In some cases consumption has resulted in severe, clinical, multisystemic symptoms, and even sudden death (Bouchard, 2015) (Table 39.2).

Thyroid tissue as an ingredient invariably contains an unknown amount and ratio of thyroid hormones that have the potential to result in hyperthyroidism. Thus, in accordance with 9 CFR 310.15(a)[2], livestock thyroid glands and laryngeal muscle tissue shall not be used for human food. Accordingly, thyroid tissue does not appear to fit within any category of "dietary ingredient" in 201(ff)(1). It is not considered a "dietary substance" because it is not part of usual food or drink for humans and even if thyroid tissue could be identified as a "dietary ingredient," it would fall under the category of "adulterated" in accordance with Section 402(f)(1)(A) of the Federal FD&C Act (the Act) [U.S.C. 342(f)(1)(A)] because it presents a significant or unreasonable risk of illness or injury.

Contamination of dietary supplements by thyroid tissue is identified by analysis of product for the presence of the biomarkers thyroxine (T_4) and triiodothyronine (T_3). Clinical symptoms of thyrotoxicosis factitia are not readily identifiable through blood analysis of either thyroxine (T_4) and/or triiodothyronine (T_3) due to the fact that even in the presence of normal or low levels, severe adverse events associated with toxic exposure can occur (Bouchard, 2015).

Diagnosis of exposure of an individual from either acute or chronic consumption of excessive thyroid hormones can be identified primarily through blood analysis for the suppression of circulating TSH. Any argument to support allowing residual or trace amounts of thyroid hormone in a dietary ingredient because it is present in many common foods that we normally eat is not a valid argument. First, consumption of meat containing bovine thyroid tissue has been shown to lead to thyrotoxicosis (Hedberg et al., 1987; Kinney et al., 1988). Second, the mere fact that a substance exists in minuscule quantities in a food humans typically consume does not make that substance a "dietary" one. There are many substances found in typical human foods that people avoid eating, and which could never be termed a "dietary ingredient." Examples of substances people may unintentionally ingest include pesticides and heavy metals. Just because they may be there in trace amounts from environmental contamination does not make them a dietary ingredient.

Supplementing the diet with oral thyroid hormone from a glandular supplement is not needed or recommended in normal, euthyroid individuals. Medical literature contains numerous case reports of adverse events in individuals who ingested herbalal supplements adulterated with thyroid hormone.

[2] Under 21 CFR 316.3(b)(2), active moiety means "the molecule or ion, excluding those appended portions of the molecule that cause the drug to be an ester, salt (including a salt with hydrogen or coordination bonds), or other noncovalent derivative (such as a complex, chelate, or clathrate) of the molecule, responsible for the physiological or pharmacological action of the drug substance."

Many describe life-threatening events. In April 2006, French health authorities reported an incident causing one death and several hospital intensive care unit admissions after taking a "slimming aid" consisting of powdered thyroid extract (Thyroid Extract, 2006). All had symptoms of thyrotoxicosis, including heart palpitations and altered consciousness.

Another case series described five individuals who took Enzo-caps, which claimed to be a natural food product containing papaya, garlic, and kelp, as a weight loss adjunct. All five patients suffered from symptoms suggestive of hyperthyroidism. Each tablet was found to contain up to 112 μg of T_4 and 11.1 μg of T_3. It was later found to also contain a sympathomimetic agent and diuretic. For comparison, the mean dosage of levothyroxine for treatment of diagnosed, hypothyroid, adult patients is 1.7 μg per kg body weight per day, for a typical daily dose of 100–150 μg (Bouchard, 2015; Braunstein et al., 1986). Depending on age, subpopulations can have enhanced sensitivity to thyroid hormone. An average daily dosage for an elderly, adult, hypothyroid patient is 12.5–50 μg/day (Bouchard, 2015).

Thyroid glandular tissue is just one example of the importance of analysis for certain biomarkers as part of a standard process of manufacturing for identification of contamination of raw materials and end-products, by even minute amounts of endocrine disrupting agents. Standard operating procedures for identification of these types of adulterants cannot be overemphasized as companies perform the due diligence necessary to protect consumers in a global environment.

Biomarkers Associated With the Presence of Carcinogens

Aristolochic Acid

Aristolochic acid refers to a family of nitrophenanthrene compounds found concentrated in the roots/rhizomes of plants of the family Aristolochiaceae, and in particular in the genus Aristolochia. Lower concentrations are found in the fruit and leaves. There are many other genera in the family Aristolochiaceae that can be found distributed around the world. Many are used as medicinal plants. These include species of plants in the genera Asarum, Bragantia, Stephania, Clematis, Akebia, Cocculus, Diploclisia, Saussurea, Menispermum, and Sinomenium, as well as Mu tong, Fang ji, Guang fang ji, Fang chi, Kan-Mokutsu (Japanese), and Mokutsu (Japanese).

In the latter part of the 20th century reports started to appear for serious adverse events associated with renal failure and renal fibrosis occurring in individuals ingesting herbal weight loss aids. The herbal product was labeled to have contained Stephania tetrandra, a botanical

not known to contain aristolochic acid, but was later found to be inadvertently substituted with the botanical Aristolochia fangchi. Subsequent reports confirmed that the renal lesions were related to exposure due to ingestion of products containing aristolochic acids (Vanhaelen et al., 1994; Schmeiser et al., 1996; Nortier et al., 2000; Muniz-Martinez et al., 2002).

Similar diagnoses were reported elsewhere in Europe, Asia, and the United States. In July 1999, two cases of nephropathy, associated with the use of Chinese botanical preparations, were reported from the United Kingdom. Both of these patients had ingested botanical preparations for the treatment of "eczema." Renal biopsies showed a pattern of extensive tubular loss, most prominent in the outer cortex, and severe interstitial fibrosis. These pathological features are typical of what has now come to be called "Chinese herb nephropathy" due to the toxicity associated with ingestion of aristolochic acid.

In 2001, after reports of rapidly developing renal failure and urothelial carcinoma associated with the use of herbal preparations containing aristolochic acid containing dietary ingredients, manufacturers and distributors of supplements were advised to remove these products from the market. Public health statements were released, advising consumers not to consume these supplements (Schwetz, 2001). An FDA import alert (IA #54-10) called for the detention of any botanical, drug, or other products found to contain the more than the 69 types of aristolochic acids; herbs known to contain aristolochic acids; and/or herbal preparations that had been found to have been replaced by herbs containing aristolochic acids. At that time it was clear that consumption of herbal products containing aristolochic acids, both intentionally and through apparent misbranding, was associated with a rapid onset of renal interstitial fibrosis, renal failure, and an increased incidence of urothelial carcinomas. The rapid onset, severity, and irreversibility of the damage suggested that detection of any amount of aristolochic acid should be viewed as a potential health risk.

The carcinogenic potential of aristolochic acid started to appear in the 1980s. In addition to renal damage, safety studies reported an increased incidence in pathologic lesions indicating aristolochic acid–induced carcinogenicity in rodents orally administered aristolochic acid (Mengs et al., 1982). The rodents developed multiple cancers that included lymphoma, as well as cancers in the kidney, bladder, stomach, and lung. Short-term studies resulted in tumors in the urinary tract in addition to the other renal pathological changes indicative of Chinese herbal nephropathy (Mengs et al., 1982; Mengs, 1987; Mengs and Stotzem, 1993).

The precipitating event for aristolochic acid was an outbreak in Belgium. In 1992, a Belgian cohort of 70 patients, known to have consumed a slimming regimen

containing a powdered extract of several Chinese herbs, was found to have interstitial renal fibrosis, with 30 individuals progressing to end-stage renal disease (Vanherweghem et al., 1993; Cosyns et al., 1994; Depierreux et al., 1994; Vanherweghem, 1998). The diagnosis was made based on an unusual and distinctive pattern of renal nephropathy and the finding of biomarkers for aristolochic acid—DNA adducts in the urothelium indicating exposure and potential toxicity. The renal fibrosis occurred 12—24 months after the initial injury with an increased incidence of urothelial cancer being associated with this pattern of renal nephropathy (Hung, 2015; Debelle et al., 2008).

The International Agency for Research on Cancer (IARC), an arm of the World Health Organization, would later conclude that there was sufficient evidence to determine that aristolochic acid—containing herbs are carcinogenic in humans, thus classifying them as Group I carcinogens (IARC, 2002).

To this day, reports from around the world, and especially in east Asia, continue to link rapid onset of renal failure and/or renal cancer with consumption of teas brewed from the ground root of these botanicals (Gillerot et al., 2001; Tanaka et al., 2001; Krumme et al., 2001; Cronin et al., 2002; Yang et al., 2003; Lee et al., 2004).

Pyrrolizidine Alkaloids—*Symphytum* Spp. (Common Name, Comfrey)

In June 2001, FDA published an Advisory to dietary supplement manufacturers to remove comfrey as an ingredient in dietary supplements. The Advisory alerted the supplement industry to the available scientific information that firmly establishes that dietary supplements that contain comfrey or any other source of PAs are adulterated under the Act. Also, the Agency stressed that manufacturers need to identify and report adverse events associated with any product that contains an ingredient that has the potential to contain PAs. The Agency cited serious adverse health effects and opined on the presence of PAs as potent hepatotoxins.

Comfrey, like a number of other plants (e.g., *Senecio* species), contain PAs. The toxicity of PAs to humans is well documented (Huxtable and Cheeke, 1989; Winship, 1991; McDermott and Ridker, 1990; Burrows and Tyrl, 2013). FDA's position with regard to comfrey is that the PAs present in comfrey are toxic chemicals that can lead to serious adverse health effects if taken into the body. It is clear that oral exposure is potentially hazardous. It is equally clear that PAs are harmful when allowed to enter the body through broken skin, or other nonoral routes, such as suppositories. The Federal Trade Commission has limited them to external use only.

Accordingly, FDA believes that external use of comfrey products, containing PAs, present minimal risks to consumers when such products are not used as suppositories and are not applied to broken skin.

Hepatic veno-occlusive disease and neoplasia as well as pulmonary hypertension are the major documented forms of injury to humans (Burrows and Tyrl, 2013) from chronic or excessive intake of PA-containing herbals. Laboratory animal studies, epidemiological studies, and veterinary case reports suggest that the toxic effects are much broader. Animal exposure has resulted in pulmonary, kidney, and gastrointestinal pathologies including cancer (Burrows and Tyrl, 2013).

Four countries, the United Kingdom, Australia, Canada, and Germany, have restricted the availability of products containing comfrey, and other countries permit use of comfrey only under a physician's prescription.

There is variability in the levels of PAs in various species of plants, thus, the concerns FDA has about a comfrey-containing dietary supplement or ingredient depends on the exact species identified. Identification of this biomarker is a crucial component for the development, manufacture, and distribution of a dietary supplement derived from plants that have the potential to containing PAs as part of the process for quality control. This is especially important in light of the potential for chronic exposure to result in hepatic lesions, including cancer, if due diligence is not adhered to by the manufacturer prior to marketing.

The FDA ruling banned internal use of *Symphytum officinale* L. (common comfrey), *Symphytum asperum* Lepech (rough or prickly comfrey), and *Symphytum xuplandicum* Nyman (Russian comfrey), as well as any other plant/substance containing PAs. While FDA did not examine the safety of other comfrey species such as *Symphytum tuberosum* L. (tuberous comfrey), which is suggested to contain negligible amounts of PAs, FDA and potential manufacturers of products would rely on the presence of the PA to determine whether this species is to be permitted to be used as a dietary ingredient. Only after such sampling and analysis of this biomarker of toxicity, would they be in a position to provide an opinion on whether its use in dietary supplements would not present a significant or unreasonable risk of illness or injury under the conditions of use recommended on the label. Because the burden and responsibility for assuring that such a product is not adulterated under the Act lies with the manufacturer, and with the associated costs involved during the product life cycle, alternative species that are known to not have an association with the presence of pyrrolizidine alkaloids should take precedence rather than risking the potential for future contamination of product.

Although FDA continues to voice its concern about the safety of dietary supplements containing comfrey,

this does not mean that FDA prohibits the marketing of dietary supplements that contain comfrey. Although dietary supplements do not require premarket approval or approval from FDA before marketing and distribution, the manufacturer is responsible for determining that its products are safe under the Act. However, the Agency is unaware of conclusive scientific data that would establish that a dietary supplement containing comfrey would be safe. Therefore, for a manufacturer interested in marketing a comfrey-containing dietary supplement, it would be required to submit information in the form of a NDI notification that forms the basis by which it establishes that such a product is safe within the meaning of the Act. A manufacturer would then have to demonstrate that the comfrey-containing ingredient did not contain the toxic PA biomarker as part of the NDI notification, as well as chemistry and additional safety data to market such a product as a dietary supplement for its intended use.

BIOMARKERS OF TOXICITY: NEW DIETARY INGREDIENTS

Premarket Notification of a New Dietary Ingredient

The Act requires a premarket safety notification for NDIs introduced into commerce following the passage of the DSHEA of 1994. Under section 413(c) of the Act (21 U.S.C. 350b(c)), an "NDI" is a dietary ingredient that was not marketed in the United States before October 15, 1994. A dietary supplement that contains an NDI is deemed to be adulterated unless one of the following two conditions are met: (1) The dietary supplement must contain only dietary ingredients that have been present in the food supply as an article used for food in a form in which the food has not been chemically altered; or (2) there must be a history of use or other evidence of safety establishing that the dietary ingredient when used under the conditions recommended or suggested in the labeling of the dietary supplement will reasonably be expected to be safe, and the manufacturer or distributor of the dietary supplement containing the NDI must provide FDA with information, including any citation to published articles, which forms the basis on which the manufacturer or distributor has concluded that a dietary supplement containing such dietary ingredient will reasonably be expected to be safe.

FDA has established requirements for premarket notification of NDIs in 21 CFR § 190.6, based on authority granted in sections 201(ff), 301, 402, 413, and 701 of the Federal FD&C Act (21 U.S.C. 321(ff), 331, 342, 350b, 371). 21 CFR 190.6(a) which states that at least 75 days before introducing or delivering for introduction into interstate commerce a dietary supplement that contains an NDI that has not been present in the food supply as an article used for food in a form in which the food has not been chemically altered, the manufacturer or distributor of that supplement, or of the NDI, shall submit to the Office of Nutritional Products, Labeling and Dietary Supplements, Center for Food Safety and Applied Nutrition information including any citation to published articles that is the basis on which the manufacturer or distributor has concluded that a dietary supplement containing such dietary ingredient will reasonably be expected to be safe. That notification should include pertinent information that satisfies the regulatory requirements established under 21 CFR 190.6, documentation demonstrating clear identification of the test article, history of use, and weight of evidence for a reasonable expectation of safety.

If a dietary supplement containing an NDI is subject to the notification requirement and this requirement is not met, or if there is no history of use or other evidence of safety establishing a reasonable expectation of safety, the dietary supplement is deemed to be adulterated under section 402(f)(1)(B) of the act because there is inadequate information to provide reasonable assurance that the product does not present a significant or unreasonable risk of illness or injury.

Within this context, biomarkers are used at many critical points of the product life cycle to establish safety. This includes but is not limited to identification of possible contamination or adulteration of product at any point in the process for quality control; physiological effects of use of product through the evaluation of animal and human research; a comprehensive evaluation of the peer-reviewed literature concerning any evidence to substantiate use and safety of product; the establishment of labeling including cautions of use for specific subpopulations of individuals; epidemiological evaluation of use and historical and ancillary use of product.

Premarket Notification for New Dietary Supplement as Enhancers of Metabolism, Energy, and Weight Loss

Usnic Acid

On November 20, 2001, US FDA warned consumers to stop using LipoKinetix, a dietary supplement marketed for weight loss, because it was associated with a number of serious adverse event reports involving hepatotoxicity (Favreau et al., 2002) including acute hepatitis, irreversible liver injury, liver failure, and eventual transplant. US FDA reported on six persons who developed acute hepatitis and/or liver failure while using LipoKinetix. The injuries reported to FDA occurred in

persons between 20 and 32 years of age, and no other cause for liver disease was identified in the cohort. In all cases, no preexisting medical condition that would predispose the consumer to liver injury was identified. Liver injury occurred fairly rapidly, between 2 weeks and 3 months, after starting LipoKinetix. Although the product contained multiple dietary ingredients such as norephedrine (PPA), caffeine, yohimbine, diiodothyronine and sodium usniate, usnic acid was the dietary ingredient suspected to have led to hepatotoxicity in the adverse event reports.

Usnic acid is typically derived from botanicals of *Usnea* spp. (Ingólfsdóttir, 2002), but it is also present in other genera of lichens, including *Alectoria*, *Cladonia*, *Evernia*, *Lecanora*, and *Ramalina*. Usnic acid is a complex dibenzofuran derivative, produced naturally by certain lichen species. In recent years, usnic acid and its salt form, sodium usniate, have been marketed in the United States as an ingredient in dietary supplement products, mostly with claims and marketing to promote weight reduction, enhancement of metabolism, and inhibition of bacteria.

Although lichens containing *Usnea* have been formulated into topical products and used as traditional medicines in other countries, FDA is unaware of any evidence that usnic acid was marketed before October 15, 1994. Similar to many NDIs on the market, FDA has not received any notification for usnic acid or usniate as an NDI for which a premarket notification pursuant to 21 U.S.C. 50b(a)(2) is a requirement. The NDI notification process, a premarket gate to ensure reasonable expectation of safety, is designed to pick up toxicological signals in the data before the dietary ingredient contained in the dietary supplement reaches the market. The notification process can only work in a premarket capacity if notifications for NDIs are submitted to FDA.

Lichens have evolved an innate capacity to survive extreme environmental conditions. They excrete bioweathering and bioactive secondary metabolites (e.g., usnic acid), which provide chemical protection from invading biologicals such as viruses, bacteria, protozoa, competing fungi, algae, plants, and animal predators. Although lichens produce a vast array of secondary metabolites, representing diverse classes of chemical compounds (e.g., lactones, aromatic compounds, quinines, terpenes, diphenyl esters, dibenzofuranes, and aliphatic acids) (Fiedler et al., 1986; Huneck and Yoshimura, 1996; Huneck, 1999), the most characterized and studied is the polycyclic usnic acid (Correche et al., 1998). *Usnea* content varies depending on the lichen species and region. *Alectoria* spp. are known to contain up to 6% usnic

acid, whereas the thallus of *Usnea laevis* from the Venezuelan Andes contains approximately half that amount (Marcano et al., 1999). Although *Usnea* spp. synthesize and excrete usnic acid in response to a toxic environment, usnic acid is a useful biomarker for assessing pollution as well as toxicity in dietary supplements.

Although adverse events suggest that usnic acid is the culprit for liver toxicity, we do not have a definitive mechanism for how this occurs. Subchronic and chronic toxicology studies in rodents and clinical studies in humans are absent. What is known regarding usnic acid toxicity is related to its apparent mechanism of action to uncouple oxidative phosphorylation in mitochondria (Johnson et al., 1950; Abo-Khatwa et al., 1996; Cardarelli et al., 1997). This mechanism could account for its ability to kill microorganisms (Lauterwein et al., 1995), accelerate metabolism, cause weight loss, and induce liver toxicity (Krähenbühl, 2001; Sonko et al., 2011; Yellapu et al., 2011; Sahu et al., 2012; Liu et al., 2012; Moreira et al., 2013). In vitro analysis to screen for mitochondrial damage should be a consideration for research and development of products with similar claims. Biomarkers indicative of mitochondrial toxicity should be taken under consideration as a required step in the premarket analysis for justification of safety of any weight loss or energy products considering the possible seriousness of adverse events that might result due to "enhanced" metabolism.

BIOMARKERS OF TOXICITY: NEW DIETARY INGREDIENTS

Active Moiety of a New Dietary Ingredient

Red Yeast Rice—Monacolin K and Statin Activity

Another issue of concern is the physiological effect and regulatory status of the relevant article or active moiety[2] in any marketed dietary supplement or NDI. Some NDI notifications received by the FDA concern ingredients that do not meet the statutory definition of a dietary ingredient and are therefore excluded as dietary ingredients under the U.S.C. 321(ff)(3)(B)[3], section 201(ff)(3)(B) of the Federal FD&C Act (The Act) (21 U.S.C. § 321(ff)(3)(B)). Such dietary supplements may not include articles approved as a new drug or authorized for investigation as a new drug under section 505 of the Act, unless the article was marketed as a dietary supplement or food before its approval as a drug.

The case law clarifying DSHEA regarding this issue involved the dietary supplement product called

---

[3] The term "dietary supplement" is defined in 21 U.S.C. 321(ff). Under 21 U.S.C. § 321(ff)(3)(B), dietary supplements may not include articles approved as a new drug under 21 U.S.C. § 355 (section 505 of the Act), unless the article was marketed as a dietary supplement or food before its approval as a drug.

Cholestin (red yeast rice) marketed by Pharmanex (35F. Supp. 1341, 2001). Cholestin was a "traditional" Asian product known alternatively as "red yeast rice," "Hong Qu," or "Red Koji." Red yeast rice has been used both in traditional Asian cuisine and medicine. Products that are marketed as dietary supplements that contain red yeast rice, like all dietary supplements, must meet the requirements set forth in the Federal FD&C Act, as amended by the DSHEA of 1994. Red yeast rice (*Monascus purpureus*) contain monacolins that are fungal, secondary metabolites capable of inhibiting 3-hydroxy-3-methylglutaryl-CoA (HMG CoA) reductase, which is involved in the synthetic pathway for cholesterol production. They are more commonly known as Statins. By definition, the presence of biomarkers for monacolins in red yeast rice would not permit its use as a dietary ingredient in a dietary supplement. The term "dietary supplement" as defined in 21 U.S.C. 321(ff) contains a number of exclusions. For example, under section 321(ff)(3)(B)(i), an article that is approved as a new drug under 21 U.S.C. 355 is excluded from being a dietary supplement unless it was marketed as a dietary supplement or as a food before such approval. It is this provision of the FD&C Act that bears directly on the legal status of Pharmanex's product that was the subject of an FDA enforcement action on Cholestin and certain other products that contain red yeast rice, specifically sold as dietary supplements.

In 1998, FDA issued an administrative proceeding stating that Pharmanex's product, Cholestin,[4] which was promoted as a dietary supplement intended to reduce cholesterol levels, was not a dietary supplement, but instead is considered an unapproved drug under the FD&C Act (Pharmanex, Inc, 1998). FDA based its decision, in part, on the fact that the red yeast rice in Cholestin was not simply red yeast rice that traditionally had been used as food. Instead, the agency concluded that Pharmanex had taken several actions in the marketing and manufacturing of Cholestin such that the relevant ingredient in the product, Monacolin K, otherwise known as lovastatin, an approved drug in the product Mevacor, was the basis for their product claims. This prohibited Cholestin from being marketed as a dietary supplement under the exclusion clause in section 321(ff)(3)(B)(i). Traditional red yeast rice does not contain lovastatin in measurable concentrations. The fact that Pharmanex took steps to artificially induce and enhance lovastatin production in its red yeast rice product and promoted its product to reduce blood cholesterol levels caused the product to be a drug under the FD&C Act.

The FDA's final determination was that lovastatin was not marketed as a dietary supplement prior to its approval as a new drug and Pharmanex failed to show that lovastatin was previously marketed as a dietary supplement, food, or component of a food; therefore, Cholestin did not qualify as a dietary supplement.

All red yeast rice products manufactured with the purpose of increasing levels of monacolins are considered a threat to public health. Their chronic use comes with the potential for adverse events such as myopathies as well as the potential to cause damage to the kidneys with chronic usage. There is also added risk for individuals who are taking other statin medications or concurrent dietary supplements such as niacin that can potentiate the risk and incidence of adverse reactions.

On February 16, 1999, the United States District Court for the District of Utah set aside the FDA's May 20, 1998 administrative determination that Cholestin is a drug. The United States Court of Appeals for the 10th Circuit reversed the District Court's decision on July 21, 2000 and remanded the case back to the District Court for consideration of record-based issues not reached by the lower court in its original decision. On March 30, 2001, the United States District Court for the District of Utah issued a Memorandum Decision and Order on the remaining record-based issues. The District Court affirmed the FDA's administrative decision that Cholestin is a drug, not a dietary supplement. Taken together, the courts' decisions in the Pharmanex litigation means that red yeast rice products containing lovastatin are unapproved new drugs in violation of the FD&C Act and may not be marketed as dietary supplements (Pharmanex, Inc. v. Shalala, 2001).

The decision in the Pharmanex case does not, however, prohibit the marketing of all red yeast rice-containing products as dietary supplements. The decision only limits the marketing of products as dietary supplements if they contain substances that are excluded from the dietary supplement definition. The agency has not objected to the marketing of dietary supplements containing red yeast rice if they do not contain lovastatin or other substances that are approved drugs. The Congressional intent of the exclusion clause that is the basis of the agency's decision on Cholestin was to protect the research development incentives for new drugs to treat serious diseases.

There is no "action level" for lovastatin, or any other substance excluded under section 201(ff)(3)(B), which

---

[4] Cholestin consists of the yeast *Monascus purpureus* when fermented on premium rice powder. The fermentation of the rice with this yeast, under certain conditions, produces a product that contains lovastatin, the active ingredient in the prescription cholesterol-lowering drug Mevacor.

would trigger action by FDA. Rather, as was the case with Cholestin, FDA would look at the following:

- level of a substance in a proposed dietary ingredient
- consider the manufacturing, processing, and composition and determine how it compares to traditionally prepared dietary ingredients
- provision for evidence of intended use or claims for the product to determine whether a given product violates the Act

BIOMARKERS OF TOXICITY: NEW DIETARY INGREDIENTS

Safety Assessment of Multiple Dietary Ingredients in a Dietary Supplement

As with other dietary supplements to be marketed, those containing multiple dietary ingredients, must substantiate through a history of use or other evidence of safety, that under the conditions recommended or suggested in the labeling of the dietary supplement, the combination of dietary ingredients will have a reasonable expectation of safety. As with other new ingredients, at least 75 days before being introduced or delivered for introduction into interstate commerce, the manufacturer or distributor of the dietary ingredient or dietary supplement must provide the Secretary (and by delegation, FDA) with information, including any citation to published articles, which forms the basis on which the manufacturer or distributor has concluded that a dietary supplement containing such dietary ingredients will not pose an unreasonable risk for illness or injury to the general public. This is especially true when the ingredients achieve the same effect through either different or similar mechanisms of action.

New Dietary Ingredients (Supplementation with Multiple, Combinations of Dietary Ingredients) Rauwolfia and Yohimbe Bark Extract

Pharmaceutical and dietary ingredients are capable of chemical and physiological interactions that have the potential to increase the incidence of adverse events in individuals. Interactions can lead to antagonism or potentiation of drug activity and/or exacerbate underlying medical conditions that may be present with or without other diagnosed systemic disease.

Because of an assumption of safe use of dietary supplements in the general, healthy population, a lack of knowledge concerning the interactions of many dietary ingredients and the belief by many consumers that because many of the products are "natural" or of plant origin, that they can be assumed to be safe, self-medication of multiple products is one of the most common precipitating circumstances surrounding adverse events and product complaints.

Drug interactions can lead to changes in the activity of one or more dietary ingredients with concurrent use or a similar situation can occur when multiple dietary ingredients are placed in the same dietary supplement. This is significant if the dietary ingredients within the dietary supplements have similar pharmacological effects. For example, both *Rauwolfia*, containing the active ingredient, reserpine, and yohimbe bark extract, containing the α-2 adrenergic antagonist, yohimbine, can lower blood pressure. When combined in a dietary supplement, there exists the potential for an additive or synergistic response. This may go beyond permitted structure—function claims on dietary supplement products for maintaining blood pressure in the normal range. Combination products have the potential to precipitate serious adverse events such as hypotension, dizziness, reflex tachycardia, and heart palpitations, especially in individuals who may be taking other medications with a similar mechanism of action or who have other systemic, underlying health conditions.

Reserpine, an alkaloid isolated from plants in the genera *Rauwolfia*, was one of the first drugs developed for treatment of high blood pressure. Reserpine is an FDA-approved prescription medication for the treatment of hypertension. The prescribed, adult, label dosage for reserpine, for use as an antihypertensive agent, is 0.1—0.25 mg per individual per day.[5] According to a recent study, reserpine can be found in *Rauwolfia serpentina* at a concentration of 0.1442% (Kumar et al., 2010). A dietary supplement product, labeled to contain 50 mg of *R. serpentina* in each serving (1 capsule) with directions to take two capsules per day, could potentially contain upward of 0.0721 mg reserpine (0.1442% of 50 mg) per capsule and lead to a total daily exposure level of 0.144 mg reserpine. This is in the range for an amount that would be indicated in a prescription medication for an individual with hypertension.

As an FDA-approved prescription medication, reserpine contains potential risks and toxicological effects that restricts its use to uncomplicated hypertensive patients. Reserpine is classified as a pregnancy category C. When reserpine is administered parenterally it has been shown to be teratogenic in rats and to have an embryocidal effect in guinea pigs. It is unclear how reserpine affects the dietary supplement consumer who is normotensive. Furthermore, the US National

---

[5] Reserpine [package insert]. Princeton (NJ): Sandoz, 2011.

Toxicology Program has considered reserpine to be a "probable cancer-causing substance" and "reasonably anticipated to be a human carcinogen" based on sufficient evidence of carcinogenicity from studies in experimental animals (NTP, 2011). These risks are unreasonable for a dietary supplement that must have a reasonable expectation of safe use, in a healthy adult, in the general population.

The package insert states that concomitant use of reserpine with other antihypertensive agents necessitates careful titration of dosage with each agent. This is because hypotension, hypothermia, central respiratory depression, and bradycardia may develop in cases of overdose of reserpine or synergistic action of reserpine with other antihypertensives. Thus, the combination of reserpine with any other antihypertensive botanical such as yohimbe bark extract can precipitate an adverse event. Their combination would necessitate a separate NDI notification to address this impact in the normotensive consumer. In contrast, the NDI *Rauwolfia vomitoria* (NDI 013) contains the botanical with the reserpine component removed. To receive an acknowledgment from FDA at this time, all *Rauwolfia* spp.—derived botanicals, for use in dietary supplements, must demonstrate that reserpine has been removed from the end-product prior to distribution to consumers.

This example illustrates the risks that can result when dietary ingredients with similar pharmacological actions are combined in the same product without submitting a premarket NDI; without appropriate warnings to the consumer of toxicological effects that can potentially develop and without premarket analysis for biomarkers of physiologically active ingredients that should not be present in the final product for distribution.

New Dietary Ingredients (Supplementation with Multiple, Combinations of Dietary Ingredients)—Galantamine and Huperzine A (Cholinesterase Inhibitors)

In a race to market, galantamine and huperzine A, both reversible cholinesterase inhibitors, were acknowledged dietary ingredients through NDI notification before they were investigational new drugs. Therefore, they are permitted to be used in dietary supplements under the conditions of use and consumption level as described in the "acknowledged" NDI notifications. FDA has concerns with increases in serving levels for galantamine and huperzine A whether they are used together or alone. Going forward, a manufacturer or distributor would be obliged to submit an NDI with safety evidence if they were to market the same ingredient (manufactured using the same process); if they wanted to market new products with higher serving

levels of ingredients; if they wanted to produce dietary supplement combinations with other dietary ingredients (i.e., huperzine A combined with galantamine); or if they developed new technologies to manufacture the dietary ingredient. In other words, any change in formula and/or chemical composition would elicit a need to submit an NDI prior to distribution of a new product.

The chemical structures for galantamine and huperzine A are provided in Fig. 39.1. Galantamine and huperzine A are reversible inhibitors of the enzyme acetylcholinesterase (AChE) (Taylor et al., 1996). Because their acute toxicity is due to the inhibition of AChE, measurement of AChE activity in red blood cells (whole blood analysis) is a critical biomarker for monitoring the toxicity of these dietary ingredients to adequately ensure a reasonable expectation of safety under the ordinary conditions of use for the product. AChE serves to limit the duration of the neurotransmitter acetylcholine (ACh) at muscarinic and nicotinic cholinergic receptors and therefore prevents its accumulation at synaptic junctions (Hilmas et al., 2009; Williams and Hilmas, 2010). Exposure to AChE inhibitors, both reversible and irreversible, results in symptoms indicative of widespread overstimulation. Fig. 39.2 illustrates the target organs, symptoms, and clinical signs that are associated with overstimulation. These symptoms include bronchoconstriction, increases in tracheobronchial secretion, lacrimation, increased urination, increased gastrointestinal motility, diarrhea, emesis, muscle weakness, diaphoresis, decreased heart rate, and central nervous system signs such as dizziness, blurred vision, mental confusion, respiratory depression, tremors, seizures, paralysis, and coma.

Galantamine and huperzine A have a very rapid on-rate and slow off-rate or release. Their kinetic profiles indicate predicted tight interactions with AChE in docking models. Best-fit docking models for both compounds involve different functional groups. Fig. 39.3 illustrates the three-dimensional docking of galantamine to both human and *Torpedo californica* forms of AChE. Fig. 39.4 illustrates three-dimensional docking of huperzine A to human AChE. Thus, they have been used in as prophylactic and postexposure therapeutic agents in preclinical studies to protect rodents against muscular paralysis and seizures induced by nerve agents.

Safety evidence in an NDI notification would have to demonstrate that AChE inhibition was not cumulative as a result of chronic (daily) consumption. Red blood cell, muscle, and brain cholinesterase activity have all been used, primarily in in vivo and in vitro studies, to measure and evaluate peripheral and central neurotoxicity as a result of galantamine and huperzine A administration. These activities should correlate to the whole
FIGURE 39.1   Chemical structures of galantamine, huperzine A, honokiol, lobeline, magnolol, and yohimbine. *The authors would like to acknowledge Dr. Mariton Dos Santos for providing this illustration.*

blood or plasma levels of galantamine or huperzine A in the animal model (Steiner et al., 2012).

There are other botanicals that contain reversible cholinesterase inhibitors. An example is honokiol and magnolol, present in *Magnolia* spp. (Fig. 39.1). The combination of an extract of *Magnolia* with galantamine or huperzine A may pose significant synergistic activity. Another is Lobeline (Fig. 39.1), a nicotinic agonist that may also act synergistically to produce a cholinergic crisis if combined with galantamine, huperzine A, or any other ingredient with AChE-inhibiting activity.

Appropriate safety studies should measure and evaluate AChE activity as a biomarker of toxicity when these ingredients or others are suspected of combined nicotinic and muscarinic AChE activity prior to their use in a dietary supplement product.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Dietary supplements are becoming more ubiquitous in the market and are becoming accepted in the general public as important components of many foods and beverages. Some may call them functional foods, others may call them nutraceuticals, dietary supplements, botanicals, or natural products to support health. With the
FIGURE 39.2 Overstimulation of muscarinic and nicotinic cholinergic systems due to inhibition of acetylcholinesterase (AChE) inhibition. Some dietary ingredients inhibit AChE, resulting in overstimulation by the neurotransmitter ACh at both muscarinic and nicotinic receptors located in various organ systems throughout the body. This figure illustrates the various physiological markers of toxicity which result from cholinergic activation in the presence of AChE inhibition. *The authors would like to acknowledge Alexandre Katos for providing this illustration.*
FIGURE 39.3 Three-dimensional docking of galantamine into AChE from human and *Torpedo californica*. The most appropriate portions of human AChE are displayed. The ball display on the left-hand side is the active site tryptophan, and the balls of AChE on the right-hand side represent the active site serine. Galantamine, represented in ball-and-stick configuration, is shown by atom type and has a transparent solvent accessible surface to demonstrate that it is filling a pocket. This docking was performed using Insight II software by aligning the backbones of the two AChEs.

increasing costs of health care, many people are looking for ways to lead healthier lifestyles, and whether good or bad, they are listening to broad avenues of media and marketing about the pros and cons of these products. Education of the public is important but at the same time the majority of individuals do not have the background in science and nutrition to adequately understand the complexity of what they are ingesting. Thus, it is vitally important for the medical community, industry, government regulators, academia, and media outlets to work together to make sure that only high-quality products are manufactured, marketed, and distributed properly in the general marketplace.

This chapter uses examples of dietary supplements and their ingredients that have been or are currently still available to consumers in a review for the use of biomarkers as they apply to various stages of the life cycle of these products.

An additional goal of this chapter is to remedy the misconception that dietary supplements are not regulated. They are. It should be stated that they are regulated not as a pharmaceutical where a lack of efficacy is considered an adverse event for its intended use but
FIGURE 39.4 Three-dimensional docking of huperzine A, a known anticholinesterase alkaloid, into human AChE. The three-dimensional rendering shows a best-fit model for docking of huperzine A functional groups with the two tyrosine functional groups (Tyr 337 and Tyr 341) on human AChE. Although these tyrosines are normally not involved in GAL docking, they may play a role in huperzine A docking. For reference, the active site tryptophan of AChE is oriented in the background; the active site serine is on the right-hand side. Huperzine A is colored by atom using a space-filling ball model configuration to show it is filling a pocket, rather than the ball-and-stick configuration with transparent solvent accessible surface as shown in the previous figure. The two tyrosines are in a ball-and-stick model configuration. This docking was performed using Insight II software.

are more closely aligned to the guidance's found for historical and NDIs that may be found in food products for human consumption.

Information has also been provided for how biomarkers inform worldwide regulatory decisions; the development of risk assessments for the protection of public health; and for industry to be able to manufacture and distribute dietary supplements with an appropriate weight of evidence to support an expectation of tolerance and safety for the general population of consumers for their proper, intended use.

Nutriphenomics in Rodent Models: Impact of Dietary Choices on Toxicological Biomarkers

Michael A. Pellizzon, Matthew R. Ricci

Research Diets, Inc., New Brunswick, NJ, United States

INTRODUCTION

When designing an experiment involving animal models, there are many factors that will affect a given phenotype (i.e., observable or biochemical response), and these can be broken into two basic categories: the genotype of the animal and the environment. Rodent models such as mice and rats are the most commonly used animals in biomedical research because of their small size, low cost, the vast array of strains commercially available, and the ease of modifying their genetic background. There are many rodent models for studying chronic disease states such as metabolic disorders (i.e., obesity, nonalcoholic fatty liver disease (NAFLD)) or cancer, some which are driven by dietary means, genetic modification, or both. Therefore, many considerations need to be taken into account when choosing the proper rodent model for a given study. In some cases, phenotype is very predictable, but in others, rodents can have a variable response, including when presented with a dietary challenge (Enriori et al., 2007; Zhang et al., 2012).

Like genotype, most environmental factors, such as light/dark cycle, temperature, humidity, and cage density, and type are typically well controlled, but diet (unless being directly studied) is usually a last consideration and is either not disclosed or is underreported in experimental studies. Most of the time, terms such as "a standard diet" or "a normal diet" are the commonly used "descriptors" when defining a diet in methods sections of publications, and in many of these cases, it is likely that the diet was not carefully considered. The importance of diet in toxicological studies was reviewed quite some time ago by toxicologists (Greenfield and Briggs, 1971; Wise, 1982), but some toxicologists still have not embraced this concept.

As the researcher chooses a diet for their study, they should ask a number of questions. Is the formula "open" to the public? Do I have access to the exact composition of the diet? Is the diet variable from batch to batch? Can I easily modify the diet formula? Does the diet contain contaminants? By having an open and consistent formula that is easily modified as needed, it is then possible to effectively study how and why various dietary manipulations influence any given biological parameter and form valid conclusions from the data. The influence of dietary factors on an animal's phenotype is called *nutriphenomics* and will occur under any experimental condition, whether diet is intentionally being altered to influence an animal's phenotype or not. Although *nutriphenomics* is a term typically used to describe intentional diet-induced disease phenotypes, there are dietary factors that may affect certain toxicological biomarkers, which may not be noticed unless they are being directly studied. These factors include certain nutrients and non-nutrients that are found in commercially available diets. This chapter will provide an overview of dietary choices available, common diet-induced disease phenotypes, and factors in commonly used control diets that can affect *nutriphenomics* in rodent studies.

Dietary Choices

Rodent diets can be broken down into two basic categories: grain-based (GB) or (cereal-based) diets or purified diets. A third category is chemically defined diets, which include ingredients that are entirely synthetic, but it is not something that is commonly used in research mainly because of their extreme expense and will not be discussed.

Grain-Based Diets

GB diets are made with unrefined cereal grains or animal ingredients that contain multiple nutrients and non-nutrients (Fig. 40.1). GB diets typically include agricultural grade ingredients such as ground corn, ground wheat, wheat gluten, wheat middlings, barley, ground oats, soybean meal, alfalfa meal, and animal by-products such as fish meal and porcine animal meal in varying proportions. Most GB diets are "closed formulas" or proprietary, and therefore the actual concentrations of these ingredients are not disclosed. Furthermore, GB diet companies will alter levels or sources of ingredients without disclosing these changes to researchers. These changes can be necessary to maintain a given nutrient concentration because nutrient levels in GB ingredients will vary with soil conditions, climate, and timing of harvest or sequence. However, and perhaps unwittingly, this can lead to changes in other nutrients and non-nutrients. For example, protein is typically monitored closely in GB diets, and a commonly used source of protein in these diets is soybean meal (around 50% protein). Besides protein, soybean meal also contains fiber, fat, minerals, and non-nutrients, such as phytoestrogens. Phytoestrogens, as their name implies, have similarities to the chemical structure of estrogen. Phytoestrogens in soybean meal are a complex mixture of isoflavones that are in several different chemical forms (daidzin, 6″-OAc daidzin, 6″-OMal daidzin, daidzein, genistin, 6″-OAc genistin, 6″-OMal genistin, genistein, glycitin, 6″-OMal glycitin, and glycitein), and each of these compounds is present either as β-glycosides (bound to glucose) or as aglycones (not bound to glucose). Phytoestrogens in soybean meal are mainly in the chemical forms genistin and daidzin (β-glycosides) and the levels of these phytoestrogens can change significantly based on soy variety, location of harvest, and time of year (Eldridge and Kwolek, 1983; Brown and Setchell, 2001). Therefore, as soybean meal is altered intentionally in some GB diets to maintain protein, this intentional adjustment could cause unintentional changes to levels of phytoestrogens (Thigpen et al., 1999; Jensen and Ritskes-Hoitinga, 2007). Some GB diets are "open formulas," and well-known examples of these include those developed by the National Institute of Health in the early 1970s (i.e., NIH-07, NIH-31). These "open" formulas will always contain a fixed level of ingredients, but it is difficult to maintain consistency in nutrient and non-nutrient contents of a given open- and fixed-formula GB diet from batch to batch as alluded to above (Rao and Knapka, 1987).

GB diet producers also offer "phytoestrogen-free" diets by replacing soybean meal or both soybean meal and alfalfa meal (contains the phytoestrogen coumestrol) with casein (containing around 87% protein) or combinations of other plant protein sources. Although this reduces phytoestrogen levels (Jensen and Ritskes-Hoitinga, 2007), there are still grains in GB diets that contain smaller amounts of phytoestrogens including alfalfa, wheat, barley, corn, and oats (Farnsworth et al., 1975) and potentially other endocrine disruptors or confounders present in other ingredients that could mask the influence of a toxicological phenotype of interest (Heindel and vom Saal, 2008). In fact, several other potential contaminants exist, including

Purified Diet Ingredients Contain One Main Nutrient

Casein, L-Cystine → Protein

Corn Starch, Dextrose, Sucrose → Carbohydrate

Cellulose, Inulin → Fiber

Corn Oil, Soybean Oil → Fat

Vitamin Mix, Mineral Mix, Choline Bitartrate → Essential Micronutrients

Grain-Based Ingredients Contain Multiple Nutrients and Non-Nutrients

Agricultural Products
Soybean Meal, Alfalfa Meal, Ground Wheat, Ground Oats, Ground Corn, Cane Molasses → Protein, Carbohydrate, Fiber, Fat, Minerals, Vitamins, Phytoestrogens *, Toxic Heavy Metals **

Agricultural By-Products
Wheat Middlings, Wheat Germ, Beet Pulp → Protein, Fiber, Fat, Minerals, Vitamins

Animal By-Products
Fish Meal, Porcine Meat Meal → Protein, Fat, Minerals, Vitamins, Toxic Heavy Metals **

* Phytoestrogens mainly from soybean meal and alfalfa meal
** Toxic Heavy metals mainly from cereal grains and meat meals

FIGURE 40.1　Common ingredients in purified diets and GB diets and their nutrient/nonnutrient contributions.

heavy metals such as arsenic (Kozul et al., 2008; Mesnage et al., 2015), endotoxins (Hrncir et al., 2008; Schwarzer et al., 2017), and pesticides and pollutants (Mesnage et al., 2015). Often these contaminants are present at biologically relevant levels (Kozul et al., 2008; Thigpen et al., 2013; Mesnage et al., 2015; Schwarzer et al., 2017). There is evidence that the levels of contaminants in GB diets vary across batches of the same diet (Greenman et al., 1980; Jensen and Ritskes-Hoitinga, 2007; Thigpen et al., 2007), which could lead to different findings depending on the batch used.

In addition to a diverse array of contaminants, GB diets contain both very high fiber contents and variable types of fiber because of the presence of multiple cereal grains. The diversity in the types of fibers present in GB diets has been described decades ago and showed that rat and mouse GB diets varied from 8% to 22% (total fiber) and proportions of different fiber types (i.e., pectin, hemicellulose, cellulose, and lignin) were highly variable among different diets (Wise and Gilburt, 1980). Therefore, GB diets contain fermentable fiber sources (i.e., soluble fibers such as pectin and to a partial degree from hemicellulose), which have the potential to modify the gut microbiome significantly. Thus, their use may limit our understanding of how microbiota affect overall health.

Purified Diets

Purified diets are open and fixed formulas made with refined ingredients, which contain one main nutrient and are commonly phytoestrogen-free, depending on the protein source. Given their open nature, the formulas are reportable and their nutrient contents are more easily defined than diets based on less refined grains and animal by-products. For example, casein is ~87% protein (~11% moisture), corn starch is ~88% carbohydrate (~11% moisture), soybean oil is 100% fat, cellulose is >99% insoluble fiber, and vitamin and mineral mixes are chemically defined ingredients. These ingredients contain minimal non-nutrients, and as such, it is possible to repeat a given nutrient composition of a particular diet from one lot to the next while limiting non-nutrients that can influence phenotype (Wise, 1982).

Purified diets have been around since the 1920s and were used to prove the essentiality of vitamins and minerals (Knapka, 1988). Until the 1970s, researchers made their own purified diets in the lab, and it was not uncommon for the formulas to vary from one researcher to the next, or for essential nutrients to be missing or perhaps simply unreported (Greenfield and Briggs, 1971). These dietary differences among studies in a given area of toxicology (or other fields) led to confounding factors and reduced the ability of collaborating researchers to draw conclusions. In an effort to reduce what was the variable influence of diet

in toxicology studies, a committee of nutritional scientists known as the American Institute of Nutrition (AIN) set forth in 1973 to establish an open, fixed formula to meet requirements for growth, reproduction, and lactation of rats and mice (Bieri et al., 1977). Such a diet was considered important for toxicologists because it contained only a minimal level of non-nutrients that could influence the toxicological phenotype of a given rodent model. The initial formula, called the AIN-76, fulfilled the nutrient recommendations for rodents established in 1972 by the Committee on Animal Nutrition of the National Research Council (National Research Council, 1972). As researchers began using this diet, they noted that a high percentage of their rats were hemorrhaging either internally or externally; the problem was solved by adding 10-fold higher concentrations of menadione (vitamin K) (Roebuck et al., 1979). This revised formula was called the AIN-76A (Table 40.1), and additional suggestions to improve the formula were proposed in an editorial by Bieri in 1980 (Bieri, 1980). About a decade later, a new group of scientists formed another AIN committee over some of the nutritional concerns indicated by Bieri with the AIN-76A diet. This committee developed a new set of diets, which would become the AIN-93 series diets (AIN-93G and AIN-93M, for growth and maintenance, respectively) (Reeves et al., 1993). Despite some improvements, studies with the AIN-93 series diets along with certain formulation issues, such as a low phosphorus mineral mix that relies on casein to supply part of the phosphorus requirement, have suggested that more improvements are required (Lien et al., 2001). That being said, these purified diets provide toxicologists and others a phytoestrogen-free formula that has a consistent nutrient composition from batch to batch, is easy to report, and is easily modified to the researcher's advantage.

TABLE 40.1   The AIN-76A Rodent Diet

Ingredient	g	kcal
Casein	200	800
DL-Methionine	3	12
Corn Starch	150	600
Sucrose	500	2000
Cellulose	50	0
Corn Oil	50	450
Mineral Mix	35	0
Vitamin Mix	10	40
Choline Bitartrate	2	0
Total	**1000**	**3902**

Diet-Induced Metabolic Disorders

Much work has been done with respect to how diet influences disease phenotypes in rodent models, and purified diets have been crucial in this effort. In some cases, it is important to address the influence of an environmental toxicant or endocrine disruptor on a metabolic disorder.

High-Fat Diets for Diet-Induced Obesity Models

At the time of this writing, a Google Scholar search for "high-fat diet rat" and "high-fat diet mice" yielded over 359,000 articles, dating back to the 1940s. For much of this time, a high-fat diet (HFD) was made by adding various levels and types of fat to the available GB diet already in the animal facility. However, this is not ideal because (1) fat addition can lead to nutritional inadequacies (nutrient dilution) in the diet and (2) the use of GB diets has inherent drawbacks as discussed earlier (variable and unknown composition). As an example, phytoestrogens can reduce adiposity and improve insulin sensitivity in mice relative to diets with low phytoestrogens (Cederroth et al., 2007, 2008).

Because purified diets allow for the easy formulation of an HFD without nutrient dilution, it is no surprise that in the last ∼20−25 years, purified ingredient HFDs have been widely used to study obesity and its associated comorbidities in rodents. There is a dose−response relationship between dietary fat and body weight and adiposity (Donovan et al., 2009; Jiang et al., 2009) and because animals fed a higher fat diet tend to gain more weight in a shorter period of time (which is often seen as cost savings to the researcher), the popularity of using diets containing 60% of calories from fat has grown as a standard method of promoting diet-induced obesity (DIO) in rodent models.

Although most rodents tend to become obese on an HFD, there are variable responses in body weight gain, glucose tolerance, triglycerides (TG), and other parameters depending on the strain and gender (Levin et al., 1997; Rossmeisl et al., 2003) and type of dietary fat (Ikemoto et al., 1996; Wang et al., 2002; Buettner et al., 2006). Outbred Sprague−Dawley and Wistar rats have a variable response to an HFD in that some animals become obese, whereas others remain as lean as low−fat diet fed rats (Farley et al., 2003). It is common to separate these rats (based on body weight gain) into DIO and diet-resistant (DR) groups (Chang et al., 1990; Farley et al., 2003; Levin and Dunn-Meynell, 2006). DIO and DR rats have been selectively bred over time such that the propensity to gain weight or resist obesity on an HFD is known in utero, allowing the researcher to look early in life (prior to the onset of obesity) for genetic traits that may later predispose them to their DIO or DR phenotypes (Levin et al., 1997; Ricci and Levin,

2003). Diet-induced obesity in Sprague−Dawley and Wistar rats can induce glucose intolerance (Drake et al., 2005; Laurent et al., 2007), fatty liver (Ross et al., 2012), inflammation (De Souza et al., 2005; de La Serre et al., 2010), cardiac dysfunction (Burgmaier et al., 2010), and increased muscle lipid deposition (Storlien et al., 1991) and affect development of offspring when fed to pregnant rats (White et al., 2009).

Mouse models of DIO are in more widespread use compared with those of rats, and the most commonly used mouse model of DIO is the C57BL/6 mouse, substrains of which are available from different breeders. Although it is rarely reported, there is some variability in weight gain in this strain, with one paper reporting that about 2/3 of the mice on an HFD became obese (Enriori et al., 2007). In C57BL/6 mice, HFDs induce obesity (Van Heek et al., 1997), cause insulin resistance (IR) (DeFuria et al., 2009), increase muscle triglyceride levels (Park et al., 2005), reduce glucose tolerance (Gallou-Kabani et al., 2007), cause inflammation (Weisberg et al., 2003), induce fatty liver (Ito et al., 2007a), change gut microflora populations (Ravussin et al., 2012), affect cognition (Pistell et al., 2010), and alter neurogenesis (Park et al., 2010), among other phenotypes. Other mouse strains such as the A/J or SWR/J are resistant to DIO (Surwit et al., 1995; Prpic et al., 2003). However, strains that may exhibit similar levels of obesity may have varied metabolic responses. For example, C57BL/6 mice are more glucose intolerant, compared with obese AKR mice that are more insulin resistant (Rossmeisl et al., 2003).

Diet-Induced Atherosclerosis/ Hypercholesterolemia Models

Western-type diets containing high levels of saturated fat and cholesterol are commonly used to "push" atherosclerosis risk factors (elevated total cholesterol [TC] and low-density lipoprotein cholesterol [LDL-C]) in certain rodent models such as mice, hamsters, and guinea pigs. Not surprisingly, different animal models require different diets.

Mice and Rats

Most wild-type mice and rats are not ideal models of cardiovascular disease research because they typically have very low levels of LDL-C and high levels of high-density lipoprotein cholesterol (HDL-C). This is in contrast to humans in whom the reverse is true. Although diets containing high levels of cholesterol and saturated fat (∼0.5% cholesterol, ∼40 kcal% fat) can increase TC, both LDL-C and HDL-C (Srivastava et al., 1991, 1992; Srivastava, 1994) increase, which limits atherosclerosis development (Getz and Reardon, 2006). The addition of the bile acid and cholic acid to diet (in combination with cholesterol) will increase LDL-C (Nishina et al.,

1990, 1993; Zulet et al., 1999; Jeong et al., 2005; Yokozawa et al., 2006) by both facilitating fat and cholesterol absorption and reducing conversion of cholesterol to bile acids (Horton et al., 1995; Ando et al., 2005). However, cholic acid can also independently influence genes that regulate lipoprotein metabolism and inflammation and reduce plasma TG and HDL-C (Nishina et al., 1990; Ando et al., 2005; Getz and Reardon, 2006) and reduces body weight gain (without changing food intake), glucose intolerance, and plasma insulin either with or without the presence of cholesterol (Ikemoto et al., 1997). Therefore data from cholic acid–containing diets should be interpreted carefully.

Genetically modified mice such as those with mutations that slow the removal of cholesterol from the blood have led to more "human-like" phenotypes and can show significant elevations in circulating LDL-C and atherosclerotic lesions, especially when dietary cholesterol is added. Some of these knockout mouse models (such as the LDL receptor knockout and the apolipoprotein E knockout [apoE KO]) can be very responsive after 12 weeks on a high cholesterol diet (0.15%–1.25% cholesterol) (Lichtman et al., 1999; Collins et al., 2001; Joseph et al., 2002). Lesion development is very dramatic in apoE KO mice fed a Western-type diet, and beginning stages of atherosclerosis (i.e., fatty streak lesions) can be found at 6 weeks (Nakashima et al., 1994). A combination of multiple genetic modifications (e.g., apoE + matrix metalloproteinase double KO) with a high-fat lard-based diet with cholesterol (0.15%) was found to increase plaque rupture after only 8 weeks (Johnson et al., 2005). With these mouse models, the main influence on atherosclerosis is dietary cholesterol rather than the level of fat (Davis et al., 2001; Wu et al., 2006), but certain threshold levels of dietary cholesterol may exist, at least within the context of a low-fat purified diet (Teupser et al., 2003). Very high–fat diets (i.e., 60 kcal% fat) are capable of inducing some atherosclerosis (Subramanian et al., 2008; King et al., 2009), and the fatty acid profile and carbohydrate form (i.e., fructose, sucrose) can be manipulated to modify the atherosclerosis phenotype to the researchers advantage (Merat et al., 1999; Collins et al., 2001; Merkel et al., 2001).

Hamsters

Although hamsters typically have a high percentage of HDL-C when fed a low-fat/low-cholesterol diet (similar to rats and mice), dietary cholesterol alone will increase LDL-C, and like humans, saturated fat can increase these levels further (Otto et al., 1995; Alexaki et al., 2004). Diets containing high levels of saturated fat and cholesterol can drive the initial stages of atherosclerosis (fatty streaks, foam cells) in as little as 6 weeks (Kahlon et al., 1996). Even a diet high in saturated fat

without added cholesterol can increase aortic cholesterol accumulation compared with a lower saturated fat diet with added cholesterol (Alexaki et al., 2004). The different response of the hamster (compared with the rat or mouse) to dietary cholesterol is related to different mechanisms of cholesterol processing by the liver (Dietschy et al., 1993; Horton et al., 1995; Khosla and Sundram, 1996). With the hamster, it is also important to consider the source of dietary protein because hamsters fed casein- and lactalbumin-based diets had higher levels of LDL-C and atherosclerosis than those fed an equal amount of soy protein, and like humans, males may be more susceptible than females (Blair et al., 2002).

Guinea Pigs

Unlike other wild-type rodents, guinea pigs have a similar cholesterol profile and lipoprotein metabolism to humans (more LDL-C vs. HDL-C) when maintained on a low-fat/low-cholesterol diet (Fernandez and Volek, 2006). Like hamsters, diets high in saturated fat can elevate TC and LDL-C levels and a diet with added cholesterol (at least up to 0.3%, w/w) can cause further elevations in LDL-C and induce atherosclerotic lesions (i.e., fatty streaks) after 12 weeks (Lin et al., 1994; Cos et al., 2001; Zern et al., 2003). Carbohydrate/fat ratio is also important to atherosclerosis development, as high-cholesterol diets that are high in carbohydrate and moderate in fat are more capable of promoting atherosclerosis (likely via increased number of smaller LDL particles) than those low in carbohydrate but very high in fat (Torres-Gonzalez et al., 2006). Also, plasma TC levels are higher with casein versus soy protein (Fernandez et al., 1999) and with sucrose versus starch (Fernandez et al., 1996), in the context of a cholesterol-containing diet. The sensitivity of LDL-C to dietary manipulation with minimal change to HDL-C highlights the value of the guinea pig for studies examining the influence of drug therapies on lowering LDL-C (Conde et al., 1996; Aggarwal et al., 2005).

High-Fructose/Sucrose Diets for Hypertriglyceridemia and Insulin Resistance

In humans and rodents, the presence of higher levels of dietary carbohydrate as fructose or sucrose is capable of causing hypertriglyceridemia (hyperTG) and IR via increasing lipogenesis and glucose production in the liver (Daly et al., 1997; Basciano et al., 2005). Sprague–Dawley and Wistar rats are both established models of sucrose-induced IR and hyperTG (Pagliassotti et al., 1996, 2000), which can develop as quickly as 2 weeks in rats fed mostly sucrose (i.e., 68 kcal%) relative to corn starch (Pagliassotti et al., 1996). The fructose component of sucrose is largely responsible for the hyperTG and IR produced by high-sucrose diets (Sleder et al., 1980; Thorburn et al., 1989; Thresher et al., 2000).

Although very high levels of sucrose or fructose are commonly used for driving IR in rodents, even lower levels of dietary sucrose (17% of energy) can cause this after chronic feeding periods (i.e., 30 weeks) (Pagliassotti and Prach, 1995). High-fructose diets can also raise liver TG levels and induce liver inflammation (Kawasaki et al., 2009) as well as adipose tissue and kidney inflammation (Oudot et al., 2013). Furthermore, gender is important in the development of sucrose-induced IR and hyperTG in rats as females (unlike males) are typically not responsive to elevations in dietary sucrose (Horton et al., 1997). Unlike HFD, high sucrose or fructose diets promote marginal weight gain in rats, and this typically requires a prolonged period of time and a significantly greater energy intake (Chicco et al., 2003).

Similar to rats, hamsters are sensitive to metabolic alterations by high-fructose diets (~60% of energy) and quickly develop IR and hyperTG only after 2 weeks (Kasim-Karakas et al., 1996; Taghibiglou et al., 2000), but they may not be as sensitive to sucrose-induced hyperTG and IR (Kasim-Karakas et al., 1996), suggesting that the level of dietary fructose is important for this model. The addition of dietary cholesterol (0.25%) allows for the simultaneous development of hypercholesterolemia, greater IR, and hyperTG in this model compared to fructose alone (Basciano et al., 2009). The ability to induce these three metabolic disturbances together makes the hamster an attractive model for studying these conditions in one model without the need to alter background genetics.

In contrast to rats and hamsters, mice are used less frequently as a model for sucrose/fructose-induced phenotypes, as the commonly used C57BL/6 strain either does not develop IR or develops the phenotype more slowly (Nagata et al., 2004; Sumiyoshi et al., 2006). For example, glucose intolerance (attributed to reduced pancreatic insulin secretion) develops in C57BL/6 mice fed a high-sucrose diet over the course of 10—55 weeks (Sumiyoshi et al., 2006). However, the mouse genome is much easier to manipulate than that of the rat and in certain cases can cause knockout models to have hyperTG with high dietary fructose (Hecker et al., 2012).

Nonalcoholic Fatty Liver Disease

NAFLD encompasses a spectrum of disease states, from steatosis (fatty liver) to nonalcoholic steatohepatitis (also called NASH; steatosis with inflammatory changes), which may be followed by progression to fibrosis, cirrhosis and hepatocellular carcinoma (Zafrani, 2004). There are several different dietary approaches to induce NAFLD. These different dietary approaches produce different severities of disease along the NAFLD spectrum and likely work by different mechanisms.

Of the dietary approaches discussed here, methionine—choline deficient (MCD) diets produce the most severe phenotype in the shortest timeframe. Used for over 40 years, MCD diets will quickly induce measurable hepatic steatosis (mainly macrovesicular) in rodents by 2—4 weeks, and this progresses to inflammation and fibrosis shortly thereafter (Weltman et al., 1996; Sahai et al., 2004). Fat levels in MCD diets can vary, though they typically contain about 20% fat by energy (most "control" diets, purified ingredient or grain based, tend to be ~10% by energy). The mechanism for steatosis includes increased hepatic fatty acid uptake, impaired very low density lipoprotein secretion (due to lack of phosphatidyl choline synthesis), and increased fatty acid transport proteins (Kulinski et al., 2004; Rinella and Green, 2004). MCD diet—induced NASH is reversible in rats by switching to a diet with sufficient methionine and choline (Mu et al., 2010). The disadvantage of using MCD diets is that they induce rapid weight loss (due to a vastly lower caloric intake) and the rodents do not become insulin resistant (Kirsch et al., 2003; Rinella and Green, 2004), unlike the typical obese, insulin-resistant human NAFLD patient.

Similar to MCD diets, choline deficient (CD) diets also tend to contain higher levels of fat, though it is often difficult to know the specifics because, unfortunately, authors rarely publish the details of the diets. CD diets induce steatosis, inflammation, and fibrosis over 10 weeks without any difference in body weight compared with the control group (Fujita et al., 2010). This lack of weight loss makes CD diets more appealing to some researchers. If weight gain is desired, a CD HFD (i.e., 45 kcal% fat) can increase body weight of C57BL/6 mice further than a matched low-fat diet (10 kcal% fat) with or without choline after 8 weeks, but mice remain glucose tolerant (Raubenheimer et al., 2006). Even longer feeding periods of up to 1 year have found that a CD 45 kcal% fat diet (same as Raubenheimer et al.) can drive hepatocarcinoma in mice relative to those simply fed a choline-sufficient 45 kcal% fat diet (Wolf et al., 2014). The mechanisms involved with liver fat accumulation may be different from those at work during MCD diet feeding (Kulinski et al., 2004). When both CD and MCD diets were fed to rats for 7 weeks, the MCD diet group had higher scores of liver inflammation and steatosis than the CD group. However, the CD fed rats gained weight, were insulin resistant, and had higher plasma lipids than the MCD group (Veteläinen et al., 2007).

As discussed earlier, HFDs are well known to increase body weight and body fat and induce IR in rodent models. HFD (with sufficient methionine and choline) can also increase liver fat levels quite rapidly (within days) as well as hepatic IR before significant

increases in peripheral fat deposition occur (Samuel et al., 2004). Chronically, HFDs-induced liver fat accumulation may not follow a linear progression and liver fat levels may actually decrease and then increase again during prolonged HFDs feeding (Gauthier et al., 2006). When fed for equal lengths of time, HFD feeding results in 10-fold lower liver fat levels compared to what accumulates on an MCD diet (Romestaing et al., 2007). In general, HFD feeding does not produce liver fibrosis but only mild steatosis as compared with MCD diets (Anstee and Goldin, 2006), thus highlighting an important difference between these dietary regimes. It is important to remember that the term "HFDs" encompasses a wide variety of diet formulas that can be expected to alter the liver phenotype in various ways.

In a dietary combination approach, Matsumoto et al. (2013) used a high fat (60% of energy), CD diet containing only 0.1% methionine by weight (most purified ingredient diets based on casein contain 5—8 times this amount). Fatty liver, markers of liver injury, and inflammation were increased after 1—3 weeks, and after an initial loss of body weight, the C57BL/6 mice gained weight at a trajectory similar to control animals (Matsumoto et al., 2013). In contrast, A/J mice exhibited reduced weight and inflammation with no evidence of fibrosis (Matsumoto et al., 2013). Increasing methionine from 0.1% to 0.2% in the context of a 45 kcal% fat diet increased body weight gain and still allowed for NASH to develop after 12 weeks in C57BL/6 mice (Chiba et al., 2016). Thus it seems that HFDs containing lower than normal levels of methionine and choline allow for the development of NASH without massive weight loss. This idea of modifying so-called "standard" HFDs is powerful because it allows the researcher to "fine-tune" the phenotype to meet their needs.

Combination HFDs with 40 kcal% fat using a vegetable-based shortening (combination of palm oil and partially hydrogenated soybean oil), 2% cholesterol, and 20% as fructose source have been used often by those interested in developing both NASH and metabolic disease. Both lard or the shortening were capable of increasing intrahepatic lipid levels in ob/ob knockout mice, which are genetically obese and already have a higher intrahepatic lipid level on a low-fat diet, and a similar effect was found in C57BL/6 mice, but the shortening was found to elevate the lipid level even more than lard in both these mouse models after 12 (for ob/ob) and 16 (for C57BL/6) weeks (Trevaskis et al., 2012). To develop more advanced NASH including fibrosis, it is necessary to feed C57BL/6 mice up to 30 weeks (Trevaskis et al., 2012). Therefore, prolonged feeding is necessary to drive a combination of fibrosis with metabolic disorders in wild-type mice.

Diets High in Sodium (and Fructose) for Hypertension

Diet-induced hypertension is possible in both rats and mice though there are more published papers using rats, perhaps because of their larger size, the amount of physiological data available, and robust blood pressure response that some strains present.

The main dietary contributor to diet-induced hypertension is the level of NaCl. Levels of NaCl well above what are normally found in purified (∼0.1%) or GB diets (∼0.3—0.4%) are required to raise blood pressure in most rodent models. The Dahl salt-sensitive (SS) rat shows a significant rise in blood pressure within 2—4 weeks after being fed a purified diet containing 8% NaCl (Ogihara et al., 2002; Karmakar et al., 2011), though lower levels of NaCl (4%) will still raise blood pressure (Konda et al., 2006) albeit more slowly (Owens, 2006). This rise in blood pressure can be attenuated by supplementing the diet with extra potassium (Ogihara et al., 2002).

Aside from the NaCl level itself, the background diet can also affect the hypertension phenotype. When either low (0.4%) or high (4%) NaCl was added to both a GB diet and a purified diet, Dahl SS rats that were fed the purified diet had higher blood pressure and more renal damage compared with GB diet—fed rats (Mattson et al., 2004). Given the many differences between GB and purified diets, it is difficult to know exactly which components were responsible. The possibilities include the source of protein (Nevala et al., 2000), carbohydrate (Buñag et al., 1983), fat (Zhang et al., 1999), fiber (Preuss et al., 1995), and/or the level of minerals such as potassium (Ogihara et al., 2002), all of which can greatly differ between GB and purified diets.

Aside from salt-sensitive rats, outbred rat strains such as the Sprague—Dawley (which are in widespread use for obesity research) can develop hypertension. When fed an 8% NaCl diet, hypertension develops, but this usually occurs over a longer time period and to a lesser magnitude compared with Dahl SS rats (Thierry-Palmer et al., 2010). Sprague—Dawley rats can also develop hypertension as they become obese on an HFD (Dobrian et al., 2000). Diets high in fructose (around 60% of calories) but with normal levels of NaCl (0.1%) can induce metabolic abnormalities, including increased blood pressure (Vasudevan et al., 2005; Sánchez-Lozada et al., 2007) and kidney damage in both Sprague—Dawley and Wistar rats (Hwang et al., 1987; Vasudevan et al., 2005; Sánchez-Lozada et al., 2007). The IR induced by such high-fructose diets (Hwang et al., 1987) is believed to play a causal role in the development of hypertension (DeFronzo, 1981).

Even in a spontaneous rat model of hypertension (such as the spontaneously hypertensive rat [SHR],

which will develop hypertension on a variety of diets), diet can be used to modify the onset or degree of this disease. For example, dietary supplementation with antioxidants (such as vitamins E and C) can lower blood pressure in stroke-prone SHR (Noguchi et al., 2004), as can dietary calcium supplementation (Sallinen et al., 1996). As mentioned earlier, the mouse is not as widely used for the study of diet-induced hypertension. Inbred mice such as the C57BL/6 can develop elevated blood pressure on purified diets high in NaCl (8%), though this appears to be on the order of several months (Yu et al., 2004).

Although C57BL/6 mice are sensitive to diet-induced obesity when fed an HFD, mean arterial blood pressure was slightly, but significantly increased relative to a low-fat diet (around 3 mm Hg) after 7 days of feeding a very HFD (i.e., 60 kcal% fat, mainly lard). The addition of 5% NaCl to the HFD increased blood pressure by 4.5 mm Hg compared to baseline measures on an HFD with normal NaCl levels (i.e., 0.3%) and was also increased (by 2.1 mm Hg) compared to those fed a low-fat diet with similar 5% NaCl levels (Nizar et al., 2016). From a mechanism standpoint, they observed that after being exposed to an acute NaCl load, high fat feeding reduced sodium excretion compared with low fat feeding.

Metabolic Disease Development and the Importance of Fiber Type

Although increasing dietary fat in the diet is a major factor affecting weight gain and metabolic disease development in rodents, the underlying agents that may be key to driving these effects are the type of fiber and the gut microbiome. Over 2000 years ago, Hippocrates proposed a link between gut health and disease development ("All disease starts in the gut"), and recent studies in rodent models have shown that there is merit to this blanket statement when it comes to metabolic disease and possibly other diseases. The presence of the 100 trillion bacteria in our lower gastrointestinal tract (made up of 500−1000 different species) has important implications in this link between the gut and metabolic disease development. These bacteria are "fed" with the fiber present in our diets, in particular, soluble fiber (i.e., prebiotic fibers), and in turn this fiber can affect bacterial composition rapidly, leading to changes in gut health. Replacement of cellulose (i.e., insoluble fiber typically used in purified diets) with soluble fibers (such as inulin) in a HFD has been found to have a dramatic effect on gut health, including reduced adiposity, improved gut morphology, improved insulin sensitivity, better glucose tolerance, increased beneficial bacteria and SCFAs, and reduced gap junctions between enterocytes, the latter of which reduces permeability and slows transfer of bacterial substances such as lipopolysaccharides thus limiting low-grade inflammation. All of these

effects are preceded by changes in gut microbiota (Chassaing et al., 2015, 2017; Zou et al., 2017). These effects by inulin on gut and metabolic health were found to be mediated by interleukin (IL)-22 rather than changes in short-chain fatty acids in one study (Zou et al., 2017). IL-22 is produced by immune cells to promote both epithelial cell proliferation and induce antimicrobials, which provides a direct link to how fiber-induced changes in gut microbiota influence low-grade inflammation and metabolic disease risk (Zou et al., 2017). However, the particular diet may play some role in this process as Brooks et al. reported that short-chain fatty acid production was important to the beneficial influence of soluble fiber on reducing adiposity and liver triglyceride levels when animals were fed a lower level of inulin (7.5 g%) in the context of a high-fat (21 g% as milk fat)/high- sucrose (34 g%) diet (Brooks et al., 2017). Therefore, it's important to consider the diet background when forming conclusions regarding how fiber is mediating its effect.

Know Your Control Diet

The choice of the control diet used in a diet-induced metabolic disease study can profoundly affect data interpretation. When a study is performed using a GB diet as a "control" diet for a purified HFD, it is not possible to know whether the differences between the HFD and the GB diet are driven by the higher level of fat or because of the other factors that differ between the diets. To know that the observed differences are due to the high fat content, it is important to have a low-fat diet that matches the nutrient sources in the HFD (except for the fat and carbohydrate levels). This is easy to do with purified ingredients because each ingredient contains one main nutrient. However, all too often do we find that a GB diet has been used as the "control" diet for a purified HFD (Warden and Fisler, 2008; Pellizzon and Ricci, 2018). Using a GB diet as a comparator diet can lead to a severe misinterpretation of how a purified HFD influences the gut morphology and microbiota. This was highlighted in recent studies that demonstrated that mice fed a high-fat purified diet (i.e., 60 kcal% fat, mainly lard) had a reduced cecum and colon size relative to those from mice fed a GB diet, whereas there was no difference in gut morphology in the matched low-fat purified diet (10 kcal% fat, increased carbohydrate in place of lard) (Chassaing et al., 2015; Dalby et al., 2017). Furthermore, the same high-fat purified diet altered ileal and cecal microbiota profiles significantly from those fed the GB diet, whereas those fed a matched low-fat purified diet were similar to the high-fat fed group (Dalby et al., 2017). Although fat level is an important variable for driving adiposity, fiber type can mediate effects on gut morphology and microbiota in rodents, which can in turn alter metabolic

disease development by an HFD. Therefore, it is important to choose the control diet carefully and consider the fiber type when designing any metabolic disease studies (Pellizzon and Ricci, 2018).

Potential Effects of Grain-Based Diets and Low-Fat Purified Diets on the Rodent Phenotype

Similar to the importance of choosing the proper control diet, choosing the diet in any study should not be overlooked as this may lead to significant misinterpretation of data. Like mice with a certain genetic background, each diet background is unique and there is no such thing as a "standard chow", a common reference made for the diet used in methods sections of publications. In fact, this vague term and the lack of reporting about the particular diet being fed suggest a general lack of consideration for the diet background in most studies, which is perplexing, given how dietary factors have been shown to alter study outcomes in so many cases. Both GB and purified low-fat diets (such as the AIN diets) can alter an animal's health status (either unfavorably or favorably) and interact with, attenuate, or completely mask the influence of a toxicological compound of interest on a given phenotype. Therefore, the details of the diet used (i.e., diet number, formulation, if available) should be reported in any study for the scientific community to critically evaluate the validity of the findings.

Grain-Based Diets
Phytoestrogens and Development/Maturation

As discussed previously, GB diets can contain soybean and alfalfa meals, which are known to contain biologically relevant and variable levels of phytoestrogens including genistin, daidzin, glyceitin, genistein, daidzein, and coumestrol. In contrast, purified diets such as the AIN-76A and AIN-93 series diets contain no phytoestrogens. When ingested, these phytoestrogens undergo biotransformation into more absorbable forms such that genistin and daidzin are converted into the isoflavones genistein and daidzein. Daidzein can undergo further metabolism by resident bacteria to S-(-) equol and enter the circulation. This latter form, equol, is found in highest concentrations in the serum and urine of adult rats and mice consuming soybean meal—containing GB diets, and it remains high in newborn pups after in utero exposure to these diets (Brown and Setchell, 2001). As mentioned earlier, different GB diet batches (i.e., same diet, but different mill dates) can vary in isoflavone concentrations three- to fourfold, and this can have a concentration-dependent influence on circulating phytoestrogens levels (Thigpen et al., 2004). However, these circulating levels can differ significantly in mice fed different GB diets, even when dietary isoflavones levels are similar (Brown and Setchell, 2001) suggesting that it is difficult to predict circulating isoflavone levels based on the concentration in the diet. Once in the circulation, these phytoestrogens are free to target estrogen receptors, in particular estrogen receptor β, but with a lower affinity compared to estradiol (Oseni et al., 2008). The effects can be either pro- or antiestrogenic, depending on the stage of life. Examples of a proestrogenic effect are found during development and maturation and include a dose-dependent reduction in timing of vaginal opening (VO) and an increase in uterine weights when rats and mice have prepubertal exposure to phytoestrogens (Thigpen et al., 2002, 2007; Heindel and vom Saal, 2008). Examples of antiestrogenic effects include the antagonistic effect of soy isoflavones on endogenous estrogens in certain cancers as discussed in the next section. The levels of phytoestrogens in GB diets are also high enough to negate effects of endogenously administered endocrine disruptors (such as bisphenol A) on DNA methylation and oocyte development, and their variability may contribute to inconsistencies in data where such compounds are studied during earlier stages of life (Thigpen et al., 2013).

Phytoestrogens and Cancer

Aside from altering pubertal onset, GB diets have the potential to inhibit carcinogenesis, and the presence of many plant-based compounds such as phytoestrogens is likely key to the reduced frequency and slower onset of tumors in certain cancer models relative to phytoestrogen-free diets such as the AIN-76A (Fullerton et al., 1991, 1992). There can be several mechanisms by which phytoestrogens play a role in carcinogenesis, but one is likely through their ability to bind estrogen receptors (Nikov et al., 2000). Their action may be either pro- or anticarcinogenic depending on age, mode of cancer induction, phytoestrogen dose, and rodent model being studied (Bouker and Hilakivi-Clarke, 2000). Genistein can dose-dependently increase mammary tumor area in estrogen-sensitive ovariectomized mice (Allred et al., 2001), but in contrast, early life (gestation and lactation) exposure to genistein can dose-dependently *reduce* tumor formation in a carcinogen-induced mammary cancer model with intact ovaries (Fritz et al., 1998). In a prostate cancer mouse model (transgenic mice with prostatic adenocarcinoma), genistein at levels found in GB diets can reduce prostate weight of mice with adenomas and improve survival (Mentor-Marcel et al., 2005). Phytoestrogens can, depending on the dose, either inhibit or promote the efficacy of drugs called selective estrogen receptor modulators (SERMs). For example, in a transgenic mouse model of mammary carcinogenesis, lower doses of isoflavones (211 mg/kg diet) abrogated tamoxifen's ability to reduce carcinogenesis relative to either

higher concentrations of isoflavones (491 mg/kg) or phytoestrogen-free diets (GB diet or purified) based on casein (Liu et al., 2005). Therefore in studies evaluating the influence of SERMs on tumors, it is important to eliminate exposure to phytoestrogens or any other compounds in diets that can bind estrogen receptors.

GB diets that contain low levels of phytoestrogens are available but it is not possible to truly control other factors within these GB diets, given each ingredient contains multiple nutrients and non-nutrients. Aside from offering a clean background and consistent composition that is phytoestrogen free, the refined nature of the ingredients in purified diets allows for easy customizations, which provide researchers an additional advantage in the cancer field. Making select changes to various nutrients such as increasing the level of fat calories in place of carbohydrate, reducing fiber, and certain vitamins (i.e., lower folate) and minerals (i.e., lower calcium) can increase tumor incidence in wild-type mice without carcinogen exposure given a long enough time-frame (Newmark et al., 2001; Yang et al., 2008). Therefore, purified diets allow the researcher to conduct studies with animals that may be more relevant to humans in addition to minimizing the presence of estrogenic compounds that can influence carcinogenesis.

Arsenic and Heavy Metals

GB diets are commonly based on cereal grains such as ground wheat, ground corn, and ground oats and meat meals such as fish meal, all of which can contain varying levels of toxic heavy metals (Newberne, 1975; Greenman et al., 1980; Wise, 1982). It has been suggested that the levels of these heavy metals in rodent GB diets are not high enough to affect animals from a disease standpoint (Greenman et al., 1980). However, some toxic heavy metals such as arsenic can be found in these diets at biologically relevant levels, and it is critical to consider potential dietary contributions especially when determining the effect of lower doses of heavy metals on the phenotype of rodent models. One study found that arsenic levels were quite high (390 ppb) and other heavy metals (i.e., cadmium, lead, nickel, and vanadium) were also present in a GB diet—all of which were virtually absent in the purified *AIN-76A diet* (Kozul et al., 2008). Of the 390-ppb arsenic, 56 ppb was considered inorganic arsenic, whereas none was detectable in the *AIN-76A*. This level of inorganic arsenic in this particular GB diet was higher than what is designated by the Enviromental Protection Agency as safe in drinking water (National Research Council, 1999, 2001), and therefore can severely compromise data from studies using GB diets to evaluate the influence of lower doses (i.e., 10–100 ppb) of arsenic (or other heavy metals). In fact, similar gene expression levels in both type I and type II metabolism genes (cytochrome P450 enzymes, involved in xenobiotic metabolism) as well as inflammatory genes were found in liver and lung of GB diet—fed mice with or without arsenic in water (10 or 100 ppb). In contrast clear differences in gene expression were found between dosed or control mice fed the *AIN-76A* (Kozul et al., 2008). Although arsenic in GB diet was at 4 to 40 times the level being studied and was likely to blame for the lack of expressional changes, it could be also that other factors in the diet were masking the effects.

Follow-up studies suggest that arsenic levels much lower than those found in GB diets can significantly influence an animal's phenotype. For example, 100-ppb arsenic in the water consumed by mice fed a purified diet can impair inflammatory factor activation and the immune response to infection (Kozul et al., 2009a,b). When these same investigators wanted to see how arsenic exposure early in life (i.e., during gestation and lactation) influenced the immune response in these mice, profound reductions in postnatal growth and development were observed with only 10-ppb arsenic, which was likely attributed to reduced energy from milk (i.e., lower fat content) of lactating dams fed arsenic (Kozul-Horvath et al., 2012).

Other Compounds or Contaminants

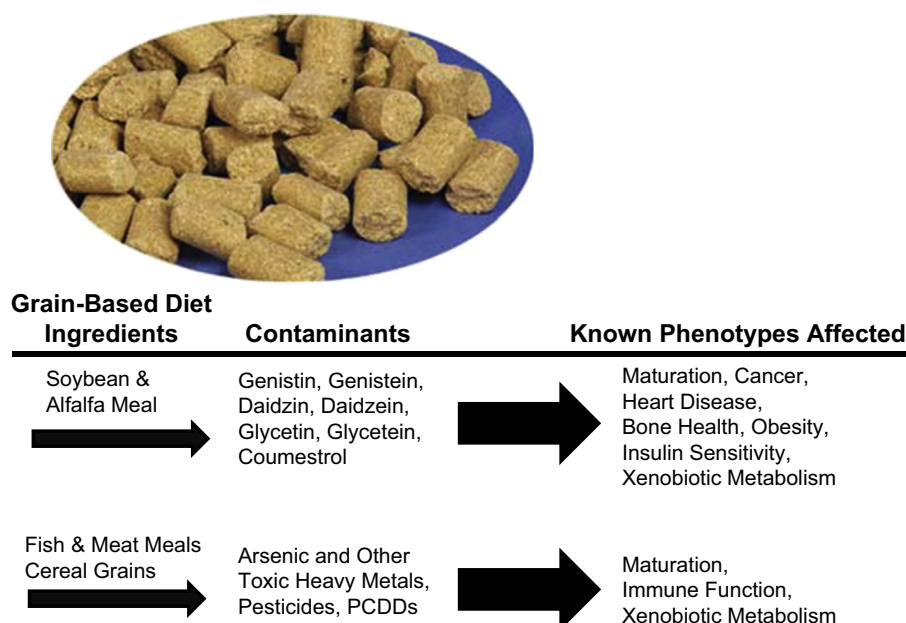
A list of phytoestrogens and toxic heavy metals in GB diets and how they may influence phenotypes are summarized in Fig. 40.2. In addition to these contaminants, other compounds that may be present in GB diets at varying concentrations include mycotoxins (zearalenone), herbicide and pesticide residues, polychlorinated dibenzo-p-dioxins (PCDDs), and dibenzofurans, which can influence various toxicological phenotypes by targeting estrogen receptors and the aryl hydrocarbon receptor (AhR) (Rao and Knapka, 1987; Schecter et al., 1996; Thigpen et al., 2004). These factors may work alone or together (additively or synergistically) with other contaminants previously discussed (i.e., phytoestrogens, heavy metals) to influence phenotype. For example, GB diets were found to activate AhR of cells that modulate immunity defense and detoxification in the intestine and throughout the body in mice (Ito et al., 2007b; Li et al., 2011). Although it is unknown what ligand(s) in GB diets affected the AhR, a similar effect on the AhR was found when mice were fed a purified diet containing a high concentration of a known ligand of the AhR (indole-3-carbinol) found in cruciferous vegetables. Although GB diets do not contain cruciferous vegetable sources, it may be that other known ligands of this receptor such as isoflavones and PCDDs known to be present in these diets could very well be responsible for these effects (Amakura et al., 2003).


FIGURE 40.2 GB diet contaminants that can influence various phenotypes in rodents.

Purified Low-Fat Diets and Health Status of Rodents

As pointed out earlier, purified diets have been used in laboratory animal research since the 1920s and were essential for determining nutrient recommendations because researchers were able to remove specific vitamins and minerals to determine requirements. However, there are phenotypical responses to purified diets that may not be favorable, and in some cases, they have led to unfavorable health outcomes. Research has pointed out where the potential flaws may lie, which have led to improvements in the purified diet formulas in use today.

Kidney Calcinosis

The *AIN-76A* diet has a long history of use since its initial conception in 1976, but along the way, it has come under criticism with good reason. One initial observation found with feeding the *AIN-76A* was that it promoted nephrocalcinosis (or kidney calcinosis (KC)), particularly in rats. Nephrocalcinosis is an abnormal condition of the kidney in which deposits of calcium (Ca) form in the filtering units. This may reduce kidney function and eventually lead to significant damage and kidney stone formation. Although calcium and phosphorus levels were in the recommended range for rodents, studies done carefully were able to determine that a low Ca to phosphorus (P) molar ratio (0.75) in the *AIN-76A* was the culprit for KC in weanling female rats (Cockell et al., 2002; Cockell and Belonje, 2004). This phenotype develops very quickly (i.e., 2–4 weeks) and is irreversible in these rats (Ritskes-Hoitinga et al., 1989; Peterson et al., 1996; Matsuzaki et al., 2002; Cockell and Belonje, 2004). Other factors that may affect development of KC within this diet include the type of carbohydrate, fiber, and sulfur-containing amino acid (AA) supplement—specifically, fructose (Bergstra et al., 1993), insoluble fiber cellulose (Anderson et al., 1985), and DL-methionine (Reeves et al., 1993b). That said, it is important to point out also that the Ca to P ratio is likely most important to this phenotype given GB diets such as the NIH-07 or NIH-31M (Ca to P ratio = 0.9) were found to cause mild KC in young, female rats (Rao, 2002).

When the AIN committee met to formulate the *AIN-93* series diets, increasing the Ca to P ratio above 1 was at the top of their list (Reeves et al., 1993a). The *AIN-93* diets contain a Ca to P ratio of 1.3:1 and that, with a lower level of sucrose (10% vs. 50%) was able to "fix" the KC problem, but at the expense of having a mineral mix that is deficient in phosphorus and relying on casein (0.7% phosphorus) to fill the phosphorus void. Even still, a previous report suggested that some rats still have a mild degree of KC when fed the *AIN-93G* diet, suggesting this "fix" was not enough (Cockell and Belonje, 2004).

Pubertal Onset

Given what was discussed above regarding the influence of phytoestrogens on pubertal onset, one might speculate that a phytoestrogen-free diet would prevent precocious pubertal onset in rodents. However, a phytoestrogen-free diet such as the *AIN-76A* or *AIN-93G* diet can also reduce the timing of VO and increase

uterine weight, even in some cases when compared with phytoestrogen-containing GB diets, depending on the animal model (Thigpen et al., 2002, 2007). This is thought to be due to the higher metabolizable energy (or caloric density) content of purified diets (3.9–4 kcal/g diet in *AIN-76A* and *AIN-93G*, respectively) compared with GB diets (3–3.5 kcal/g) (Thigpen et al., 2002, 2007). GB diets typically contain 15%–25% fiber (both insoluble and soluble) and around 3%–5% soluble fiber (Pellizzon and Ricci, unpublished observations), whereas the AIN diets contain 5% of it (only insoluble fiber). Therefore, although it is currently unknown what particular dietary factor(s) in purified diets is "estrogenic," it is possible that a reduced fiber content (and therefore higher metabolizable energy level) and perhaps even lack of soluble fiber are responsible and can easily be addressed by simply adding more fiber in purified diets.

Metabolic Effects

Aside from KC, the metabolic phenotype, including plasma and liver lipids, glucose tolerance, and blood pressure, can be significantly altered by purified diets and in some cases, not on purpose. For example, the *AIN-76A* and *AIN-93G* can have adverse effects on metabolic phenotypes in rodents, including increased body weight, blood and liver lipids, and blood pressure, compared to GB diets (Fullerton et al., 1992; Reeves et al., 1993b; Lien et al., 2001; Mattson et al., 2004). These diets contain sucrose in two concentrations (50% and 10% in the *AIN-76A* and *AIN-93G* diets, respectively), and high sucrose has been found to reduce glucose tolerance in C57BL/6 mice (Sumiyoshi et al., 2006) and induce IR, hyperTG, hepatic steatosis, and hypertension in rats (Hwang et al., 1987; Pagliassotti and Prach, 1995; Pagliassotti et al., 1996), even at lower concentrations, at least in rats (Thresher et al., 2000).

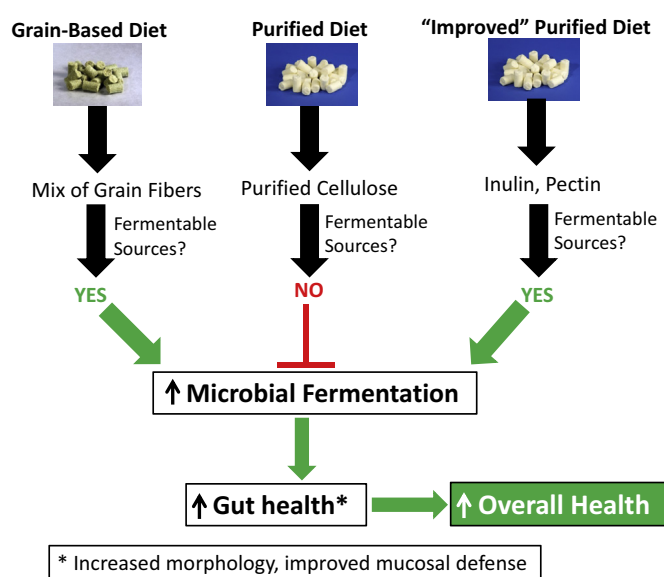
As mentioned above, fiber levels are also very low in purified diets compared with GB diets. Furthermore, purified diets typically have only insoluble fiber (cellulose), whereas GB diets have both insoluble and soluble fiber sources from cereal grains. Crude fiber levels of GB diets are typically listed at 5%–6%, but these diets typically contain four times more total dietary fiber than the crude fiber analyses indicate (Wise and Gilburt, 1980) (~18% insoluble and ~2–5% soluble). In comparison, the *AIN-76A* and *AIN-93G* contain 5% fiber by weight (50 g per 3902 kcals and 50 g per 4000 kcals for *AIN-76A* and *AIN-93G*, respectively) as cellulose (100% insoluble fiber). Modification of total fiber and fiber type in purified diets to be similar in composition to GB diets may lead to a healthier rodent phenotype. For example, addition of soluble fibers such as inulin can also reduce body weight, adiposity, and


FIGURE 40.3   Current purified diets may be improved by adding soluble fiber sources.

blood and liver lipids and improve glucose tolerance of rodents, and these changes are likely due to increases in short-chain fatty acids produced by fermentation of inulin by gut microbiota (Delzenne et al., 2002, 2007). Other mechanisms likely exist, including more direct effects of microbiota to reduce inflammation, and increase epithelial cell formation and mucosal layer thickness for improved barrier function (Chassaing et al., 2017; Zou et al., 2017). Additional fiber (both nonfermentable and fermentable) can also influence risk for other chronic diseases including cancer (Jacobs, 1986; Taper and Roberfroid, 2002) and may improve life span in rodents fed purified diets, which is usually shorter than those fed GB diets (Fullerton et al., 1992). Therefore, an increase in total fiber level and addition of soluble fiber are warranted in purified diets for normal growth and health maintenance of rodents (Fig. 40.3).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The use of animals in research has provided us with an important means to understand more about our biology in general and the many toxicological factors in our environment that can affect our health. When designing any study using rodent models, diet needs to be considered, and one should ask three questions before making a decision: Can I report the diet? Can I repeat the diet? Can I revise the diet? Purified diets allow for each of these questions to be answered as "yes" and such diets are required in toxicological studies to minimize background contaminants.

INTRODUCTION AND BACKGROUND

The use of engineered nanomaterials (ENM) and their applications has grown dramatically since the turn of the 21st century because of multiple technological benefits of the use of material at nanoscale. More than 1600 "nanoenabled" products in commerce, all required workers for that to happen (http://www.nanotechproject.org/cpi/), and, according to recent estimates, 6 million workers will be potentially exposed to ENM in 2020 (Roco, 2011).

Nanotechnologies is in fact an umbrella name for a great number of technologies that utilize material at nanoscale for different purposes. For these reasons, nanotechnologies have been recognized as highly cross-cutting technologies, whose products, based on the use of nanomaterials, utilize physical and chemical properties of ENM, different from their chemically identical bulk counterparts (Savolainen et al., 2010).

However, during the production and use of ENM, there is the chance of exposure of workers, consumers, and the environment (Savolainen et al., 2010; Kuhlbusch et al., 2011; Valsami-Jones and Lynch, 2015). The effects of such exposure cannot be predicted based on our current understanding of chemicals, given the fact that material at nanoscale has both a particulate identity and a molecular identity, which are responsible for the potential biological effects. A recent review has summarized work conducted in relation to exposure to ENMs in the workplace and processes that may lead to such exposure (Kuhlbusch et al., 2011). For example, it could be shown that exposure to TiO_2 nanomaterials may arise during cleaning and maintenance operations as well as in the case of a failure of normal operation (Plitzko, 2009), to TiO_2 and silver during the reactor and vacuum pump operations (Lee et al., 2011), to carbon nanotubes (CNTs) during spraying, preparation, ultrasonic dispersion, wafer heating, and opening the water bath cover (Lee et al., 2010), or to precious metal nanoparticles (NPs) in a furnace room and in an electro-refining area (Miller et al., 2010).

Although it has been argued that size as such does not cause harmful effects (European Commission, 2011), a number of studies have convincingly shown that ENMs cause toxic effects not induced by chemically identical but larger particles (Rossi et al., 2010; Palomäki et al., 2011; Catalán et al., 2012). These effects are likely due to exposure to the unique features of ENM, either to their intrinsic properties or to their small entity that allows them to reach targets not reachable by their larger, chemically identical counterparts (Kreyling et al., 2009). An important issue in this context may also be the biocorona formed to surround NPs, and larger particles, once they reach biological environments (Monopoli et al., 2012).

Another major challenge in the assessment of hazards of ENM to experimental animals, humans, and environmental species is, that being in a particulate form, the behavior of ENM differ dramatically from that of traditional soluble chemicals having an impact, not only on the kinetics of ENM in biological environments but also on their potentially harmful effects (Pietroiusti et al., 2018).

The properties of nanomaterials cause marked challenges to the assessment of hazards of ENM via the lungs, but also via other exposure routes. However, in the lungs, when the NPs most readily reach the body, they become

covered by biomolecules (Monopoli et al., 2012) rendering their kinetic behavior and effects more difficult to assess. The special features of the airways add to the complexity to the hazard assessment of ENM via the inhalational route. In general terms, assessing effects of ENM is demanding because the associations of harmful effects of ENM features (physicochemical and biological) are not well understood.

To this end, novel approaches for the prediction of material at nanoscale need to be developed (Kinaret et al., 2017a,b). There are currently a number of ongoing attempts to develop such hazard prediction tools and frameworks [www.nanosolutionsfp7.com/; www.guidenano.eu/; www.nanomile:eu-vri.eu/; www.sun-fp7.eu/]. Some of the known effects of ENM include those of titanium dioxide (National Institute of Occupational Safety and Health—NIOSH, 2011) and of metal oxides and metals (Saber et al., 2013), and carbon-containing materials induced pulmonary inflammation (Ryman-Rasmussen et al., 2009a; Palomäki et al., 2011; Mercer et al., 2013; Kinaret et al., 2017b). These effects include, among others, inflammation, granuloma formation, and fibrosis of the lungs (Rossi et al., 2010; Ryman-Rasmussen et al., 2009b; Saber et al., 2013). It has also been shown that both tangled and rigid rod-like CNTs (Mitsui-7) can reach the lung and subsequently the subpleural space and cause collagen deposition. Subpleural space is also the site of pulmonary mesothelioma initiation (Ryman-Rasmussen et al., 2009b; Mercer et al., 2013). However, only rigid, rod-like CNTs have been shown to induce mesothelioma in rodents (Takagi et al., 2012; Sargent et al., 2014). In addition, several fibrous and crystalline ENM have been shown to induce genotoxic effects in vivo and in vitro (Catalán et al., 2012; Kinaret et al., 2017a).

In the light of reports on the production of pleural effusion and pulmonary fibrosis following exposure to nanomaterials (Ryman-Rasmussen et al., 2009a,b), and also the carcinogenicity of CNTs (Chernova et al., 2017), search for biomarkers as tools to protect workers has been emphasized (Schulte and Hauser, 2012; Bergamaschi, 2012; Iavicoli et al., 2014; Bergamaschi et al., 2017). Being able to develop biomarkers of exposure to ENM would greatly increase the certainty of assessment of potential risks of exposure to ENM. In fact, it is quite obvious that the (ENM) biomarkers will become available when detailed molecular mechanisms of ENM-induced diseases can be better characterized. Until then, bridging data between in vitro and in vivo reactions are required. The understanding of possible diseases of particles is currently based on biokinetics (absorption, distribution, metabolism, excretion: ADME) viewed, with regard to the various ENM considering both their physicochemical characteristics and their interactions with biomolecules, and even considering particulate matter (PM) toxicity,

such as asbestos. At the current state, these two areas are serving as starting points for knowledge and understanding within the new fields of molecular biology. Several topics have to be considered in the development of biomarkers of exposure for ENM, including foreign body recognition systems and/or immune systems, especially of innate nature. These studies are applicable to acute and chronic in vivo responses including virtually permanent deposition of PMs to the reticuloendothelial system (RES). In any case, for sound growth of the nano-material industry and protection of workers and users, promotion of new studies and usage of available data in a reasonable balance is practical and essential.

The development of novel biomarkers for ENM is also hampered by the lack of a systematic database on ENM toxicity, even though there is a plethora of detailed information on specific toxicity of several ENM. This renders ENM risk and safety assessment a challenge, especially because information on exposure to ENM in occupational setting or other environments is lacking for most of the materials (Kuhlbusch et al., 2011; Valsami-Jones and Lynch, 2015; Pietroiusti et al., 2018). This situation is reflected by the fact that there are no occupational exposure limits implemented for any of the ENM anywhere (Van Broekhuizen and Reijnders, 2011, Van Broekhuizen et al., 2012). It is not surprising that there are concerns regarding the safety of ENM in work places, consumer products, and the environment.

Epidemiological studies were crucial in identifying a correlation between exposure to different sizes of particles and fibers in causing a disease (Donaldson and Seaton, 2012). The search for biomarkers of exposure to, and effects of particles could only become possible once the elucidation of the molecular mechanisms involved in particle-induced diseases, including fibrosis, lung cancer, and mesothelioma (Mossmann, 2000; Grosse et al., 2014) had been established. Such correlations were identified later between ambient PM_{10} and ultrafine particles (UFP) and cardiovascular diseases (Dockery et al., 1993) or pulmonary function (Pope and Kanner, 1993). The relevance of oxidative and inflammatory markers due to exposure to particles and fibers and especially nanomaterials has been recently reviewed by Bergamaschi et al. (2017). In addition, in some cases, ions released from the NPs such as silver, gold, and iron can be measured in urine and in blood (Iavicoli et al., 2014).

From the outset, attempts have been directed to develop biomarkers of exposure to nanomaterials based on their ability to induce oxidative stress and inflammation (Gulumian et al., 2006; Johnston et al., 2013; Manke et al., 2013). Biomarkers of oxidative stress and inflammation have been shown to have an association with the biopersistence of particles and fibers (Searl et al., 1999) resulting in frustrated phagocytosis and oxidative cellular stress, especially in the lungs. The challenge

that has remained in the development of biomarkers of exposure to nanomaterials and other particulates has been the lack of specificity toward ENM. Hence, so far these biomarkers seem to work at a group level in a given epidemiological study, but they seem not to be suitable for the assessment of exposure of a given worker to ENM because so many exposures to different kind of PM, including fungi, bacteria, wood dust, and man-made mineral fibers among others induce a similar response (e.g., Savolainen et al., 2010; Bergamaschi et al., 2017).

The search for appropriate biomarkers for exposure to NPs will be of great relevance to the need for such exposures to be detected early enough in the process of toxicity and also pathogenicity. Successful identification of such biomarkers will prevent the recurrence of the experience with larger particles where exposures continued unabated for very long periods until pathological changes were observed, producing diseases such as fibrosis and cancer. In addition, earlier lessons of the benefits of biomarkers for oxidative stress and inflammation might help also in the search for biomarkers for ENM. It is, though, of importance to remember the lack of specificity of such biomarkers, and for that reason also search for biomarkers with a better specificity would be of value (Palomäki et al., 2011; Kinaret et al., 2017a,b).

CLASSIFICATION AND CHARACTERISTICS OF NANOMATERIALS

According to the definition given in the technical report of the International Standards Organization (ISO) (ISO/TR 14786, 2014), nanomaterials may include nanosized objects with one or more external dimension in the nanoscale. Nanomaterials may therefore be distinguished by their shape as either NPs (all three dimensions in the nanoscale), nanofibers (two dimensions in the nanoscale, including nanowires, nanotubes, and nanorods), or nanoplates (one dimension in the nanoscale).

Because of the multiplicity in chemical composition, shape, and size of NPs, as well as multiplicity in the effects they produce in in vitro cell cultures and in vivo—in pulmonary, cardiac, reproductive, renal, and cutaneous systems (Kumar et al., 2012)—it will therefore be useful to classify NPs into general groups: carbon-based, inorganic metal, or metal oxides as well as organic NPs, with the hope that biomarkers that might be specific to a certain group but not to other groups of NPs may emerge .

The classification of nanomaterials may be made as carbon-based NPs that include fullerenes, carbon nanofibers, graphene, and carbon black (CB); inorganic metal-based NPs that include gold and silver NPs; and metal oxide NPs that include among others titanium dioxide,

zinc oxide, and cerium oxide; quantum dots (QDs); and finally organic NPs that include organic polymers.

Carbon-Based Nanoparticles: Fullerenes

Fullerenes are carbon-based allotropes in a hexagonal network of carbon atoms, which may be in the form of a hollow sphere, ellipsoid, tube, or plane. When in spherical cages, they may contain between 28 to more than 100 carbon atoms, the most widely studied of which are those containing 60 carbon atoms (C60), first synthesized by Kroto et al. (1985). When in layers, they are called graphenes, and when in hollow cylinders they are called CNTs, which may be single layer (SWCNT), double layer (DWCNT), or multiple layers (MWCNT). Finally, CB, composed of partially amorphous graphitic material, is mostly spherical in shape (Aitken et al., 2004).

Inorganic Nanoparticles

Inorganic NPs are particles in nanometric dimensions composed of pure metals or metal oxide, or are of metallic composition. The most common examples include gold, silver, aluminum, titanium, silica, tungsten, manganese, copper, cerium, iron, molybdenum, and palladium NPs. They are also synthesized in various geometries, examples being spherical, nanoshells, nanorods, tripods, tetrapods, nanocages, and star-shaped nanorice-shaped gold NPs (Chen et al., 2003; Chen et al., 2005; Nehl et al., 2006; Wang et al., 2006; Murphy et al., 2008).

Generally, QDs are fabricated from groups II—VI or groups III—V elements of the periodic table (Aitken et al., 2004). Examples include indium phosphate (InP), indium arsenate (InAs), gallium arsenate (GaAs), gallium nitride (GaN), zinc sulfide (ZnS), zinc—selenium (ZnSe), cadmium—selenium (CdSe), and cadmium—tellurium (CdTe) metalloid cores (Hines and Guyot-Sionnest, 1996; Dabbousi et al., 1997). Newer, heavier structures (e.g., CdTe/CdSe, CdSe/ZnTe) and hybrids composed of lead—selenium (PbSe) have also been synthesized (Kim et al., 2003).

Organic Nanoparticles

The highly branched and symmetrical molecules known as dendrimers are the most recently recognized members of the polymer family. Their unique branched topologies give dendrimers properties that differ substantially from those of linear polymers. Dendrimers were first synthesized by Vögtle in 1978 (Buhleier et al., 1978). They are three-dimensional globular, monodisperse, highly branched polymers prepared in a series of repetitive reactions from simple branched monomer units emitted from a central core with an exterior corrugated surfacing whose size and shape can be precisely

controlled. Dendrimers are fabricated from monomers using either convergent or divergent step-growth polymerization. Dendrimers' unique architecture enhances their ability to exhibit high functional structures (Zeng and Zimmerman, 1997; Pricl et al., 2003; Lee et al., 2005; Namazi and Adeli, 2005). Subsequently, a wide range of dendrimers of different structural classes are synthesized using divergent (built from the central core to the periphery) or convergent (built from the periphery toward the central core) strategies—using repeat units ranging from pure hydrocarbons to peptides, or coordination compounds.

Attempts to classify nanomaterials in their risk assessment for regulatory purposes have included those that are based on a set of performance metrics that measure both the toxicity and physicochemical characteristics of the original materials, as well as the expected environmental impacts through the product life cycle (Tervonen et al., 2008) or more recently based on features that control nanomaterial biological interactions (Castagnola et al., 2017) or on their structure–activity relationship (Gajewicz et al., 2018).

Toxicity Testing of Nanomaterials

The introduction of a radical overhaul for testing synthetic chemicals in animal models for their adverse effects on humans and the environment has recently been advocated. As such, design of integrated testing strategies has been proposed, using modern methods including cell culture techniques with the implementation of a combination of biochemical knowledge of cellular pathways with genomics, proteomics, and metabonomics (Hartung, 2009).

Although these in vitro techniques may be useful in the initial identification of the toxicity of NPs and in the elucidation of the mechanisms involved in their toxicity, long-term animal studies comparing the toxicity and carcinogenicity of certain types of NPs have been strongly advocated (Shi et al., 2013). The necessity for conducting such long-term studies has emanated from the fact that mineral particles and fibers in general and certain NPs in particular are shown to be biopersistent (Oberdörster, 2010).

In addition, these short-term biological tests are shown to produce false positives in the case of non-biopersistent fibers because although they may have effects in vitro, they do not persist long enough in the lungs for a sufficient dose to build up and produce effects in vivo (Donaldson and Tran, 2004). This possibility was confirmed with biopersistent and non-biopersistent nanofibers, where it was found that the biopersistence was influenced by both fiber dimensions and solubility (Searl et al., 1999). Moreover, concerns were raised as to the ability of short-term in vitro assays to accurately predict the in vivo effects of the functionalized products of inhaled CNTs (Zhang et al., 2013). However, once the functionalized side chains are removed and the biopersistent core structure is presented naked to the organism, both ex-A and ex-N NPs become identical (Sayes et al., 2007; Warheit et al., 2009).

DEFINITION AND MEANING OF BIOLOGICAL MONITORING AND ITS APPLICATION TO ENGINEERED NANOMATERIALS

Biological monitoring (BM) deals with the systematic or repetitive measurement of chemical or biochemical markers in fluids, tissues, or other accessible matrices from people exposed to or with past exposure to xenobiotics. BM can be used with the purpose of identifying potential hazards of new and emerging chemicals—potentially including ENMs—thus identifying groups at higher risk of health outcomes (Schulte and Hauser, 2012). The main objectives of such periodical measurements are (1) the assessment of individual or group exposure; (2) the identification of early, specific, nonadverse biological effect parameters that are indicative, if compared with adequate reference values, of an actual or potential condition leading to health damage; and, ultimately (3) the assessment of health risk to exposed subjects (Manno et al., 2010). Biomarkers are recommended for use in assessing the effects or exposure to harmful substances, specifically where there are low or intermittent levels of exposure, mixtures of toxicants that may act synergistically, or exposure resulting in disease with long latency period. Biomarkers are increasingly used as surrogate indicators of designated events in a biological system due to the inaccessibility of target organs; in spite of this limitation, it is thought that biomarkers are more directly related to the adverse effects that one attempts to prevent than any ambient measurement, and this supports the use of BM in risk assessment (Smolders et al., 2010). On the other hand, BM is more complex in terms of standardization and interpretative efforts as compared to ambient monitoring; the use of biomarkers requires a toxicological knowledge for their interpretation and ethical issues should be addressed as generally required in human studies.

Assessing even subtle health effects resulting from exposure to ENM is challenging for several reasons, including the heterogeneity of nano-objects in real life, and the lack of available tests with a known sensitivity and specificity to detect physiological and biological modifications clearly related to particle exposure.

Hazard studies have identified the most significant biological responses and target organ/systems affected by different ENM (Pappi et al., 2008; Aschberger et al.,

2010; Savolainen et al., 2010). Unfortunately, research over the past few years has not been conducted with the aim of identifying threshold exposures. The effects of ENM on human health are—to a large extent—unknown, and currently there is no report of any definitive human disease that is caused or worsened by ENM exposure. The current body of information on the human health effects potentially related to ENM comes from the studies on incidental NPs, air pollution epidemiology, and studies on occupational exposures with similarities to NPs such as welding fumes, ultrafine CB, or diesel exhausts (Madl and Pinkerton, 2009). Epidemiological studies have found hazardous respiratory effects from occupational exposure to some industrial processes involving generation of significant amounts of UFP, such as CB (Wellmann et al., 2006), fumed silica (Merget et al., 2002), metal oxides (Antonini, 2003; Luo et al., 2009), and fibers of concern.

The main effects attributed to ENM are (1) lung inflammation and fibrosis; (2) genotoxicity and DNA oxidative changes; (3) carcinogenic or procarcinogenic effects; and (4) vascular impairment resulting from endothelial activation, prothrombotic effects, and accelerated atherosclerosis. Although the respiratory and cardiovascular systems represent the main or the most studied targets of ENM, recent researches suggest that other organs can be indirectly affected by ENM exposure. Lung effects largely depend on the physicochemical characteristics and surface properties of instilled/inhaled particles. While the surface properties of insoluble particles are the main determinants of their interaction with biological systems, those ENM that rapidly dissolve into toxic ions lead readily to inflammation (Donaldson et al., 2013). Some ENM, such as titanium dioxide (TiO_2), copper oxide (CuO), ZnO and iron oxide NPs, cationic polystyrene, and C60 fullerene, have demonstrated prooxidative and proinflammatory properties both in vitro and in vivo, mainly related to their surface reactivity and chemical composition (Madl and Pinkerton, 2009), although not all NPs cause inflammation via a mechanism involving oxidative stress. The tissue response to CNTs following instillation or inhalation is characterized by transient inflammatory changes, oxidative stress, fibrosis (Shvedova et al., 2008), and cancer (Chernova et al., 2017).

Through a process of translocation across biological barriers, NPs can reach and deposit in secondary target organs where they may induce adverse biological reactions. Therefore, a correct assessment of NP-induced adverse effects should take into account the different aspects of toxicokinetics and tissues that may be targeted by NPs.

Cardiovascular effects have been assessed in workers handling TiO_2 nanomaterials, thus suggesting that exposure to particles with a diameter <300 nm might affect parasympathetic function leading to higher heart rate variability in workers (Ichihara et al., 2016). Acute exposure to TiO_2 NPs acutely alters cardiac excitability and increases the likelihood of arrhythmic events (Savi et al., 2014) and also induces myocarditis in mice (Hong et al., 2015).

Recent experimental findings, considering the role of new players in gut physiology (e.g., the microbiota), shed light on several outcomes of the interaction between ENM and gastrointestinal tract, fostering for long-term unpredictable consequences (Pietroiusti et al., 2017). Ruiz et al. (2017) have demonstrated that TiO_2 NPs exacerbate experimentally induced colitis and that TiO_2 in blood is significantly higher in human beings suffering from inflammatory bowel diseases during the acute phase of the disease. Few in vivo studies demonstrated that NPs may affect kidney function, leading to both tubular and glomerular changes (Iavicoli et al., 2016). The issue of potential effects of manufactured NPs on brain functions, given that NP's potential to induce oxidative stress, inflammation, cell death by apoptosis, or changes in the level of expression of certain neurotransmitters, has been recently reviewed (Bencsik et al., 2018).

Studies on the relationship between particulate pollutants (including elemental carbon) and health effects have generated a panel of circulating biomarkers reflecting inflammation end points, endothelial activation, platelet activation, oxidative damage to DNA and lipids, and antioxidant capacity (Loft et al., 2008; Møller and Loft, 2010).

Challenges of the Development of Biomarkers of Exposure to Engineered Nanomaterials Due to Their Biokinetics

Considering the behavior of ENM in a biological system, i.e., in a cell or an organ, as shown in Fig. 41.1, there are three issues of special interest: primary NPs, secondary aggregated NPs, and NPs firmly attached to the cellular matrix.

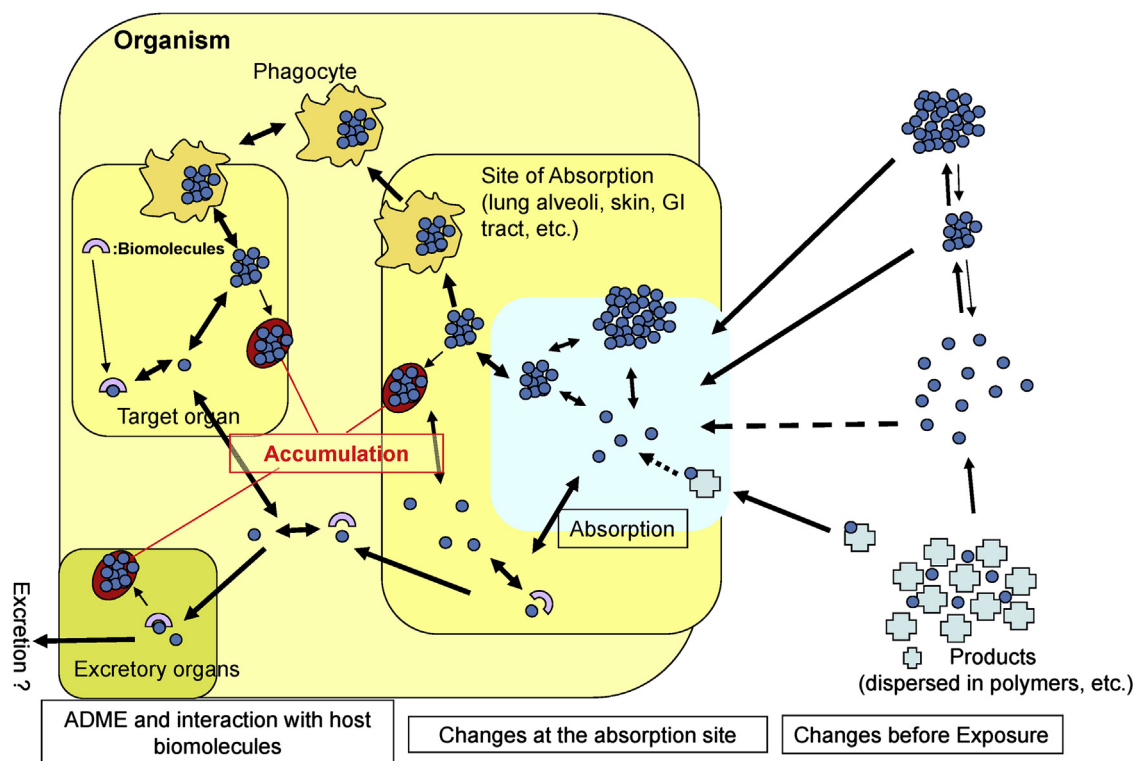
The first stage occurs before the exposure, the second at the site of absorption, and the third at the level of distribution, metabolism, and excretion and deposition at the potential final destiny of the particle, if any. At the third stage, the active dispersion mechanisms and attachment of the NP through bonding by the host with other insoluble foreign particles determine the final fate of the ENM. For the functionalized NPs, initial toxicity may depend largely on the functionalized side chain moieties that interact first with the organism's biomolecules. However, as shown in Fig. 41.2, metabolic activity of the host organism may eventually succeed in removing the side chains, leaving the biopersistent core structure, such as C_{60} for fullerene-based functionalized products.


FIGURE 41.1   A pictorial representation of absorption, distribution, metabolism, excretion, and deposition of engineered nanomaterials in cells and tissues.

The diversity and complexity of an ever-increasing number of NM with varying physicochemical properties, and the complex and changeable nature of nano-biointeractions, make the biological behavior of NM not predictable on the basis of their inherent properties. Recent findings indicate that the physicochemical properties and the integrity of NPs can change dramatically following internalization by cells in vitro and in vivo, even for NPs with high colloidal stability such as polymer-coated gold NPs (Kreyling et al., 2015).
FIGURE 41.2   Symbolic scheme of metabolism of functionalized nanoparticles. When the side chain is different, then the molecules A and B are chemically and toxicologically different. However, once the functionalized side chains are removed and the biopersistent core structure is presented naked to the organism, both ex-A and ex-B nanoparticles become identical.

While the material-intrinsic properties determine the "synthetic identity," the context-dependent properties of the nanomaterial influence its "biological identity"—which is shaped, in part, by the adsorption of biomolecules that form a "corona" on the surface of NPs; the composition of this "bio-corona" depends on the particular biofluid and may exhibit dynamic changes as the NP crosses from one biological compartment to another (Monopoli et al., 2012; Fadeel et al., 2013). Moreover, particles of similar size and composition can raise qualitatively different effects in relation to their methods of synthesis, as for amorphous silica NPs (DiCristo et al., 2015).

Besides intrinsic characteristics of particles, the presence of contaminants can cause significant changes in their chemical identity, leading to increase in biological activity. This issue is clearly described by synergistic effect of NP and endotoxins on cytokine production and immune cells activation (Bianchi et al., 2015; Li and Boraschi, 2016). Such changes in surface characteristics and chemical identity have important implications for biomarker research because experimental setting may not be truly representative of particle–cell interactions in a real-life scenario. As a result, our current testing strategy is actualized by using simplified models, different dosing regimens, and exposure routes and so represents a compromise to understand what could happen in humans, which requires more caution in the interpretation of findings with consideration of the weight of evidence (Bergamaschi et al., 2015).

BIOLOGICAL INTERACTIONS RELEVANT TO BIOMARKERS OF EXPOSURE TO ENGINEERED NANOMATERIALS AT MOLECULAR, CELLULAR, AND ORGAN LEVEL

Biological interfaces of ENM are numerous and complex, existing both on the cell surface and inside the cell. When compared between primary (nonaggregated) and secondary (aggregated) NPs of the same origin, the target biomolecules may be different. In particular, the host defense mechanisms against the insoluble, i.e., biopersistent, NPs may be similar to those used by the cells against bacterial and viral infections. The most important differences between normal chemical toxicity and ENM toxicity are the activation of the innate immune system against foreign bodies, the subsequent influence on the acquired immune system, and the so-called indirect oxidative stress responses, which eventually lead to cell death (apoptosis and necrosis), cell proliferation and tissue modification (e.g., fibrosis), and indirect genotoxicity and carcinogenesis.

Studies on asbestos-induced noncancerous and cancerous diseases have revealed several key events at the molecular level in the cells. As for the morphological events, fiber carcinogenesis has mesothelial cells and phagocytic cells of the immune system as targets. The former target is subject to direct damage by the exposure, resulting in clastogenicity and indirect attack by phagocytes nearby. The indirect danger signal from the phagocytes protects damaged mesothelial cells from apoptosis, thus increasing the chances of the attacked cells to proceed to neoplastic forms. (Nagai and Toyokuni, 2010). The importance of the length and the aspect ratio (length/thickness) of the fiber in the frustrated phagocytosis has been thoroughly reported (Stanton et al., 1981; Pott et al., 1994: Roller et al., 1997). It is likely that the chronic active inflammatory lesions are more important than fibrous scar formation (Poland et al., 2008; Donaldson et al., 2010; Takagi et al., 2012). Condensation of secondary elements to the fibers, such as iron in the body for the Fenton reaction, is postulated as a direct mechanism or as an augmenting factor of fiber mesotheliomagenesis (Nagai et al., 2011).

Another classical example of particle-induced carcinogenesis is thorotrast (Mori et al., 1983). The size of thorium dioxide primary particles in emulsion, used as an X-ray contrast medium, is approximately 10 nm in diameter (Riedel et al., 1983). Primary particles are concentrated initially in the first line of macrophages to form larger clusters and when these macrophages die off by either alpha ray effect or by foreign body-based oxidative stress, the cluster is released to the intercellular space, and phagocytosed again by the second line of macrophage, resulting in the formation of larger clusters (Nishizawa et al., 1987). As a whole, the biological half-life time has been reported as over 400 years in some reports (Janower et al., 1968). It has been proposed that the carcinogenic effect is linearly proportional to radioactivity of the emulsion, indicating that the permanent retention of the particle in the RES is not responsible for the effect (Wesch et al., 1983). However, this event clearly shows that biopersistent ENM administered into the bloodstream or into a place where the particle eventually enters the bloodstream will be gradually concentrated into larger clusters and permanently trapped by the RES.

The recognition of foreign NM has been studied at the molecular level. The mechanisms of foreign body recognition share the same signal pathways and reactions to the recognition of bacteria and viruses, i.e., the innate immune system. NALP3/NLRP3 inflammasome was reported as a mediator of the sensing mechanism of foreign ENM via lysosomal damage and endogenous "danger" signals (Dostert et al., 2008; Palomäki et al., 2011). It seems important to identify both the direct oxidative stress by immediate responses to the ENM

and the indirect IFN signaling-mediated oxidative stress for the understanding of ENM generated cell injury and cell growth that may eventually lead to tissue/organ damage and carcinogenesis (Mullan et al., 2005; Chakrabarti et al., 2011).

The precipitating types of adjuvant, such as aluminum salts, are reported to induce cell migration to the site of coadministered antigen and induce cell killing so that the mesh of DNA from the dead cell activates the immune activity via distinct signaling pathways (Marichal et al., 2011). Diesel exhaust and pollen allergy enhancement might be considered as a similar phenomenon to the ENM attribution to the immune system—more toward adverse immune reactions, such as allergy, persistent immune activation triggering autoimmune diseases, and immune suppression (anergy) (Siegel et al., 2004; Marichal et al., 2011). The finding that the double-stranded DNA from the host tissue may take part in enhancing immunization of an externally applied antigen may add some consideration to the lifelong deposition of biopersistent ENM and the induction of production of biomolecules that could serve as bioindicators of exposure to ENM.

Protein scaffolding and nanomaterials is another aspect of biological interaction. An example is the acceleration of bone-implant connection as a result of accelerated bone formation by CNTs used at the interface of the implant and grafted tissue (Saito et al., 2008; Usui et al., 2008). The authors claim that there is minimal inflammatory reaction at the interface. These findings address the issue of whether primary particles deposited in the mesenchymal connective tissue would stimulate noninflammatory reaction, such as direct stimulation of fibroblast or mesenchymal stem cells to produce progressive pathology such as fibrosis, angiogenesis, noninflammatory granulation tissue formation, or bone formation. The systemic distribution of single fibers we found after MWCNT intraperitoneal injection poses an unanswered question whether tissue reaction would eventually take place in those deposition sites.

Examples of Given Biomarkers

Mesothelin is reported to increase in the serum of human patients with mesothelioma (Imashimizu et al., 2011) and in a rat study where multiwall CNTs were given via intraperitoneal exposure (Sakamoto et al., 2010). MIP1alpha is also reported to be secreted by macrophages treated with titanium dioxide (Xu et al., 2010). There are many other putative markers reported in relation to toxicity of NPs, such as CD146 and IMP3 (insulin-like growth factor 2 mRNA-binding protein 3) (Okazaki et al., 2013). Many of them are waiting for further validation.

Histological biomarkers for MWCNT of asbestos size against mesotheliomagenesis include our finding that the chronic inflammatory lesion consisting of MWCNT-laden activated macrophages without acute inflammatory cell infiltration, granuloma formation, and fibrotic scar formation (Fig. 41.3), considered as a phenotype of frustrated phagocytosis, is important for mesotheliomagenesis (Takagi et al., 2012). This phenotype is considered to be supported by a study on SWCNT (Mangum et al., 2006). This finding may be in good correlation with the acute phase biomarkers posted by several research studies (Poland et al., 2008; Murray et al., 2012). For a morphological picture demonstrating the impact of MWCNT on the mesothelial lining in the peritoneal cavity in sensitive mice strain refer Fig. 41.4 (Takagi et al., 2012).

Biomarkers of Exposure

Once inhaled, NPs can deposit in lung cells including alveolar macrophages and translocate through or between epithelial and endothelial cells into the blood and lymph circulation, potentially reaching sensitive target sites including bone marrow, lymph nodes, spleen, heart, and central nervous system. Translocation to many organs by ENM has been demonstrated and quantified (Geiser and Kreyling, 2010; Holgate, 2010), but its clinical relevance is not known. The likelihood of being taken up can vary dramatically among exposure conditions and by the behavior of particle aerosols in which nano-objects are commonly present and taken up as agglomerates and/or aggregates of various aerodynamic diameter. The internal dose of common chemicals is usually assessed by measuring both the amount of the substance and/or its metabolites or as a product of interaction with biomolecules. An ideal biomarker of exposure should be specific for the exposure of interest and also detectable in small quantities, measurable by noninvasive techniques, and capable of providing a positive predictive value to a specific health status (Mutti, 2001). Toxicokinetic and toxicodynamic data, which are available for a few ENM (e.g., metal NPs, fullerenes, and single-walled CNT) suggest that translocation rates from the portal-of-entry to secondary organs are very low (Kreyling et al., 2002; Choi et al., 2010; Geiser and Kreyling, 2010). So far, few studies have provided quantitative demonstration of ENM translocation from the lung. Recent research undertook biokinetic analysis in rats, using near-infrared imaging, to follow the fate of intratracheally instilled NPs of various size, surface modification, and core composition. Choi et al. (2010) found that noncationic NPs smaller than 34 nm in diameter, which did not bind serum proteins, reached the regional lymph nodes quickly. However, larger NPs are consistently retained in the lungs. When the ENM
FIGURE 41.3 (A) A nanoparticle short or small enough to be phagocytosed by a single macrophage is easily removed from the initial exposure site, and either ends up trapped in the reticuloendothelial system or distributed systemically via bloodstream to renal glomeruli, choroid plexus, and other organs. (B) A relatively long fiber (cf. Stanton et al., 1981) such as asbestos, multiwall carbon nanotubes, and some single wall nanotubes are phagocytosed by more than one macrophage, resulting in the release of various cytokines and other inflammatory mediators without the formation of granulomas or scars. This state is reported to last for a considerably long period, resulting in mesotheliomagenesis in cases of the peritoneal/pleural cavity, and local fibrosis in pulmonary alveoli. (C) Certain types of nanomaterials, either primary or secondary particles, that are small enough to be phagocytized by a macrophage can induce frustrated phagocytosis from a certain level of overload to the macrophage. It is not well known what kind of condition leads to subsequent formation of foreign body granuloma. Lack of formation of such granuloma can be seen for a long period in some condition. In case of MWCNT, it is experienced that the fibers recovered from the pleural cavity are almost always the straight ones without branching. (D) Large aggregate and agglomerate are entrapped by a group of macrophages and result in formation of foreign body granuloma and eventually fibrous scarring. This reaction effectively segregates the foreign body from the inflammatory system and thus does not seem to contribute to mesotheliomagenesis and further expansion of diffuse fibrosis. These different types of engineered nanomaterials have a different potential for penetrating barriers and hence reaching different organs. They also have different ability to induce the synthesis of biomolecules that could serve as a biomarker of exposure to ENM.

diameter falls below 6 nm, and the particles are zwitterionic, about half of the NPs rapidly enter the bloodstream from alveolar airspace and are mostly cleared from the body by means of renal filtration. Thus, while the size seems of minor importance for the toxicity, it dramatically affects particle translocation and biokinetics.

Although some ENM have been demonstrated to easily cross biological barriers, the number of ENM entering the systemic circulation could be too low to lead to any significant internal dose, and hence not be detected in peripheral tissues in humans. There is a general consensus on the likelihood that particles whose aerodynamic diameter is between 0.1 and 1.0 μm reach the lower respiratory tract, but their deposition is low compared with particles with lower and higher aerodynamic diameter because of symmetric human lung

morphology (Broday and Agnon, 2007). The daily dose of inhaled NP in humans is limited to a maximal NP aerosol concentration of $10^{12}/m^3$ (beyond that, coagulation rapidly occurs under ambient conditions), and the daily volume of air inhaled by an adult is $15\,m^3$. Assuming a particle deposition of 0.3, the daily deposition amounts to about 5×10^{12} NPs (Oberdörster, 2010). As a result, it may take years to reach an appreciable internal dose, whereas the biologically effective dose (i.e., the entity within any dose of particles in tissue that drives a critical pathophysiologically relevant form of toxicity, e.g., oxidative stress, inflammation, genotoxicity, or proliferation) may be achieved independently from the mass of inhaled particles (Donaldson et al., 2010).

Low-soluble ENM (e.g., CNT or TiO_2)—even though they can partially break down in contact with
FIGURE 41.4 Atypical mesothelial hyperplasia of the tendinous portion of diaphragm of a mouse with 3 μg of MWCNT injected intraperitoneally (sampled at terminal sacrifice, i.e., 365 days after i.p. inoculation of the MWCNT (Takagi et al., 2012). (*Black arrows*: hobnail appearance of the atypically hyperplastic mesothelial cells. *Asterisk*: lymphatic drainage of the peritoneal cavity.) The polarized image is of the *dotted area*). (*White arrow*: an MWCNT fiber in a macrophage-like cell [birefringent]). *Cancer Science. Reproduced with permission.*

phagocytic cells—show a slow clearance leading to accumulation over time with exposure. For many particles, size and agglomeration state are influential in dictating toxicity; thus, particle dissolution and the release of ions—which would be expected to be greater for smaller particles—may affect organ distribution. Cho et al. (2013) studied the absorption, distribution, and excretion patterns of TiO_2 and ZnO NPs following oral administration. Zinc concentrations in blood, organs, and urine were higher than concentrations of titanium when NPs were administered orally for 13 weeks. The urine concentration of Ti in the TiO_2-treatment groups showed no significant differences compared with the control group; in contrast, the concentration of Zn in the urine of ZnO-treatment groups was significantly increased in the middle- and high-dose groups and showed positive trend dose-responses. In vivo, NPs are mostly retained in the liver, and fragments of the organic shell are excreted through the kidneys, probably due to proteolytic digestion (Kreyling et al., 2015).

Following liver accumulation, metal NPs show a protracted elimination and slow release of particles from the target organ into systemic circulation (Johnston et al., 2010), giving rise to detectable trace amounts in body fluids. Demonstration of translocation of ENM from lung into systemic circulation is theoretically possible for metallic NPs, which release metal ions or dissolve in biological media. Similar to metal species in welding fumes, metallic elements are measurable in blood and urine with appropriate analytical methods, giving an estimate of current or past exposure. For instance, Lee et al. (2012) measured silver concentration in blood and urine in Korean workers exposed to silver NPs, whereas in the study of Lee et al. (2015) molybdenum blood concentration was measured as a candidate biomarker for MWCNT exposure.

To estimate the dose retained at the portal of entry, it can be informative to assess the tissue dose reaching the target organ, e.g., the lung. Sampling of exhaled breath condensate (EBC) provides a matrix for the simultaneous monitoring of exposure and effects on target organ. As EBC mainly consists of water that is practically free of potentially interfering solutes, it is an ideal biological fluid for elemental determinations based on electrothermal atomic absorption spectroscopy or inductively coupled plasma-mass spectrometry. This novel approach has represented a significant advancement over the analysis of alternative media (blood, serum, urine, hair), which are not as reliable (owing to interfering substances in the complex matrix) and reflect systemic rather than lung (target tissue) levels, e.g., of pneumotoxic metallic elements (Goldoni et al., 2004). Particles of rutile and/or anatase were found in the EBC of exposed workers in 70% of the postshift samples, the mean concentration of titanium in production workers being $24.1 \pm 1.8\,\mu g/L$, whereas in the research workers the values were below the limit of quantitation, e.g., $4.0 \pm 0.2\,\mu g/L$. Thus, the concentration of titanium originating from TiO_2 in EBC might serve as a direct exposure marker in workers producing TiO_2 pigment; however, the stability of its concentrations in EBC not being influenced by current exposure support the use as a biomarkers of deposited dose following long-term exposure (Pelclova et al., 2015a).

Biomarkers of Effect

A biomarker of effect is defined as any measurable biochemical, physiological, or other alteration within an organism that, depending on magnitude, can be recognized as an established or potential health impairment or disease (Henderson et al., 1989). Biomarkers should not be considered as diagnostic tests, but rather as indicators reflecting early modifications preceding progressive structural or functional damage at the molecular, cellular, and tissue level, i.e., changes possibly leading to adverse effects but completely reversible on the removal from the exposure of concern. Biomarkers of effect can be used to evaluate whether a well-characterized exposure is associated with a shift in the distribution of relevant biochemical or functional end points, indicative of early changes in the target or critical organs/tissue. To assess such early events associated with exposure to ENM, the choice of potential

biomarkers can give insights on local and systemic oxidative stress, systemic inflammation, and inflammatory response in target organs, as in respiratory and cardiovascular systems.

Biomarkers of Lung Inflammation and Systemic Effects

Because airway inflammation is the main outcome investigated following NM exposure, inflammatory biomarkers deserve greater importance for biomonitoring purposes. Breath analysis has been proposed as a noninvasive approach that allows the identification of the inflammatory and oxidative stress biomarkers involved in the pathogenesis of various clinical conditions (Montuschi, 2007) and for investigating occupational lung diseases (Corradi et al., 2010), exposure to welding fumes (Gube et al., 2010) or particles from aircraft engines (Desvergne et al., 2016). Besides macromolecules (e.g., DNA or RNA), an increasing panel of biomarkers reflecting oxidative stress and inflammatory pathways can be determined in EBC. Thiobarbituric acid reactive substances, such as MDA—a product of membrane lipoperoxidation—and 8-isoprostane—a peroxidation product of prostaglandin metabolism—can be quantified; proinflammatory cytokines, such as leukotrienes B4 (LTB4), can be determined as biomarkers of inflammation. Inflammatory response in the airways is characterized by an influx of neutrophils, whose activation is associated with a respiratory burst resulting in overproduction of hydrogen peroxide (H_2O_2), changes in pH, and depletion of the glutathione (GSH) pool.

Various classes of proteins and volatile compounds can be measured in EBC, including the saturated hydrocarbons and oxygen-containing substances formed during the fatty acid lipid peroxidation of cell membranes. A wide variety of carbonyl compounds are generated as secondary oxidation products during respiratory burst. In particular, saturated aldehydes, such as 4-hydroxy-trans-nonenal (HNE) and 4-hydroxy-trans-hexenal (HHE), are formed by the peroxidation of omega-3 and -6 fatty acids, the basic components of cell membrane phospholipids. EBC concentrations of MDA, HNE, and HHE were significantly higher in workers exposed to TiO_2 aerosols as compared with unexposed people (Pelclova et al., 2015b). Oxidative stress biomarkers (MDA, HNE, HHE, C6—C10, 8-isoprostane, 8-OHdG, 8-OHG, 5-OHMeU, 3-ClTyr, 3-NOTyr, o-Tyr, and C11) were elevated in the EBC of workers exposed to NPs during iron oxide pigment production compared with control subjects (Pelclova et al., 2016).

Recently, Lacombe et al. (2018) performed an in-depth proteomics characterization of EBC; a total of 229 unique proteins were identified in EBC among which 153 proteins were detected in both EBC pooled samples. A detailed bioinformatics analysis of these 153 proteins showed that most of the proteins identified corresponded to proteins secreted in the respiratory tract (lung, bronchi).

Breath can be analyzed also in the gaseous phase (as exhaled breath). For instance, nitric oxide (NO) is produced by all cellular components of pulmonary inflammation (macrophages, epithelial cells, mast cells, lymphocytes, and granulocytes). Studying NO exhaled from the lower airways offers a unique possibility to study features of pulmonary NO metabolism noninvasively in all states characterized by lung inflammation. In a follow-up study, Wu et al. (2014) found an increase in fractional exhaled nitric oxide (FENO) among workers handling nano-TiO_2 powders, but not in all of the NM exposed categories investigated; the values recorded were over the threshold of 35 ppb, suggesting a chronic airways inflammation. Differences in FENO between workers of an MWCNT facility and nonexposed, with no difference in lung function or the pneumoproteins have been found by Vlaanderen et al. (2017).

Pneumoproteins, such as Clara cell protein (CC16) and surfactant-associated protein B (SP-B) in the serum, have been validated as markers of alveolo−capillary barrier integrity/permeability in human studies on gaseous/particulate pollutants (Broekaert et al., 2000; Gulumian et al., 2006). There is evidence that acute exposures to certain pulmonary irritants can cause a transient increase in serum CC16 levels, and limited evidence also suggests that a transient increase in serum CC16 levels can be caused by a localized pulmonary inflammation without impairment of pulmonary function. The biological interpretation of chronic changes in serum CC16 is less clear, owing to chronobiological variability. In workers in indium tin oxide production plants, significant positive relationships were found between S-In and surfactant protein A (SP-A), and surfactant protein D (SP-D) levels, sensitive markers of interstitial lung disease. SP-A and SP-D levels were elevated significantly in the workers with moderately high indium exposure (Liu et al., 2012).

Early events at vascular level can be assessed by a panel of circulating biomarkers reflecting inflammation end points, platelet activation, and antioxidant capacity (as assessed by the activity of Cu/Zn-superoxide dismutase, and glutathione peroxidase-1). Inactivation of antioxidant enzymes within erythrocytes, plasma interleukin-6 (IL-6), and soluble tumor necrosis factor-receptor II (sTNF-RII), investigated during a longitudinal study, showed a positive association with vehicle emissions tracers (Delfino et al., 2010). High-sensitivity C-reactive protein in plasma, plasma fibrinogen, and IL-6 could represent good candidates for BM of ENM.

Acute phase proteins, such as C-reactive protein (CRP), are commonly used as biomarkers of (inflammatory) disease, and associations have also been shown between inflammatory biomarkers including CRP and exposure to PM air pollution. 70-nm silica nanoparticles (nSP70) induced a higher level of acute phase proteins such as haptoglobin, CRP, and serum amyloid A (SAA) than larger silica particles (diameter >100 nm) (Higashisaka et al., 2011). In addition, the level of these acute phase proteins was elevated in the plasma of mice after intranasal treatment with nSP30. The same authors identified hemopexin (another acute phase protein) as a potential biomarker for predicting the effects of silica NPs (Higashisaka et al., 2012).

Following intratracheal instillation of titanium dioxide (TiO$_2$), CB, diesel exhaust particles and CNTs, tissue mRNA expression of acute phase protein, and plasma levels of Serum Amyloid 3 were increased. Interestingly, these inflammatory biomarkers significantly correlated with the magnitude of neutrophilic influx in bronchoalveolar lavage fluid, thus suggesting that lung inflammation is associated with the expression of biomarkers predictive of cardiovascular outcomes (Saber et al., 2013).

Exposure to NPs could enhance the adhesion of endothelial cells and modify the membrane structure of vascular endothelium, which plays an important role in the regulation of fibrinolysis. Radomski et al. (2005) showed that both urban dusts and engineered carbon particles, such as CNT and CB—except C60CS—stimulated platelet aggregation and accelerated the rate of vascular thrombosis in rat carotid arteries with a similar rank order of efficacy. All particles resulted in upregulation of GPIIb/IIIa in platelets. In contrast, particles differentially affected the release of platelet granules, as well as the activity of thromboxane-, ADP-, matrix metalloproteinase-, and protein kinase C-dependent pathways of aggregation. Exposure to nano Ag (0.05−0.1 mg/kg i.v. or 5−10 mg/kg i.t. instillation) enhanced platelet aggregation and promoted venous thrombus formation in rats (Jun et al., 2011). Therefore, assessment of platelet aggregation and expression of GPIIb/IIIa in platelets may be useful to evaluate possible prothrombotic effects induced by NM. Early systemic prothrombotic effects induced by fine particle (<2.5 μm) exposure were detected by the quantification of levels of the plasminogen activator inhibitor-1 (PAI-1) (Kilinc et al., 2011). Elevated PAI-1 is closely associated with enhanced thrombosis by impairing fibrinolysis; metal NPs have proven to increase PAI-1 expression in endothelial cells in vitro (Yu et al., 2010).

Vesterdal et al. (2010) showed that exposure of young and aged apolipoprotein E knockout mice (apoE−/−) to CB (Printex 90, 14 nm average size) by intratracheal instillation, resulted in modest vasomotor impairment, with a lack of association with nitrosative stress (3-nitrotyrosine), and without increases in the expression of vascular adhesion molecule and intercellular adhesion molecule (ICAM-1) on endothelial cells or in plaque progression.

Interestingly, workers exposed to a mixture of NM showed statistically significant changes across exposure risk classes for high sensitive C reactive protein levels and inflammatory cell activation (increased ICAM-1 in macrophages), IL-6, and fibrinogen. Moreover, the depression of antioxidant enzymes, namely SOD and GPx, were associated with NM handling (Liou et al., 2012).

Erdely et al. (2011) demonstrated that the pulmonary exposure to CNT triggered the induction of primary cytokines such as IL-6 and IL-1β, which regulate multiple pathways of the inflammatory cascade as well as secondary inflammatory mediators, chemokines (CCL2, 4, 19, 22; CXCL1, 2), which directly regulate leukocyte recruitment to the inflammatory site. Iavicoli et al. (2018) investigated the adverse effects induced by subchronic intravenous administration of palladium NPs (PdNPs) on the immune system of female Wistar rats by evaluating cytokines (e.g., IL-1α, IL-2, IL-4, IL-6, IL-10, IL-12), the granulocyte−macrophage colony-stimulating factor , the INF-γ, and TNF-α serum levels at different dose levels (0, 0.012, 0.12, 1.2, and 12 μg PdNPs/kg b.w. till 60 days). Subchronic exposure to PdNPs induced a decreasing trend in serum levels in most of the cytokines investigated, with the highest concentration (12 μg/kg) determining significant inhibitory effects.

In a small cohort of workers occupationally exposed to MWCNTs, Shvedova et al. (2016) found significant changes in the ncRNA and mRNA expression profiles between exposed (inhalable concentration 14.42 ± 3.8 μg/m^3; respirable concentration 2.83 ± 0.6 μg/m^3 as elemental carbon concentrations in breathing zone samples from workers) and nonexposed workers. A dysregulation of profile of genes involved in cell cycle regulation/progression/control, apoptosis, cell proliferation, and carcinogenetic pathways was characterized in eight workers having direct contact with MWCNT-containing aerosols in the previous 6 months (Shvedova et al., 2016). In a concomitant study on the same group (Fatkhutdinova et al., 2016), it was found that exposure to MWCNTs in the order of 3 times above the recommended exposure level proposed by the NIOSH (1 μg/m^3) caused significant increase in IL-1β, IL-4, IL-5, IL6, TNF-α, inflammatory cytokines, and KL-6 in sputum samples. Moreover, the level of TGF-β1 was increased in serum obtained from young (<30 years old) exposed workers. In the serum samples, levels of IL-1β, IL-4, IL-10, and TNF-α were significantly elevated in the MWCNT exposed group.

Vlaanderen et al. (2017) assessed 51 immune markers and three pneumoproteins in serum among 22 workers of an MWCNT producing facility and 39 age- and

gender-matched, unexposed controls, considering potentially confounding parameters (age, body mass index, smoking, and sex). These authors found significant upward trends for immune markers C—C motif ligand 20, basic fibroblast growth factor, and soluble IL-1 receptor II with increasing exposure to MWCNT.

Biomarkers of Oxidative DNA Damage and RNA Methylation

Panel studies and cross-sectional investigations on health effects of PM exposure have found consistent associations between exposure to combustion-derived particles and products of oxidative damage to DNA and lipids (Loft et al., 2008; Møller and Loft, 2010). Among the DNA oxidation products, 8-hydroxy-2-deoxyguanosine (8-OHdG) and 8-hydroxyguanosine (8-OHG), measured in DNA of peripheral blood cells and urine, have been the most studied. Base excision repair products of oxidative damage to DNA in urine seem to originate mostly from the oxidation of the deoxynucleotide pool and do not represent solely repairing/excretion of the oxidized-DNA guanine, but biomarkers of effective dose.

Urinary 8-OH-dG concentration has been investigated as a potential biomarker of oxidative stress in response to exposure to incidental NPs emitted from photocopiers, and it was found significantly increased as compared with background levels (Khatri et al., 2013). In EBC of workers occupationally exposed to TiO_2 aerosols, Pelclova et al. (2015b) found an increase in markers of oxidation of nucleic acids (including 8-hydroxy-2-deoxyguanosine [8-OHdG], 8-hydroxyguanosine [8-OHG], 5-hydroxymethyl uracil [5-OHMeU]). Conversely, in workers handling nanomaterials in 14 plants in Taiwan, 8-OH-dG urinary and plasma levels did not show significant differences compared with controls (Liou et al., 2012).

The DNA-damaging potential of many NPs of different composition (metals, metal oxides, silica, QDs, fullerenes, nanofibers, SW-, and MWCNT) has been demonstrated in vitro (Gonzalez et al., 2008; Singh et al., 2009; Magdolenova et al., 2013). NM can affect DNA also by direct mechanisms, including a mechanical interference with cellular and nuclear components, such as microtubules of the mitotic spindle (Gonzalez et al., 2008). Although interactions between the particles and the assay cannot be totally excluded, the use of Comet assay in human biomonitoring studies could provide valuable information for hazard identification of NM (Karlsson, 2010; Karlsson et al., 2015). Modified Single Cell Gel Electrophoresis (SCGE) provides parallel information on oxidative DNA damage caused by NM, such as CNT, detecting oxidized/damaged pyrimidines

and purines (Muller et al., 2008; Migliore at al., 2010), and revealing dose—effect and dose—response relationships between the mass concentration of NM and the frequency of micronucleated lymphocytes. Both tests have been applied in a cohort of nanomaterial workers in Taiwan, but there were no significant differences in changes between the exposed and control workers between baseline and the 6-month follow-up (Liao et al., 2014).

DNA methylation, a major genomic mechanism of gene expression control, can be affected by ROS, which are considered as one of the main cellular stressors generated by PM exposure as well as by some metals. Stoccoro et al. (2013) highlighted the ability of certain NPs to induce an impaired expression of genes involved in DNA methylation reactions leading to global DNA methylation changes, as well as changes of gene-specific methylation of tumor suppressor genes, inflammatory genes, and DNA repair genes, all potentially involved in cancer development. Moreover, some nano-sized compounds are able to induce changes in the acetylation and methylation of histone tails, as well as microRNA (miRNAs) deregulated expression.

Brown et al. (2016) assessed the promoter methylation of inflammatory genes (IFN-γ and TNF-α) after MWCNT exposure and found a correlation between these changes and initial cytokine production. In addition, methylation of a gene involved in tissue fibrosis (Thy-1) was also altered in a way that matched collagen deposition. These authors also found that MWCNT exposure lead to DNA hypomethylation in the lung and blood, which coincided with disease development (i.e., fibrosis).

MiRNAs are noncoding small RNAs that regulate the expression of broad gene networks at the posttranscriptional level, interacting with several mRNA targets, and their use as possible biomarkers of the effects of acute and chronic environmental exposure has been suggested (Vrijens et al., 2015). Some nano-sized compounds are able to induce selected miRNAs deregulated expression, and this may help in finding specific fingerprints. Ng et al. (2011) demonstrated that gold nanoparticles (AuNPs) altered the expression of 19 genes in human fetal lung fibroblasts, upregulating the miRNA-155 (miR-155) and downregulating the *PROS1* gene—a gene encoding a vitamin K-dependent plasma protein that functions as a cofactor for the anticoagulant protease, activated protein C to inhibit blood coagulation. Silencing of miR-155 established *PROS1* as its possible target gene. DNA methylation profiling analysis of the *PROS1* gene revealed no changes in the methylation status of this gene in AuNP-treated fibroblasts, whereas chromatin condensation and reorganization was observed in the nucleus of fibroblasts exposed to AuNPs.

Nagano et al. (2013) compared the effectiveness of serum levels of liver-specific or -enriched miRNAs (miR-122, miR-192, and miR-194) with that of conventional hepatic biomarkers (alanine aminotransferase and aspartate aminotransferase) as biomarkers for nSP70 induced liver damage in mice.

Toward Specific Biomarkers for Engineered Nanomaterials Exposure

Research of biomarkers reflecting exposure to certain particles and fibers of concern have already generated a large amount of data supporting the validity of intermediate end points to assess changes before clinically apparent disease occurs (Gulumian et al., 2006) and several biomarkers can reliably help in assessing exposure and effects of NM (Iavicoli et al., 2014; Bergamaschi et al., 2017). The challenge that remains for the use of biomarkers of exposure for NM is the lack of specificity of all the biomarkers developed so far that could hamper the applicability of biomonitoring to nano-object.

It should be recognized that the existence of nanospecific (i.e., size-dependent) effects is an arbitrary assumption because the threshold of 100 nm does not infer, per se, new properties, whereas a gradual change in surface reactivity could actually modulate biological interactions independently from size. Properties other than size, such as shape, surface area, surface charge, and reactivity, can more effectively describe the dose leading to biological effects, as in the classical particle and fiber toxicology science (Auffan et al., 2009; Fubini et al., 2010; Donaldson and Poland, 2013). This does not mean that there are no changes specifically induced by some particles at certain size thresholds, but these changes should be interpreted as mode of actions instead as "new" toxicological properties (Donaldson and Poland, 2013; Lynch et al., 2014). For instance, the more toxicity and DNA damaging potential of nanosized than microsized CuO particles in A549 cells has been attributed to the ability to deliver Cu^{2+} inside cells ("*Trojan horse*" effect). In contrast, the micrometer particles of TiO_2 caused more DNA damage compared to the NPs, which is likely explained by the crystal structures.

New achievements in biomarker discovery came from the study of the intercellular communication pathways (Valadi et al., 2007; Raposo and Stoorvogel, 2013; Lin et al., 2015). In vitro studies have revealed that cellular uptake of NPs provoked micro vesicular endosome (MVe) formation intracellularly; however, few studies have studied the biological consequences once the exosomes have been secreted extracellularly in vivo. On i.t. instillation (4 μg or 20 μg) with 43-nm diameter magnetic iron oxide nanoparticles (MIONs), Zhu et al. (2012) observed a dose-dependent generation of exosomes in the alveolar region of BALB/c mice. These exosomes were quickly eliminated from alveoli into systemic circulation and largely transferred their signals to the immune system, with activation of splenic T cells. Interestingly, the maximum dose used in this study is equal to a half-workday deposition mass in human lung tissue at the permissible exposure limit of iron oxide fume (at a concentration of 10 mg/m^3) suggested by the Occupational Safety and Health Standards (OSHA, USA). These findings suggest that respiratory exposure to MIONs can activate systemic T cells in susceptible individuals, through exosome-mediated signaling pathways.

Systems Toxicology, the integration of classical toxicology with quantitative analysis of large networks of molecular and functional changes, is also expected to provide information on the dynamic interaction between molecular components of biological systems and about the possible mechanisms, by assessing whether specific biological pathways are activated/perturbed by specific NM, thus identifying fingerprints and nanospecific end points useful for hazard identification and, ultimately, for risk assessment (RA) (Costa and Fadeel, 2016). Comparative proteomic studies have shown strong similarities in the pulmonary response to different ENM with known hazardous particles and fibers. One repeated aspiration study (4 μg per mouse, twice a week, for 3 weeks) allowed the identification of a pattern of 109 proteins representing cellular processes affected by both SWCNT and crocidolite asbestos; S100a9, a high-sensitivity marker of inflammation, can be proposed as a biomarker of human response to SWCNT exposure (Teeguarden et al., 2011). Mice exposed by pharyngeal aspiration to 40 μg CNT showed increased inflammatory blood gene expression and serum cytokines followed by an acute phase response (e.g., CRP, SAA-1, SAP). At 28 days, serum acute-phase proteins with immune function including complement C3, apolipoproteins A-I and A-II, and 1-macroglobulin were increased (Erdely et al., 2011). CNT exposure resulted in measurable systemic markers but lacked specificity to distinguish from other pulmonary exposures.

A toxicogenomic approach has been used in assessing specific mechanisms at the molecular level, identifying patterns of cellular perturbations in specific pathways, through identification and quantification of global shifts in gene expression in cell models challenged with ENM. Pulmonary exposure to CNT resulted in an elevated series of measurable potential biomarkers in blood, including genes expressed in the circulating blood cells and/or soluble proteins not unique to the type of particles (Erdely et al., 2009). In particular, MWCNT-induced gene upregulation of more than half of the tested genes in the lung related to inflammation, oxidative stress,

coagulation, and tissue remodeling and to a significant increase in the circulating blood gene expression of several biomarkers of neutrophil response. Interestingly, several genes were activated in the circulating blood cells but not in the lung, at least at 4 h after exposure to MWCNT, e.g., osteopontin (a marker of early mesothelioma), colony stimulating factor-1 (CSF-1), and insulin growth factor receptor 1. Exposure to CNT also triggered the induction of primary cytokines such as IL-6 and IL-1b, which regulate multiple pathways of the inflammatory cascade as well as secondary inflammatory mediators, and chemokines, which directly regulate leukocyte recruitment to the inflammation site.

Guo et al. (2012) analyzed mRNA expression profiles in lungs of mice exposed to $0-80$ µg of MWCNT by pharyngeal aspiration until 56 days postexposure and identified sets of genes associated with human lung cancer risk and progression with significant odds ratios. C57BL/6 mice exposed to 18, 54, and 162 µg Printex 90 carbon black nanoparticles (CBNP) showed perturbation of pathways, networks, and transcription factors of predicted phenotypes (e.g., pulmonary inflammation and genotoxicity) that correlated with dose and time. Comparison to inflammatory lung disease models (i.e., allergic airway inflammation, bacterial infection, and tissue injury and fibrosis) and human disease profiles revealed that induced gene expression changes in Printex 90 exposed mice were similar to those typical for pulmonary injury and fibrosis. Very similar fibrotic pathways were perturbed in CBNP-exposed mice and human fibrosis disease models, thus supporting the use of toxicogenomic profiles in human health risk assessment of NPs (Bourdon et al., 2013).

Palomäki et al. (2015) performed proteomics analyses of human macrophages exposed to tangled or rigid, long MWCNTs, or crocidolite asbestos, using hyphenated techniques and concluded that not all types of CNTs are as hazardous as asbestos fibers.

Kinaret et al. (2017b) have systematically investigated transcriptomic responses of the THP-1 macrophage cell line and lung tissues of mice, specifically induced by several carbon nanomaterials (CNMs). They observed only a minute overlap between the sets of intrinsic property-correlated genes at different exposure scenarios, suggesting specific transcriptional programs working in different exposure scenarios. However, when the effects of the CNM were investigated at the level of significantly altered molecular functions, a broader picture of substantial commonality emerged. As a result, in vitro exposures can efficiently recapitulate the complex molecular functions altered in vivo.

High-throughput (omics) methods, if applied in a rigorous manner, hold great promise for the development of (novel) biomarkers and biomarker signatures.

In addition, achievements in this field may make more consistent the regulatory approach to hazard assessment based on dynamic adverse outcome pathway (AOP) models. (Vietti et al., 2016; Labib et al., 2016). With the aim to evaluate the application of global gene expression data in deriving pathway-based points of departure for MWCNT-induced lung fibrosis, as a noncancer end point of regulatory importance, Labib et al. (2016) showed an early perturbation of similar biological pathways regardless from MWCNT types across the doses and postexposure time points studied. The authors also showed that transcriptional benchmark dose (BMD) values for pathways associated with fibrosis ($4.0-30.4$ µg/mouse) were comparable to the BMDs derived by NIOSH for MWCNT-induced lung fibrotic lesions (namely, $21.0-27.1$ µg/mouse), thus suggesting that transcriptomic data can be used to derive acceptable levels of exposure to NM in product development (Labib et al., 2016).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

BM is an important component of the occupational and environmental health surveillance, especially when occupational and/or environmental exposure monitoring data are unavailable or difficult to obtain. The literature on short-term effects of air pollutants and the available literature on NM, suggest identifying multiple biomarkers—a biomarker profile—to assess both effects at the "portal of entry" (e.g., inflammatory changes, short-term respiratory changes, respiratory, eye or skin irritation) and systemic effects (e.g., heart-rate variability, platelet aggregation and prothrombotic changes, acute phase proteins) in susceptible subgroups of the general population exposed to incidental NPs or to a mixture of pollutants.

Table 41.1 summarizes a panel of biomarkers of exposure and effect potentially available for human biomonitoring studies aimed at assessing early effects and health outcomes.

In spite of the lack of validation of "nanospecific" biomarkers, it is proposed that at this stage that the sensitivity rather than the specificity of biomarkers should be privileged to identify potentially predictive biomarkers suggestive of the biological pathway and mechanistic changes underlying the causality of exposure conditions and association with hazards (e.g., at workplace) and also to identify predictive biomarkers (Bergamaschi et al., 2015). For the moment, all studies carried out so far (see the review by Liou et al., 2015) have used a cross-sectional design and consequently do not allow confirming the observed effects and understanding the dynamics of their occurrence and

TABLE 41.1   Appraisal of Biomarkers of Exposure or Effects Relating to Ultrafine Particle or Engineered Nanomaterial

Quality of Biomarker

Biomarkers of exposure	• Exhaled particles and/or elements in EBC (estimate of the "deposited dose" or "target tissue dose") • Elements analysis in biological fluids (excretion, body burden) • Protein modification ("corona")
Biomarkers of effective dose/early effect	• Lipid peroxidation products in EBC or blood (MDA, TBARS, conjugated dienes, LTB4, F2- and 8-isoprostane) • DNA excision base products (8-OHdG, 8-oxo-Gua, 8-OHG) • Exhaled NO (FeNO) and nitrosative stress products (3-nitrotyrosine) • Carbonyl compounds (4-HNE, 4-HHE) in EBC • Serum pneumoproteins (CC16) • Platelet activation/aggregation and prothrombotic changes • Acute phase proteins: hsCRP, SAA, Haptoglobin, Hemopexin • IL-6 and sTNF-RII • Coagulation factors (fibrinogen, plasminogen activator inhibitor-1[PAI-1]) • Vascular adhesion molecules (VCAM-1) and intercellular adhesion molecule (ICAM-1)
Biomarkers reflecting alterations in cell structure/function	• Fibrogenic markers (KL-6 glycoprotein; MMP-1, MMP-7, MMP- 9) • Osteopontin (Early mesothelioma development) • Micronucleus • DNA strand breaks (Comet assay + FPG-ENDO III) • Epigenetic markers: DNA (hypo)methylation; MicroRNAs (miRNAs) • Extracellular micro- and nanovescicles, exosomes (EMVs' cargo characterization)

The table includes biomarkers validated in human studies on people exposed to different ultrafine or fine particulates or known fractions, and biomarkers specifically investigated in relation to ENM.

Note: *4-HNE*, 4-hydroxy-2-nonenal; *8-isoprostane*, 8-isoprostaglandin F2α; *8-OHdG*, 8-hydroxy-2′-deoxyguanosine; *8-OHG*, 8-hydroxyguanosine; *8-oxo-Gua*, 8-oxo-7,8-dihydroguanine; *CC16*, Clara cell protein; *EBC*, exhaled breath condensate; *FPG-ENDOIII*, lesions detected as sites in DNA sensitive to formamidopyrimidine DNA glycosylase and endonuclease III; *hsCRP*, high sensitivity C-reactive protein; *IL-6*, plasma Interleukin 6; *LTB4*, Leucotriene-B4; *MDA*, malondialdehyde; *NO*, nitric oxide; *SAA*, serum amyloid A; *sTNF-RII*, soluble tumor necrosis factor-receptor II; *TBARS*, thiobarbituric acid reactive substances.

duration. Consequently, this kind of study could only help to identify some "intermediate" biological changes of effects. Only the study of Lee et al. (2015) showed a reduction, though not clinically significant, in lung function parameters in a cohort of workers occupationally exposed to nanoscale CB. Longitudinal panel studies with repeated exposure and effect biomarker measurement are necessary to investigate whether this unspecific "intermediate" biological changes could be indicative or predictive of clinical effects and apply them in health surveillance programs. To provide a coherent approach and make future epidemiological research a reality, a well-defined framework is needed for the careful choice of materials, exposure characterization, identification of study populations, definition of health end points, and evaluation of the appropriateness of study designs, data collection and analysis, and interpretation of the results (Riediker et al., 2012). Moreover, the scientific, methodological, political, and regulatory issues that make epidemiological research in nanotechnology-exposed communities particularly complex. Standardization of data collection and harmonization of research protocols are needed to eliminate misclassification of exposures and health effects. Forming ENM worker cohorts from a combination of smaller cohorts and overcoming selection bias are also challenges (Guseva Canu et al., 2018).

In conclusion, BM of exposure and effect should represent a valuable component of an integrated strategy and a proactive approach to risk assessment and management. Hence, it is an opportunity for companies committed to the responsible development of nanotechnology and also an ethical obligation toward all populations of workers that everything is done to assure a safe working environment.

Biomarkers of Exposure and Responses to Ionizing Radiation

Roger O. McClellan

Independent Advisor, Toxicology and Risk Analysis, Albuquerque, New Mexico, United States

INTRODUCTION

The health effects of ionizing radiation from external sources and internally deposited radionuclides have been more extensively investigated than any other hazardous agent or class of agents (McClellan, 2014). Thus, ionizing radiation is an ideal toxicant to evaluate relative to the concept of biomarkers. The previous edition of this book included a chapter entitled "Biomarkers of Radiation Injury and Response" (Ray et al., 2014). This chapter complements the earlier chapter and draws heavily on the author's experience from over 60 years of conducting, managing, and interpreting research on the health effects of radionuclides deposited internally following ingestion or inhalation exposure.

As I will relate later, the earliest knowledge of radiation-induced health effects came from human experience, initially ad hoc observations followed much later by more formal epidemiological studies. Epidemiological investigations are by their very nature studies of "human misfortune" in that people should never purposely exposed to provide human evidence of the effects of radiation exposure, the populations studied have been inadvertently exposed. The research my colleagues and I conducted with controlled exposures of laboratory animals was intended to complement and extend the findings from epidemiological studies. Special attention in the controlled exposure animal studies was directed to gaining information on a range of radionuclides with different decay characteristics (beta- vs. alpha-emitters and half-life) and radiation dose patterns for which human data did not exist and was unlikely to be obtained.

As I will relate later, most of the experimental studies my colleagues and I planned and conducted involved multiple levels of exposure and intake. For every radionuclide and chemical form studied, parallel investigations were conducted to provide kinetic descriptions of the disposition of the radionuclide and allow estimation of the radiation dose delivered to various tissues over time following intake. In each life span study (LSS), a continuum of intakes and cumulative doses were evaluated. At the highest intakes and radiation doses, acute deaths were observed. At lower intakes and radiation doses, the health effects observed were debilitating and caused intermediate term deaths. At yet lower intakes and radiation doses, the effects were indistinguishable from the health effects seen in aging controls except the occurrence of neoplasms was elevated compared to controls. At the lowest intakes and radiation doses, the life span and causes of death in the radionuclide exposed animals, including occurrence of cancer, were not distinguishable from that observed in control animals.

The contents of this chapter build on two recent book chapters prepared by the author. There is a review of "Concepts in Veterinary Toxicology" (McClellan, 2018) and a comprehensive review of "Radiation Toxicity" (McClellan, 2014). In this chapter, the findings from both epidemiological studies and controlled exposure investigations in laboratory animals will be discussed in a "biomarker" context building on my earlier review of radiation toxicity. This context recognizes that the use of biomarkers is really an extension of the practice of medicine, from the time of its origins, with skillful interpretation of signs and symptoms used to diagnose disease and guide treatment. The author strongly endorses the use of biomarkers of both exposure and health effects to aid in understanding the health effects of radiation exposures from external sources and internally deposited radionuclides. Some radiation-induced effects are characterized by a threshold in the dose—response relationship with an increase in the frequency and severity of the health effect

as radiation doses are increased above a threshold level. Other effects, such as cancer, have a stochastic (random occurrence) relationship relative to dose and the incidence of the disease increases above background rates in proportion to the increase in radiation dose. The author offers words of caution on the use of biomarkers for interpreting and assigning attribution or causality to radiation exposure for effects such as cancer, that occur randomly, i.e., in a stochastic dose—response manner over and above their random occurrence in nonexposed individuals.

Knowledge available today is generally not adequate to accurately predict the occurrence of most cancers before they are clinically manifested. Excess Relative Risks (ERRs) for cancer occurrence are statistically estimated in epidemiological studies and in a few experimental studies and attributed to an etiological agent such as radiation exposure. However, current scientific knowledge is not sufficient to identify which of the cancer cases observed in a cohort are specifically caused by a specific etiological factor versus unknown causality. Unfortunately, most experimental studies are designed to test outcomes of a deterministic nature rather than a stochastic nature.

In my opinion, the advancement of the development and application of biomarkers, especially biomarkers of radiation exposure and the resultant radiation-attributable health effects, is going to require a rigorous, critical assessment of the current status of this specialized area. This will provide a basis for developing a pragmatic and strategic approach to the planning and conduct of future research building on our past collective experience. The development and application of biomarkers for ionizing radiation and other hazardous agents is at a critical juncture. New methods and approaches are needed! The quantitative nature of radiation science suggests that lessons learned and concepts developed with ionizing radiation as a hazardous agent may be useful applied to chemical agents.

KEY DEFINITIONS AND UNITS

Some key definitions are provided in Table 42.1 for keywords and phrases regularly used in radiation science to augment the Glossary provided for this textbook. A concise summary of key units used in radiation science and radiation protection is provided in Table 42.2. The earliest units, termed conventional, have ultimately been superseded by the newer International System of Units which were first developed in Europe and more slowly accepted in the United States. In general, when referencing previous published research, I will use the units used by the previous author. The reader also needs

TABLE 42.1 Key Definitions in Radiation Science and the Effects of Radiation on Health

Alpha-Particles	A charged particle consisting of two protons and two neutrons bound together into a particle identical to a Helium-4 nucleus.
Beta-Particles	A charged particle of very small mass emitted spontaneously from the nuclei of certain radioactive elements. Physically, a beta-particle is identical to an electron moving at high velocity.
Elements	One of the distinct, basic varieties of matter occurring in nature.
Fission	Electromagnetic radiation of variable energy originating in atomic nuclei. Physically, X-rays and gamma-rays are identical.
Fusion	The process whereby the nucleus of a particular heavy element following absorption of a neutron splits into two nuclei of lighter elements with release of substantial energy. Controlled and sustained fission occurs in a nuclear reactor. Fission of Pu^{239} and U^{235} is a key component of the detonation of nuclear weapons. The process whereby the nuclei of lighter elements, especially those of hydrogen (deuterium and tritium), combine to form the nucleus of heavier elements with the release of substantial energy. A thermonuclear weapon involves fission followed by fusion.
Gamma-Rays	Electromagnetic radiation of variable energy originating in atomic nuclei. Physically, X-rays and gamma-rays are identical.
Isotopes	Forms of the same element having identical chemical properties but differing in atomic mass (due to different numbers of neutrons in their respective nuclei) and nuclear properties (radioactivity).
Nuclide	An atomic species of an element distinguished by the composition of its nucleus, i.e., the number of protons and neutrons.
Radioactive Half-Life	The time required for the activity of a given radionuclide to decrease to half its initial value due to radioactive decay.
Radionuclide or Radioisotope	An isotope or nuclide that is unstable and will spontaneously decay by emission of alpha or beta-particles.
Transmutation X-rays	Conversion of one chemical element into another electromagnetic radiation of variable energy produced by slowing down fast electrons. X-rays can penetrate the body and be absorbed or pass through the body.

TABLE 42.2 International Units for Radiation and Radioactivity Compared With Old Units

International Units	Describes	Old Units
Becquerel (Bq)	Radioactivity, the spontaneous decay of atomic nuclei 1 Bq = 1 disintegration/s	Curie = 3.7 $\times 10^{10}$ Bq
Gray (Gy)	Dose to tissue 1 Gy = energy uptake of 1 J/kg	Rad = 10 mGy
Sievert (Sv)	Effective dose,[a] dose normalized to effects of gamma radiation by applying a Radiation-Weighting factor (WR) based on the Relative Biological Effectiveness (RBE) of the radiation of interest, to the absorbed dose in an organ or tissue to derive the equivalent dose. The effective dose is usually expressed as millisievert (mSv) 1 mSv = 10^{-3} Sv	Rem[b] = 10 mSv

[a]*Allows conversion of dose from gamma, beta, or alpha radiation to a standard unit.*
[b]*Rem, originally based on Roentgen Equivalent Man.*

to be mindful that different prefixes are used, such as with Curies or Becquerels, to span many orders of magnitude from micro to milli levels of the base Unit.

RADIATION PROTECTION SYSTEM

Over the past century, a systematic approach to radiation protection has developed. Its origins were international followed by the development of national systems. International guidance is currently provided by the International Commission on Radiological Protection (ICRP). In the United States, a congressional chartered organization, the National Council on Radiation Protection and Measurements (NCRP), provides guidance with individual federal, state, and local agencies having legislated responsibility and authority for radiation protection activities to protect workers and the public. I served as an elected member of the NCRP Council (1971–2001) and now serve as a Distinguished Emeritus Member. From time to time, in the United States, the National Academies, National Academy of Sciences, National Academy of Engineering, National Academy of Medicine (previously, the Institute of Medicine) through the National Research Council (NRC), also offers independent advice on radiation issues. I have served on many of those committees, including chairing the NRC Committee on Toxicology for 7 years, and I have been an elected member of the National Academy of Medicine since 1990.

The radiation protection system is uniquely different than the system used throughout the world for chemicals. By and large, the hazards and risks of chemicals are assessed and regulations developed chemical by chemical, a very tedious and demanding process requiring substantial information on each chemical. Very early in the radiation field, it became apparent that it would be very difficult to separately consider each type of radiation (X-rays, gamma-rays, neutrons, beta-particles, and alpha-particles) and each radionuclide (I^{131}, Sr^{90}, Ra^{226}, Pu^{239}, etc.) separately.

Alternatively, a system for radiation was developed that recognized that all radiation acts via ionization of tissue in causing health effects. Thus, a holistic approach has developed based on absorbed tissue dose as the common metric irrespective of whether the ionizing radiation arises from external sources on internally-deposited radionuclides.

Current recommended dose limits are shown in Table 42.3.

Radiation-weighting factors (W_g) and tissue-weighting factors (W_t) that undergird the dose limits are shown in Tables 42.4 and 42.5. In the author's opinion, the limits shown in Table 42.3 are grounded in scientific judgment guided by risk considerations. However, they were not developed based on achieving specific limits on risk. Table 42.6 shows the detriment-adjusted nominal risk coefficients for stochastic effects (both cancer and heritable effects). One point to be made is that from 1990 to 2007, the estimates for heritable effects have been reduced, whereas the estimates for cancer have been slightly increased. As an aside, there was considerable concern beginning in the 1930s and continuing through the 1950s and 1960s for heritable effects. As new epidemiological and experimental evidence became available, it was possible to place heritable effects in better perspective. It is apparent the radiation protection system is highly quantitative and strongly grounded in a source-exposure-dose-response paradigm (Fig. 42.1). This paradigm undergirds the risk analysis system for both radiation and chemicals. An alternative presentation of the paradigm is shown in Fig. 42.2. This version emphasizes various elements of the pathogenesis of radiation-induced responses, including molecular and cellular processes that have emerged in recent decades. It is apparent that this paradigm will accommodate consideration of exposure from multiple sources to individuals or populations. Radiation dose is the control component of the paradigm for initiating consideration of responses to ionizing radiation, including an increase in overt diseases over and

TABLE 42.3   Recommended Dose Limits for Ionizing Radiation (mSv in a year)

Type of Limit	ICRP	NCRP

A. Occupational exposure
   Stochastic effects
      Effective dose limit (cumulative)
	20 mSv/year averaged over 5 years, not to exceed 50 mSv in any 1 year	10 mSv × age

Annual	50 mSv/year	50 mSv/year

Deterministic effects
       Dose equivalent limits for tissues and organs (annual)
          Lens of eye
          Skin, hands, and feet
	150 mSv/year
	500 mSv/year
		150 mSv/year
		500 mSv/year

B. Embryo/fetus exposure Effective dose limit after pregnancy is declared	0.5 mSv/month	Total of 1 mSv to abdomen surface

C. Public exposure (annual)
    Effective dose limit, continuous or frequent exposure
    Effective dose limits, infrequent exposure
    Dose equivalent limits
       Lens of eye
       Skin and extremities
	No distinction between frequent and infrequent—1 mSv/year
	15 mSv/year
	50 mSv/year
		1 mSv/year
		5 mSv/year
		15 mSv/year
		50 mSv/year

D. Negligible individual dose (annual)	No statement	0.01 mSv/year

above those caused by others, and frequently, as yet unknown risk factors.

SOURCES OF RADIATION EXPOSURE

This section briefly reviews the source of radiation exposure for the US population to provide a context for the rest of the chapter (). One overarching point needs to be made.

We all live and work in a "sea of radiation." About half of the average radiation exposure (3.1 mSv/year) comes from background. The other half (about 3.1 mSv/year) comes from anthropogenic, i.e., man-made sources, including medical uses of radiation. The anthropogenic radiation dose varies substantially between individuals because a substantial portion comes from medical procedures. From a personal view point,

TABLE 42.6 Detriment-Adjusted Nominal Risk Coefficients for Stochastic Effects After Exposure to Radiation at Low Dose Rate (10^{-2} per Sv)

	Cancer		Heritable Effects		Cancer Total Detriment	
Exposed Population	1990[a]	2007[b]	1990	2007	1990	2007
Whole	6.0	5.5	1.3	0.2	7.3	5.7

• Conventional radiography/ fluoroscopy	0.31	5
• Consumer products	0.12	2
• Occupational	<0.1	<0.1
• Industrial	<0.1	<0.1
Anthropogenic	3.10	

Data from National Council on Radiation Protection and Measurements (NCRP), 2009. Report 160, Ionizing Radiation Exposure of the Population of the United States.

I am confident that every medical procedure involving radiation doses I have had has yielded a substantial benefit that far outweighed any hypothetical or estimated risk.

HISTORICAL PERSPECTIVE

Some key early events related to discovery of radiation phenomena and radiation-induced health effects are shown in Table 42.8. Investigations on the health effects of ionizing radiation began soon after William Conrad Roentgen's discovery of X-rays in 1895. Dermatological changes were soon observed in response to short-term high-dose external exposures to X-rays. The radiation dose–response-related nature of dermal changes was soon recognized with an apparent threshold that had to be exceeded before effects were observed. This phenomenon, the severity and frequency of adverse health effects being related to dose rate and total dose would later be observed for all the various health effects caused by radiation exposure. Within a short period of time, X-rays were being used routinely to produce radiographic images. The field of diagnostic radiology was underway.

As soon as the cell-killing effects of radiation were apparent, X-rays began to be used to treat superficial skin cancers and cancers located in deep tissues. In

this same time period, naturally occurring radionuclides, such as Ra^{226} and Po^{210}, and their emissions were discovered. Marie Curie coined the term "radioactivity." It was quickly realized that radon from decay of Ra^{226} could be placed in capsules which could then be implanted in tumors to treat cancer. The field of radiation therapy was underway.

In the early 1900s, naturally occurring radioactive materials, such as alpha-particle emitting radium and thorium, were purified and added to phosphorescent
FIGURE 42.3 Dose—response relationship for induction of mutations in X-irradiated *Drosophila* (Note the substantial radiation doses studied).

FIGURE 42.4 Survival curve for Hela cells in culture exposed to X-rays. *Adapted from Puck, T.T. and Markus, P.I. (1956). Action of x-rays on mammalian cells. J. Exp. Med. 103:653—666.*

paints to create luminous dials for clocks and instruments. The painting of dials was typically done by young women who would "tip" the brushes on their lips and inadvertently ingest the material. A recent book, "*The Radium Girls,*" (Moore, 2016) provides vivid descriptions of working conditions and health outcomes in that time period. The Ra^{226} behaved like calcium and translocated to the skeleton, including the mandible. The women soon had a loss of teeth, damage to their mandibles, blood dyscrasias, and bone cancer. The carcinogenic potential of chronic radiation exposure was clearly evident. In retrospect, miners working in the mountains of central Europe several centuries earlier had likely experienced radiation-induced lung cancer related to chronic inhalation exposure to radon and its daughter products in the air arising from pitchblende containing ore.

In the 1920s and 1930s, x- and gamma-rays were used by numerous investigators to irradiate all manner of biological organisms from cells to mammals and plants and observe a range of biological effects. This included numerous studies to investigate hereditable effects and somatic effects in tissues resulting in a wide range of health effects. Again, radiation dose—response relationships were frequently documented over a range of doses although the emphasis was usually on observing some specific effects, thus, quite high dose rates and large total doses delivered over a relatively short period of time were frequently used. The results of an early study with *Drosophila* are shown in Fig. 42.3. To complement this demonstration of the mutagenic properties of radiation, shown in Fig. 42.4, is a survival curve for cells from research conducted in the 1950s by Puck and Markus (1956). Yet later, the concepts of mutations, cell
proliferation, and cell killing were joined as carcinogenesis (Gray, 1965) (Fig. 42.5).

The 1930s were also a period of major developments in radiological science. The invention of the cyclotron in 1932 by the physicist, Ernest Lawrence, at the University of California—Berkeley, provided a method for creating numerous new radionuclides of naturally occurring elements and discovering new elements. The availability of new radionuclides, such as Fe^{59} and P^{32}, provided material for radiotracer studies in laboratory animals and human subjects. The application of these new tools in medicine was facilitated by the fact that Ernest Lawrence's brother, John Lawrence, was a physician at the University of California—Berkeley medical college. In retrospect, the early research of John Lawrence, his key collaborator, Joe Hamilton, and other colleagues was pioneering work with biomarkers. The discovery of fission by Strassman and Hahn (reported in a manuscript to *Naturwissenschaften*, January 6, 1939) and the interpretation of "nuclear fission" and "daughter products" by Frisch and Meitner (in a manuscript in Nature, February 11, 1939) would be of enormous significance. The use of the terms, fission and daughters, came from Frisch's experience in biology. The physical and biological sciences have been joined ever since in the study of radiological phenomena, including radiation-induced health effects.

One of the new elements discovered at Berkeley by a team led by Glenn Seaborg was Plutonium. Seaborg, with his junior colleagues, Joe Kennedy and Ed McMillan, and assistance from Emilo Segre, a research associate, and Art Wahl, a graduate student, first discovered Pu^{238} and then very soon thereafter Pu^{239} produced in the cyclotron. On March 28, 1941, they demonstrated that Pu^{239} undergoes fission with slow neutrons with a large probability. Thus, they revealed the potential for using Pu^{239} as an explosive ingredient in a nuclear or atomic bomb.
FIGURE 42.5   The postulated role of cell killing and induction of cell killing in producing leukemia in irradiated mice (Gray, 1965).

In 1941, as World War II was beginning in Europe and on the eve of the December 7, 1941, bombing of Pearl Harbor, Hawaii, a young radiation biologist, Paul S. Henshaw, published what I view as one of the earliest classic papers in radiation biology and radiation protection in Volume 1 of the Journal of the National Cancer Institute (Henshaw, 1941). The National Cancer Institute had only been started a short time earlier. This paper, which included the phrase "tolerance dose" in the title succinctly synthesized what was known at that time about radiation-induced effects. It included a very simple schematic (Fig. 42.6) that illustrated the now well-known two fundamentally different dose—response relationships for radiation exposure. One relationship has a "deterministic" form with a clear threshold. The second is a linear, no-threshold relationship with a "stochastic" form. In 1941, it was thought that acute and chronic health effects from intake of chemicals were generally of the "deterministic" form. This underlying assumption had already begun to be used in setting occupational exposure limits for chemicals, i.e., the setting threshold limit values.

The earliest radiation protection standards were also grounded in the "deterministic" or threshold dose—response relationship. An example is the exposition in the document entitled "The Tolerance Dose" authored by Cantril and Parker (1945) released on January 5, 1945. This document outlined the basis for the radiation protection program for workers at the Hanford, WA facilities. Three radiation tolerance levels were proposed
FIGURE 42.6   Schematic rendering of two fundamentally different dose—effect relationships for radiation. (Used in "The Tolerance Dose" by Cantril and Parker, January 5, 1945). *Adapted from Henshaw, P.S., 1941. Biologic significance of the tolerance dose in X-ray and radium protection. J. Natl. Cancer Inst. 1, 789—805.*

to protect workers: (1) 0.1 R/day for x- and gamma-rays; (2) 1×10^{-14} Ci radon/cc for radon in air; and (3) 0.1 μg Ra^{226} as a maximum amount deposited in the body. Cantril and Parker (1945) emphasized that all three tolerance doses were based on "human misfortune" and were uncertain, a point Parker would repeatedly make in later years. In particular, he noted major uncertainties in considering the effects of protracted exposure in contrast to brief exposures and related limitations in the human data base, especially in dealing with newly discovered elements and radionuclides, such as Pu^{239} and new applications of radiation. He

also noted the possible role for the results of animal experiments. When doing so, he emphasized the importance of understanding the potential role of the results of the animal studies before initiating the studies. He wanted to be assured the animal studies met a clear need.

Personal Experience

The author's awareness of radiation issues and what is now known as nuclear energy dates to the summer of 1944. At that time, I moved from a small town on the prairies of southwest Minnesota, where I had lived on a farm in 1943–44 with my grandparents, to join my parents in Richland, WA. My parents had been working at Hanford in 1943–44 building unique facilities that were to produce a secret product. In August 1945, with the detonation on August 6, 1945, of a Uranium-235 fueled bomb over Hiroshima and on August 9, 1945, a Plutonium-239 fueled bomb over Nagasaki, Japan, it became known that Hanford's secret product was Pu-239. The feasibility of using Pu-239 as the fuel in a nuclear explosive device had been demonstrated in the "Trinity" tower test at Alamogordo, NM, on July 16, 1945. Robert Oppenheimer, who headed the Los Alamos, NM, bomb design and fabrication team was reported to have quoted a passage from Bhagavad Gita: "If the radiance of a thousand suns were to burst at once into the sky, that would be like the splendor of the Mighty One … I am become Death, the shatter of worlds." The world would never be the same, the Nuclear Age had begun. It soon became public knowledge that Hanford was a part of the Manhattan Project along with U-235 production facilities at Oak Ridge, TN, bomb design and fabrication activities at Los Alamos, NM, and basic science operations at Chicago, IL, and Berkeley, CA.

Useful references for the early years of the Nuclear Age are books by Hewlett and Anderson (1962), Hewlett and Duncan (1969), Szasa (1984), and Rhodes (1995). A very comprehensive text, "Radioactivity and Health: A History" (Stannard and Baalman, 1988) will be of special interest to biomedically oriented readers. J. Newell Stannard was a pioneering radiation toxicologist at the University of Rochester. The University of Rochester had a small but significant research program on the toxicity of inhaled uranium and Pu^{239} that was part of the Manhattan project. The associated graduate education program trained many radiation biologists and aerosol scientists, including many who ultimately would work at Hanford and Lovelace. Herbert M. Parker's Publications and Other Contributions to Radiological and Health Physics (Kathren et al., 1986) will be of interest to readers interested in early developments in radiation protection.

When I arrived in Richland in 1944, I was under age for radiation work so I missed out on helping Enrico Fermi start the Hanford 100B reactor on September 26, 1944, to irradiate uranium fuel to produce Pu-239 or to join workers in the Hanford facilities on December 26, 1944, to separate Pu-239 from the irradiated uranium fuel and fission products using a process developed by Glenn Seaborg. Instead, I started the third grade. The Hanford nuclear reactors were large blocks of carbon with horizontal tube channels. Uranium fuel elements clad with aluminum was placed in the tubes for irradiation under carefully controlled conditions. Purified cold water from the Columbia River flowed through the tube channels to cool the reactors. The sustained and controlled nuclear chain reaction produced neutrons and a plethora of fission products. This included Te^{131} that quickly decayed to I^{131} and large quantities of Sr^{90} and Cs^{137}. A small portion of the U^{238} atoms were transmutated to Np^{239} which then quickly decayed to Pu^{239}.

Quite by serendipity, Simon Cantril, a physician experienced in radiation oncology, and Herbert M. Parker, a radiological physicist, arrived at Hanford in the fall of 1944 and put pen to paper and documented the radiation protection program for Hanford as I noted earlier (Cantril and Parker, 1945). A key figure in that document was from the classic paper of Henshaw (1941) (Fig. 42.6). Mr. Parker was a leader in creating the field of radiation protection, originally code-named, "Health Physics," a name that stuck, much to Mr. Parker's chagrin. He was first and foremost a radiological or medical physicist, a skilled experimentalist and research team leader. Mr. Parker would later become one of my mentors in his role as head of the Hanford Research Laboratories, a position he held from 1956 until January 1965. I had the good fortune to work in those laboratories as a student intern in the summers of 1957, 1958, and 1959 and full-time from 1960 through 1965.

I did not recognize it at the time; however, in the late 1940s, as an elementary school student, I was introduced to the field of biomarkers. I noted that periodically a gray metal box would be left on the front door step of our home. I knew the box and contents must be related to my father's employment; the box had a HEW (for Hanford Engineering Works) label on it and my father's payroll number. When I inquired about the contents, my father said it contained his "pee bottles" and he needed to collect all his urine when at home to be added to the urine collected on the job. The urine was analyzed for Pu^{239} as a "biomarker" of his potential body burden of Pu-239. The initial "allowable skeletal burden" of Pu^{239} was derived from the human experience with Ra^{226}. My father was a technician in the Hanford facilities that separated Pu-239 from irradiated uranium fuel and large quantities of fission products and, thus, had the potential for exposure to Pu^{239}. Several decades later,

I learned that several dozen of the early Pu^{239} workers at the Los Alamos National Laboratory in World War II had joined together in what they called informally the IPPU Club (Voelz et al., 1997).

Let me leap ahead. In the 1980s, Glenn Seaborg visited the Lovelace Laboratories in New Mexico. During the course of his visit, we discussed studies we were conducting on inhaled Pu^{238} and Pu^{239}. He recalled that when he separated the first microgram quantities of Pu^{239} at the University of Chicago from fuel irradiated in a reactor at Clinton (Oak Ridge), TN, he was concerned about its potential toxicity. He was aware of the unfortunate experience of the Radium Dial painters and did not want to see it repeated with Pu workers. He immediately made arrangements to send a small sample of Pu^{239} to his colleague, Joe Hamilton at the University of California—Berkeley. Hamilton and his team injected Pu^{239} into rats to evaluate its disposition in the body. They found Pu^{239}, an actinide, behaved like the lanthanides and was deposited in both the skeleton and liver unlike the alkaline earth compounds, Ca and Ra, which primarily concentrated in the skeleton. These observations were key to developing and interpreting the urinary bioassay for Pu^{239}, one of the first applications of biomarkers in radiation protection starting in 1945.

In 1950, as a first-year high-school student, I enrolled in the traditional college preparation courses and, in addition, a course in Vocational Agriculture. The latter course had just been initiated in the Richland, WA high school. One of the attractions of the course was that every student also became a participant in a cooperative school farm. The farm had a variety of agricultural enterprises, including maintenance of a large flock of sheep as "off-site" controls for a large research study underway on the Hanford Site of the effects of chronic ingestion of I^{131}. There is not space here to provide supporting details but I think it is safe to assume the development of the Richland Vocational Agriculture program and School Farm was strongly encouraged by government authorities who, at the time, were conducting a large research program to understand the health effects of I^{131}.

Why study I^{131}? I have already noted it is a key constituent in freshly irradiated uranium fuel. On December 2—3, 1949, Hanford conducted a planned study, "Operation Green Run," releasing to the atmosphere 7000 to 12,000 Ci of I^{131}. The study did not go as planned! "Operation Green Run" was an attempt to understand what was happening at a facility the Soviet Union built that "copy-catted" Hanford. These facilities were located at Mayak, Russia, in the Ural Mountains. When the United States detected I^{131} in the atmosphere in 1949, it was assumed that Mayak had begun operations and was producing Pu^{239} for Russian bombs. The question was what does the detection of atmospheric

I^{131} mean in terms of Mayak production of Pu-239? One approach was to assume the Soviets Union, like the United States in early 1945, was eager to produce Pu-239 and that they were processing "green fuel." "Green fuel" is fuel that had been recently irradiated and processed without much time postirradiation to "cool down." Thus, the "green fuel" contains substantial quantities of short-lived fission product radionuclides like I^{131} and its precursors. Very soon it was suggested that "Operation Green Run" be conducted to replicate Hanford operations in 1945 providing an "algorithm" for estimating Mayak production of Pu^{239}. This "experiment" would involve substantial downwind monitoring, including use of air craft with samplers as well-characterized "green" fuel was processed. The anticipated outcome was X quantity of I^{131} in the atmosphere from Y quantity of irradiated fuel yielding Z quantity of Pu-239. "Operation Green Run" provided the answer. However, because an atmospheric inversion set up soon after fuel reprocessing was initiated, eastern Washington was fumigated with I^{131}, physical half-life 8 days, for several days as the I^{131} contaminated cloud failed to dispense as expected. Jumping ahead, a detailed epidemiological study of the "Hanford Downwinders" did not identify any increase in thyroid cancer, over and above background rates, attributable to Hanford releases of I^{131} (Davis et al., 2004).

My experiences at the School Farm also introduced me to the field of biomarkers. In the early 1950s, nuclear weapons testing resulted in airborne radioactivity around the globe; three of the most prominent radionuclides were I^{131}, Cs^{137}, and Sr^{90}. Ingested Iodine-131 goes to the thyroid, Sr^{90} behaving like Ca goes to the skeleton, and Cs^{137} behaving like K is distributed in soft tissues throughout the body. The local grown forage fed the sheep was routinely monitored for I^{131} from fallout and the thyroids of the sheep routinely monitored for I^{131} using external ionization chamber monitors placed over the thyroids. I very quickly deduced that the Hanford scientists were interested in understanding the relationship between I^{131} intake, I^{131} in the thyroid, the estimated radiation dose to the thyroid and potential development of thyroid disease, including cancer. They wanted to make certain they knew the estimated radiation doses to the thyroid the off-site controls sheep were receiving from fallout I^{131}.

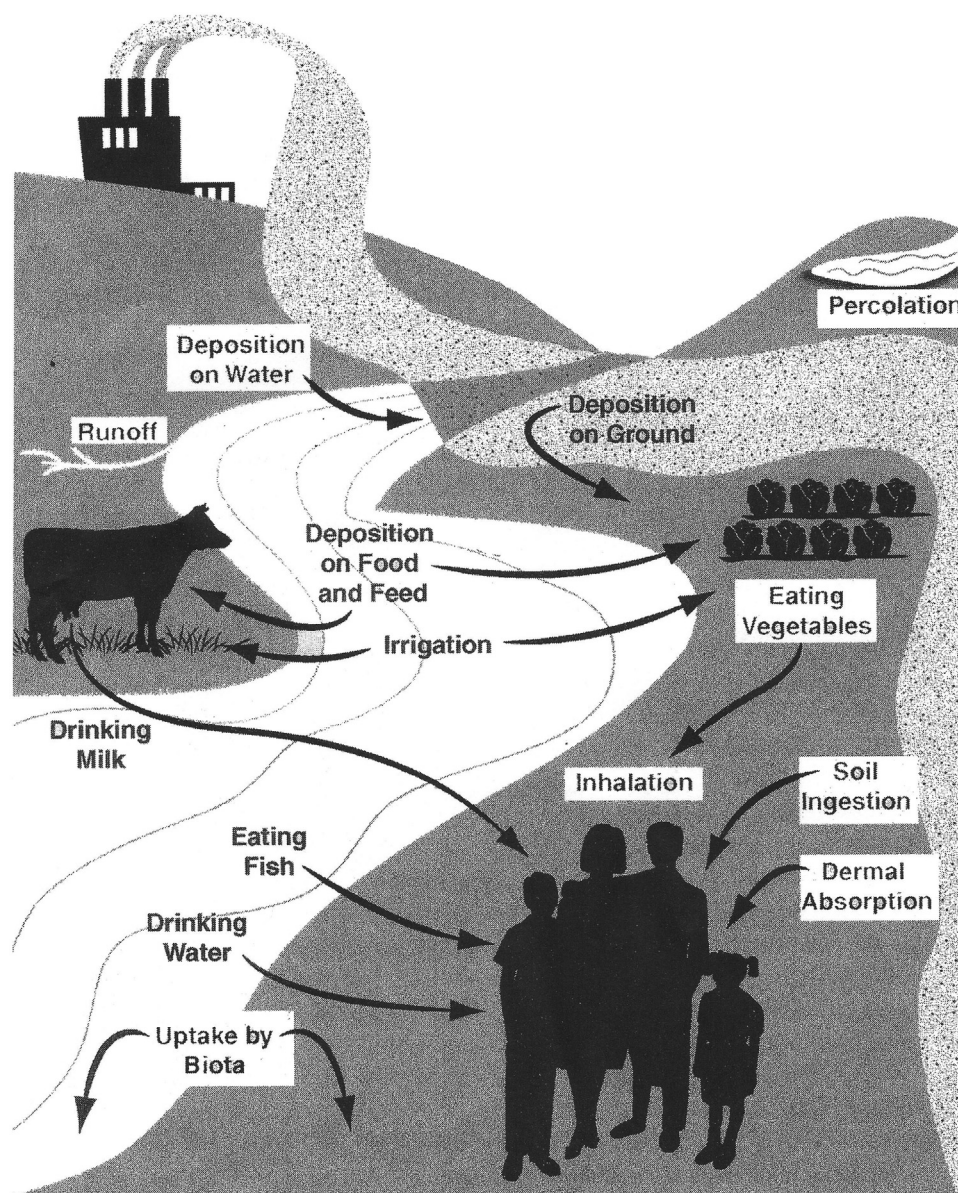
Working at the School Farm, I came in contact with a number of Hanford scientists, including Leo K. Bustad, a Veterinary scientist who would ultimately become my primary mentor. The experience as a high-school student introduced me to issues I would investigate later as a student and then as a staff scientist working in the Hanford Laboratories. The context for much of that research is shown in Fig. 42.7, which can be viewed as an extension of Fig. 42.1.


FIGURE 42.7   Schematic representation of pathways for radioactivity to reach humans (Paustenbach, 2001).

In 1954, I enrolled at Washington State College (now Washington State University) initially studying engineering and economics. In both of these fields, one quickly gains an appreciation for understanding both basic concepts and being quantitative. In 1956, I began my studies in Veterinary Medicine leading to receipt of my Doctor of Veterinary Medicine degree in 1960. In studying medicine, one quickly gains an appreciation for the importance of learning overarching concepts and synthesizing information. As one progresses into clinical medicine, the importance of understanding the role of symptoms and signs in diagnosing and treating diseases becomes apparent. One soon comes to appreciate the difference between symptoms, what the patient is experiencing, versus signs which the diagnostician observes or measures. It also becomes apparent that single signs are rarely pathognomonic of a specific disease. The diagnosis of common diseases usually involves an understanding of a combination of signs and symptoms. A single sign, some of which would clearly qualify for what we now call "biomarkers," is rarely uniquely related to a single disease. The study of infectious diseases leads students to think about exposure to single agents leading to specific diseases, essentially a deterministic relationship. Later, as students encounter more complex diseases, such as cancer (in reality a family of diseases), it becomes apparent that the underlying etiology is frequently multifactorial and the pathogenesis of the disease is quite complex. I will return to this topic later.
FIGURE 42.8   External brief radiation exposures and resulting tissue dose occur simultaneously, whereas the intake of radioactivity results in a tissue dose in a protracted tissue dose.

In the summers of 1957 and 1959, working with Bustad, I conducted research using sheep to compare the effects of brief X-irradiation of the thyroid using an external X-ray beam with the protracted irradiation of the thyroid from the beta-particle emitting I^{131} deposited in the thyroid. The brief exposures to high-dose rate X-rays were much more effective in producing pathological changes than the protracted beta-particle irradiation from the I^{131} decaying in the thyroid. This was a clear example that dose rate matters (Fig. 42.8).

In 1957, as I began my summer internship, Bustad suggested I prepare and present a few brief seminars to junior technicians and animal caretakers to acquaint them with the basic concepts of radiation biology. In retrospect, he was a very positive manipulator. What better way to have me learn basic radiation biology! He gave me a set of reprints that he thought would be helpful to me in preparing the lectures. Included in the stack were copies of the classic paper by Henshaw (1941) and "The Tolerance Dose" document by Cantril and Parker (1945) that I noted earlier which by then had been declassified. Both contained Fig. 42.6. Ironically, the use of the linear, no-threshold relationship is still being debated three quarters of a century later (NCRP, 2018).

In the summer of 1958, I investigated the uptake of various radionuclides, including Zn^{65}, from fresh nuclear reactor effluent water by bean plants, recall Fig. 42.7. I soon became aware of the importance of creating a "source-intake-body burden/tissue distribution-tissue dose-tissue response" paradigm to understand the role of any specific radionuclide toxicant, such as I^{131}, in causing disease. The potential for biomarkers at several steps was immediately obvious.

In 1960, I joined the Hanford Laboratories as a full-time staff scientist. I continued conducting research on I^{131}. This included participation in a landmark study to simulate the effects of an accidental release of I^{131}. Recall the "Green Run" release. In our new study, dairy cows were fed I^{131}, their thyroids and milk monitored for I^{131} and human volunteers drank aliquots of the milk and their thyroids monitored for I^{131} (See Fig. 42.9). The measurements of I^{131} in the cow's thyroid and milk and human thyroid certainly qualified as biomarkers. As an aside, the radiation dose to the thyroids

of the human volunteers was less than received with typical radiographic medical procedures. The interrelationships which were observed proved valuable in predicting potential outcomes following reactor accidents such as those that happened at Windscale (October 10, 1957) in Britain, Chernobyl (April 26, 1986) in the Ukraine, and Fukushima (March 11, 2011) in Japan. Of special note, regulatory officials in Japan, mindful of this data, took action to limit distribution and intake of I^{131}-contaminated milk, thereby minimizing radiation exposure of children and preventing the occurrence of thyroid disease. Intake of I^{131}-contaminated milk was not effectively controlled after the Chernobyl accident, and an increase in thyroid cancer was observed in individuals irradiated as children, in some regions downwind (Lubin et al., 2017). This outcome was consistent with the results of the extensive studies conducted at Hanford with I^{131} (McClellan, 1995).

My primary responsibility at Hanford in the early 1960s was conduct of a large-scale study in miniature pigs ingesting Sr^{90}. The health end points of concern, based on knowledge that Sr^{90} concentrated in bone resulting in irradiation of bone and bone marrow, were induction of bone cancer and hematopoietic tissue dyscrasia. The study was started with three levels of Sr^{90} intake; 1, 5, and 25 μCi of Sr^{90}/day and a control group. When health effects were not observed in the first year, levels of 125, 625, and 3100 μCi Sr^{90}/day were added. In retrospect, the latter two levels were probably overzealous additions—I was a young toxicologist eager to identify effects! It would take more experience before I would understand the need for long-term observations, especially when studying induction of cancer, and the importance of understanding exposure—dose—response relationships. In the early 1960s, scientists were just beginning to think about integrating mutational events with cell killing (recall Fig. 42.5).

The Sr^{90} pig study provided numerous opportunities to characterize potential biomarkers. All the pigs were routinely monitored in a whole-body counter to follow build up of Sr^{90} in the skeleton, routine radiographs were taken of the skeleton to detect any potential tumors, and routine hematological assessments were made anticipating the occurrence of leukemia
FIGURE 42.9 Interrelationships for radioiodine (I[131]): Intake by cows, concentration in cow's thyroid and milk, and human thyroid. *Adapted from Bustad, L.K., McClellan, R.O., Garner, R.J., 1965. The significance of radionuclide contamination in ruminants. In: Physiology of Digestion in the Ruminant. Butterworth, Washington, DC, pp. 131–143.*

(McClellan et al., 1962, 1963a,b; McClellan and Bustad, 1963, 1964; McClellan, 1966). In addition, a number of special studies were conducted to assess bone marrow function, especially the production and survival of erythrocytes and leukocytes (McClellan, 1963; McClellan et al., 1963b, 1964).

One special study is worthy of review. In the fall of 1960, I visited the University of Chicago. I left my visit to the University of Chicago with two new friends, John Doull and Eugene Goldwasser. John would become my mentor in toxicology (McClellan, 2017). Goldwasser, a biochemist, explained the basic concepts of erythropoiesis to me and gave me a small sample of partially purified erythropoietin, the hormone regulating red blood cell production, which he had just discovered. It would take a number of years before human erythropoietin was purified (Miyaka et al., 1977; Goldwasser, 1996). As an aside, the University of Chicago failed to file a patent for this discovery which would later be exploited by others for commercial development. As Goldwasser later related to me, the proceeds from a patent on erythropoietin, if it had been filed and awarded, would have supported his laboratory and that of many colleagues in an elegant manner for their total career.

On returning to Hanford, I immediately set about developing an assay system for erythropoietin using polycythemic mice, created using simulated high altitude exposure to produce hypoxia. The hypoxic mice

begin producing red blood cells ultimately achieving packed cell volumes of 70% or greater. Removed from the high altitude chamber, red cell production ceased. They were now candidates for assaying for erythropoietin. This assay was used to conduct studies to see if I could identify erythropoietin in pigs as an early marker of bone marrow damage. As expected, I did detect circulating erythropoietin in the serum of pigs following removal of large quantities of blood validating the assay system. I also detected elevated levels of erythropoietin in pigs that received large doses of radiation to the bone marrow from ingested Sr[90]. As customary, I promptly published the results in the Hanford Biology Division Annual Report (McClellan, 1963). I was running fast! I did not take time to prepare a paper for publication in a peer-reviewed journal.

Fifteen years later, in the mid-1970s, I attended my first international conference that included scientists from mainland China. After I presented a lecture on the health effects of internally deposited radionuclides, a Chinese scientist asked what my thoughts were on use of erythropoietin as a biomarker for injury from Sr[90]. I was puzzled by what prompted this very specific question and responded that I had done some preliminary research on this subject in the early 1960s. The individual who asked the question and I had a number of conversations at the conference; I was impressed by his substantial knowledge of my past research. When I

returned to the United States, I learned my new friend was the senior-most Chinese official responsible for radiation health effects research and radiation protection across China. He was aware of every publication I and my colleagues ever wrote on radiation and its effects. I did arrange for him to visit our laboratory in Albuquerque, NM. He later arranged for me to visit his laboratory in Peking at the Institute of Radiation Medicine, which he headed, within the Chinese Academy of Military Medicine, as well as other Chinese laboratories. On one of my visits to China, my friend thanked me for the extensive animal studies we conducted on ingested and inhaled radionuclides. He noted the Chinese waited eagerly to see our reports and papers; it minimized their need to conduct similar research.

In 1965–66, I was temporarily assigned to the Division of Biology and Medicine of the US Atomic Energy Commission (AEC) (now the US Department of Energy) in Germantown, MD, a suburb of Washington, DC. At that time, the AEC had a very strong scientific research portfolio, including major research programs in the biomedical and environmental sciences. The Chair of the AEC at that time was Glenn Seaborg. My primary responsibilities were for oversight of the Agency's "internally deposited radionuclide research program" and a very limited program on chemical toxicity. Quite fortuitously for me, I shared an office with Paul Henshaw, the pioneering radiobiologist I mentioned earlier, recall the Henshaw (1941) paper. Paul and I had many conversations fueled by his recalling his participation in research at Oak Ridge as part of the Manhattan Project. He also recalled he was one of the first civilian scientists to visit Hiroshima and Nagasaki following the atomic bombings and had a role in setting up the Atomic Bomb Casualty Commission (ABCC). The AEC assignment was valuable in giving me a contextual understanding of important societal issues concerning radiation that had the potential for resolution through scientific knowledge acquired from well-planned research. My field of vision was broadened to include concerns related to the use of Pu^{238} as a thermal source in space nuclear power systems, the use of nuclear propulsion in naval vessels, and development of conventional uranium-fueled reactors as well as Plutonium Recycle Reactors and Breeder Reactors. The importance of using a "source-intake-dose-mechanisms of action-attributable disease" paradigm as illustrated in Figs. 42.1 and 42.2 was reinforced and the need for considering both exposed individuals and populations became even more apparent.

In the fall of 1966, I joined the Lovelace Foundation for Medical Education and Research in Albuquerque, NM, with responsibility for a research program directed at acquiring information needed to improve the estimates of the consequences of a catastrophic nuclear reactor accident (U.S.AEC, 1957). In a sense, the Institute's mission was to understand the potential consequences of the kind of reactor accident with release of large quantities of radioactive material to the atmosphere as would occur at Chernobyl in the Ukraine on April 26, 1986.

The scope of the Lovelace research program has been described in detail in previous publications (McClellan et al., 1986; McClellan, 2014). Suffice it to note here that numerous life span studies were conducted with fission product radionuclides (Y^{90}, Y^{91}, Cs^{137}, Ce^{144}, and Sr^{90}) that emit beta-particles and gamma-rays as they decay with different half-lives and alpha-particle emitting Pu^{238} and Pu^{239}. Every major study consisted of two phases. Both phases used aerosols that were very well characterized as to their chemical composition and particle size, both real and aerodynamic size. In the first phase, animals were exposed briefly to a well-characterized radioactive aerosol to simulate an accidental intake and then animals followed for variable periods of time before they were euthanized and tissues collected for detailed radiochemical analysis. The goal of these studies was to create a kinetic model to dynamically simulate the retention and tissue distribution of the radionuclide and ultimately serve as the basis for calculating the radiation dose to important organs (see Figs. 42.1 and 42.2).

The second phase involved an evaluation of exposure-related health effects in life span studies. The most significant findings were from the extensive studies using Beagle dogs. The animals were observed clinically for up to the normal life span of control Beagle dogs, about 15 years. Initially, very frequent clinical examinations were conducted with associated hematological and serum biochemical profiles assessed. It soon became apparent that the aggressive schedule of observations was useful in documenting the early and intermediate term deaths. However, they yielded limited scientific information to predict the occurrence of late-occurring deaths. Indeed, it soon became apparent that the best prognostic information on illness in an experimental animal, including the occurrence of cancer, came from the observations of the animal caretakers who had regular contact with the animals. My physician colleagues note this situation is similar to that which they frequently encounter with their human patients.

The major finding from the studies with experiments with Beagle dogs exposed to radionuclides and conducted at Lovelace, the University of California–Davis, University of Utah and Hanford (Pacific Northwest Laboratory) was the marked influence of radiation quality (low-LET radiation vs. alpha radiation) and the radiation dose pattern on life span and cancer induction (McClellan, 2014). Alpha irradiation from Pu^{238} or Pu^{239} was 7.5–12.4 times more potent than beta radiation from Y^{91}, Ce^{144}, and Sr^{90} inhaled in fused aluminosilicate particles for causing lung cancer. A combined
FIGURE 42.10 Relationships between number of subjects required to detect excess risk and the level of detectable excess risk.

Dose, Dose Rate Effectiveness Factor (DDREF) of 2.0 is currently recommended by the ICRP. The information from the dog studies needs to be carefully considered in revision and development of a separate Dose Rate Effectiveness and Dose Effectiveness Factors for use in radiation protection.

As an aside, it is worthy of note that the dog studies with inhaled and ingested radionuclides were not designed to provide support for or against use of the LNT model for radiation-induced cancer. This is the case because of the statistical limitations of the studies based on the size of the populations studied (Fig. 42.10).

Despite the substantial investments made in the last half century in cancer research, few specific markers of prognostic value for detecting cancer have yet been developed. Perhaps the best known is prostate-specific antigen (PSA) for prostate cancer. In my opinion, I am alive today because my prostate cancer was diagnosed 20 years ago based on an elevated PSA measurement which prompted a needle biopsy followed by a radical surgical prostatectomy by a highly skilled surgeon. Fortunately, it was surgically removed before it could metastasize to other sites. Ironically, today routine PSA screening of men over 50 years of age remains controversial with ongoing debate of the benefits and risks of screening of individuals and populations at different ages. It is not enough to have biomarkers available; it is crucial they be used in a thoughtful manner. Let me emphasize that PSA is a useful biomarker of prostate cancer even though we do not yet know the specific etiology of prostate cancer. The challenges of finding biomarkers of pending cancer or even clinically evident cancer are very substantial. The prospect of identifying the etiology (for example, radiation) of a specific cancer even after diagnosis is even more daunting. I will return to that topic later.

BIOMONITORING OF EXPOSURE TO RADIATION

Many individuals and government organizations have noted the need to develop biomarkers of radiation exposure calling attention to the potential for radiation disasters from a nuclear detonation or accident (Ray et al., 2014; Pellmar and Rockwell, 2005). I share these concerns; however, I quickly note that before additional investments are made in this area, the potential funders and researchers are strongly encouraged to review all the previous research and related findings conducted in this area going back to 1946. Many approaches have been tried with very modest success. Indeed, post September 11, 2001, many of the same old approaches dating to the late 1940s and early 1950s were frequently tried again with limited awareness of the past experiences. I am particularly concerned that many government agencies and individual scientists find it convenient to build support for research on any aspect of radiation using widespread "radiation phobia" rather than by conducting a critical assessment of what has been done in the past and is required to develop a strategic assessment of needs and plan of action.

Many of these individuals do not appear to understand why nuclear weapons are of concern as weapons of mass destruction. It is not that they are great sources of radiation! The primary reason is blast overpressure with its tremendous destructive impact, including its lethal and debilitating effects on people, followed by

thermal injury, and then external radiation exposure. Radiation exposure, via inhalation or ingestion of radionuclides from a nuclear detonation, is by comparison with blast, thermal or direct radiation effects, a minor concern. For those not familiar with blast effects, I encourage them to read the classic document, "The Effects of Nuclear Weapons" (Glasstone and Dolan, 1977).

Concern for the health effects of radioactive materials purposefully dispersed is another matter. In my opinion, concerns for such potential releases resulting in overt radiation-attributable health effects have been overstated. The real concern for such accidents is dealing with the fear created by widespread radioactive contamination and potential radiation exposures at even low levels. Yet radiation phobia continues to sell research programs.

Radiation-Attributable Disease

Let us now turn attention to radiation-attributable disease, first addressing the acute radiation syndrome (ARS) followed by consideration of late-occurring health effects focusing on cancer. Mettler and Upton (2008) in their book, "*Medical Effects of Ionizing Radiation,*" provide an excellent review of the medical consequences of radiation exposure from the effects of nuclear detonations as occurred at Hiroshima and Nagasaki and nuclear accidents such as Chernobyl. Tables 42.9—42.11 provide useful summaries of symptoms and signs of ARS.

Many of the signs are indeed biomarkers of acute disease. Their use represents good old-fashioned medical practices to diagnose and treat diseases.

The chapter by Ray et al. (2014) in the earlier edition of this textbook reviews a number of more sophisticated biomarker measurements that may complement traditional, time-tested biomarkers and be useful in the triage of patients and the diagnosis and treatment of exposed individuals. However, I would argue that none of these sophisticated biomarkers offers as much information as one gains with a traditional hematologic evaluation. I am equally pessimistic as to the likelihood of developing a magic pharmacologic pill for treating the ARS, a very complex syndrome.

Late-Occurring Health Effects Attributable to Radiation Exposure

A very large body of information from human populations exists on late-occurring health effects attributable to radiation exposure from both external sources and internally deposited radionuclides, i.e., studies of "human misfortune." The human data have been reviewed by Mettler and Upton (2008), Shore (2013), and, very

recently, by the National NCRP (NCRP, 2018). McClellan (2014) reviewed the human data and also considered in some detail the information on inhaled and ingested radionuclides from life span studies in Beagle dogs.

Some of the major human populations studied following external exposure to X-radiation or gamma radiation are shown in Tables 42.12 and 42.13. Key studies in Beagle dogs are shown in Table 42.14. These studies provide clear evidence that the most significant late-occurring radiation-induced effects are cancers. These cancers occur in many organs of the body with whole-body irradiation and in the most heavily irradiated organs with partial body exposure or internally deposited radionuclides.

The most substantial data base available on late-occurring effects of radiation has been developed on the Japanese A-Bomb survivors. A cooperative program by the governments of Japan and the United States was initiated soon after World War II. The goals were (1) to provide medical care for the Japanese populations exposed at Hiroshima and Nagasaki and (2) conduct research to gain insights into the long-term effects of brief external exposure to radiation. The initial efforts were carried out by the ABCC which later became the Radiation Effects Research Foundation (RERF). Funding from the United States originally came from the US Atomic Energy Commission (now the US Department of Energy) budget and passed through the US National Academics of Science/NRC to RERF. It is important to note that substantial effort has been expanded to estimate the radiation exposure and organ doses for each individual in the ABCC/RERF cohorts. These estimates were developed taking account of precisely where each individual was when the detonations occurred and any shielding between them and the detonation (Cullins et al., 2006; Young and Bennett, 2006).

There are three ABCC/RERF cohorts. The LSS cohort includes 120,321 individuals: 82,214 in Hiroshima and 38,107 in Nagasaki. A second group is a cohort of about 3300 individuals who received their exposure in utero as a result of their mother's whole-body exposure. Information on this cohort has provided valuable insights into the incidence of malformation, growth retardation, microcephaly, and mental retardation related to radiation exposure. A third group is a cohort of 77,000 children born to survivors of the atomic bombing. Observations on this group provide valuable data for assessing heritable effects (Neel et al., 1990; Satoh et al., 1996). Grant et al. (2015) has reported on the risk of death among these children of atomic bomb survivors.

The first report on mortality in the LSS cohort was published by Beebe et al. (1962). The 14th in the series was published by Ozasa et al. (2012, 2013). A more recent publication by Grant et al. (2015) provides

TABLE 42.9 Prodromal Phase of Acute Radiation Sickness (ARS)

Symptoms and Medical Response	Degree of ARS and Approximate Dose of Acute WBE (Gy)				
	Mild (1–2 Gy)	Moderate (2–4 Gy)	Severe (4–6 Gy)	Very Severe (6–8 Gy)	Lethal[a] (>8 Gy)
Vomiting onset	2 h after exposure or later	1–2 h after exposure	Earlier than 1 h after exposure	Earlier than 30 min after exposure	Earlier than 10 min after exposure
% of incidence	10–50	70–90	100	100	100
Diarrhea	None	None	Mild	Heavy	Heavy
Onset	—	—	3–8 h	1–3 h	Within min or 1 h
% of incidence	—	—	<10	>10	Almost 100
Headache	Slight	Mild	Moderate	Severe	Severe
Onset	—	—	4–24 h	80	1–2 h
% of incidence	—	—	50	May be altered	80–90
Consciousness	Unaffected	Unaffected	Unaffected		Unconsciousness (may last sec/min)
Onset	—	—	—	—	Sec/min
% of incidence	—	—	—	—	100 (at >50 Gy)
Body temperature	Normal	Increased	Fever	High fever	High fever
Onset	—	1–3 h	1–2 h	<1 h	<1 h
% of incidence	—	30–80	80–100	100	100
Medical Response	Occupation observation	Observation in general hospital, treatment in specialized hospital if needed	Treatment in specialized hospital	Treatment in specialized hospital	Palliative treatment (symptomatic only)

WHE, whole-body exposure.

information on a longer-term follow-up from 1958 through 2009. Some detailed results from 14th mortality update will be reviewed here. The observed and excess deaths for the LSS cohort through 2003 are shown in Table 42.15. The estimates of ERR for the various causes of death are shown in Fig. 42.11. It is of interest to note that of the 86,601 individuals alive and enrolled in the cohort in 1950, a total of 46,614 individuals or 53.8% of the individuals had died by 2003 with 46.2% were surviving. The 10,929 cancer deaths represented 23.4% of the total number of deaths through 2003. In aggregate, it was estimated, using statistical methods, that 527

[a]Based on the ERR model was defined as the linear model with effect modification: $\gamma_o(c,s,b.a)[1 + \beta_1 d \bullet exp(\tau e + \upsilon 1n(a)) \bullet (1 \sigma s)]$.
[b]Non-neoplastic blood diseases were excluded from noncancer diseases.
Ozasa et al., 2012. Studies of the mortality of atomic bomb survivors, report 14, 1950–2003: an overview of cancer and noncancer diseases. Radiat. Res. 177, 229–243.
FIGURE 42.11 Estimates of excess relative risk (ERR) per Gy and 95% CI for major causes of death. [a]ERR was estimated using the linear dose model, in which city, sex, age at exposure, and attained age were included in the background rates, but not allowing radiation effect modification by those factors. [b]Confidence interval. *Horizontal bars* show 95% confidence intervals. [c]The size of plots for site-specific cancers was proportional to the number of cases. [d]ERR (95% CI) of leukemia was 3.1 (1.8, 4.3) at 1 Gy and 0.15 (−0.01, 031) at 0.1 Gy based on a linear-quadratic model with 318 cases (not displayed in the figure). [e]The lower limit of 95% CI was lower than zero, but not specified by calculation. (1950−2003). *Ozasa, K., Shimizu, Y., Suyama, A., et al. (2012). Studies of the mortality of atomic bomb survivors, report 14, 1950−2003: An overview of cancer and noncancer diseases. Radiat. Res. 177:229−243.* © 2019 Radiation Research Society.

excess cancer deaths among 10,929 deaths from solid cancers were attributable to radiation exposure. Most of these were in groups with colon doses of over 0.1 Gy and over half were in groups with colon doses of over 0.5 Gy. Contrary to common beliefs among the public and many scientists, radiation is not a very potent carcinogen. I strongly suspect most readers of this chapter are surprised by the small number of excess cancers observed to date in the Japanese A-Bomb survivors.
Solid cancer

FIGURE 42.12 Excess relative risk (ERR) for all solid cancers in relation to radiation exposure. The *black circles* represent ERR, and the *bars* are the 95% Confidence Interval for the dose categories together with trend estimates based on linear (L) with 95% Confidence Intervals (*dotted lines*) and Linear−Quadratic (L−Q) models using the full dose range and LQ model for data restricted to dose < 2 Gy. *Ozasa, K., Shimizu, Y., Suyama, A., et al. (2012). Studies of the mortality of atomic bomb survivors, report 14, 1950−2003: An overview of cancer and noncancer diseases. Radiat. Res. 177:229−243. © 2019 Radiation Research Society.*

It is important to note the 527 excess deaths attributable to radiation exposure were estimated using statistical methods. At this time there are no scientific methods for distinguishing which of the cancer cases was caused by radiation exposure versus other causes. To be blunt, none of the cancers carries a sign—"This cancer was caused by radiation!" If biomarkers had existed for identification of developing cancer, they would have been very useful for diagnostic purposes and early treatment. However, it is very unlikely that any of these prospective biomarkers would have identified which of the about 1 in 20 cancers attributable to radiation exposure was actually caused by radiation exposure.

Alternative presentations of the relationship between ERR and dose in the LSS are shown in Figs. 42.12 and 42.13. It is always important to carefully examine the scale on figures. This is a good example of why that is important. Fig. 42.12 at a glance appears to show a linear, no-threshold dose−response relationship, and Fig. 42.13 appears to illustrate a clear threshold. Now note the difference in the scales. Fig. 42.12 has an arithmetic horizontal scale and Fig. 42.13 is logarithmic. When the difference in scales is considered, it is apparent that in both figures, using the same data, with alternative dose−response models, the results are not remarkably different. How many angels can dance on the head of a pin? It depends on the size of the pin! These two figures are germane to the argument of whether the cancer response per unit dose follows a linear no-threshold relationship or not. Recall that Henshaw (1941) raised this issue (Fig. 42.4). Three quarters of a century later, the issue is still being debated. Some individuals, such as Clarke (2008), a former chair of the International Commission on Radiation Protection, have argued that the specific shape of the curve relating excess cancer risk to exposure levels approaching background is irrelevant to the setting of radiation protection standards (Fig. 42.14).
FIGURE 42.13 Excess relative risk (ERR) for all solid cancer in atomic bomb survivors in relation to radiation exposure. The *black circles* and *error bars* represent ERR and 95% CIs for the dose categories. *Solid line*—fit to the ERR data using a multiple linear regression in which weighted log colon dose was entered into the model using a restricted cubic spline transformation with five knots. Regression weights were equal to the inverse of the variance of the point estimates. *Dashed lines* are 95% CI of the fit. Figure from performing analysis equivalent to (Doss et al., 2012) with the corrected data in Ozasa et al. (2013). *Doss, M., Egleston, B.L. & Litwin, S. In the United States, the NCRP has recently released a commentary addressing implications of recent epidemiologic studies for the use of the linear, non-threshold model for radiation protection (NCRP, 2018). This very comprehensive report evaluated 29 major populations with published reports on cancer and radiation exposure based on (1) dosimetry, (2) epidemiological, and (3) statistical considerations to assess their (4) overall support for using or not using a linear, non-threshold model for radiation protection purposes. The results are summarized in Table 42.16.

The NCRP Commentary concludes "that no alternative dose-response relationship appears more pragmatic or prudent for radiation protection purposes than the LNT model." I fully concur.

In my opinion, the continuation of the LNT debate over the past 75 years relates in part to the debate rarely being properly framed with several groups of scientists talking past each other. In some cases, individuals have entered the debate on the use of LNT models for setting radiation protection standards with a lack of understanding of how radiation protection standards are set. Few of the radiation protection standards or regulations are actually set based on achieving some specific risk target, i.e., less than one extra cancer over a lifetime in a population of 10,000 individuals. Rather, the numerical radiation protection standards were initially set based on scientific judgment and have evolved over time. Post hoc analysis can provide estimates of excess risk for a given numerical standard. However, those results should not be confused with setting a standard based on achieving a risk limit.

PATH FORWARD

Information from a NRC Biological Effects of Ionizing Radiation VII Report (NRC, 2006) can be used to illustrate some of the challenges faced in development of biomarkers of cancer, including those attributable to exposure to ionizing radiation. That report indicated "a comprehensive review of biological and biophysical data supports a 'linear-no-threshold' (LNT) risk model — that the risk of cancer proceeds in a linear fashion at lower doses without a threshold and that the lowest dose has the potential to cause a small increase in risk to humans." The report defined low doses as those in the range of near zero up to about 100 mSv (0.1 Sv) of low-LET radiation. The BEIR VII Committee was so bold as to suggest approximately one extra cancer would occur in 100 people from a single 100 mSv exposure to low-LET radiation in addition to the 42 cancers that would be diagnosed with cancers from causes unrelated to radiation (Fig. 42.15). In this figure, each of 100 hypothetical individuals is represented by a symbol. The 57 open circles are individuals that died without cancer. The 42 darkened circles are individuals that died with cancer attributed to causes other than radiation. The single star is an individual that died with cancer statistically attributed to radiation exposure. It is immediately clear from the figure that cancer is a very common disease. Most of these cancers occur late in life and, thus, as life spans are extended more cancers are likely to be observed. The competition between cancer, cardiovascular disease, and other causes of death continues! Most of the observed cancers caused the

[a]A representative recent publication is listed for each study. Others are found in the text.

[b]Judged quality of the dosimetry, epidemiology, and statistics scores: 1 = weak-to-moderate, 2 = moderate, 2.5 = moderate-strong, 3 = strong.

[c]Ratings of the support for LNT: 1 = essentially no support (null or negative; or unreliable and inconclusive), 2 = weak-to-moderate support, 3 = moderate support, 4 = strong support. Study ratings were based on reported solid cancer (or close surrogates) risk unless noted otherwise.

[d]Studies excluded: ecological studies of risks around nuclear sites (no dosimetry and extremely low exposures); the 15-Country worker study and other studies that overlap with the more recent INWORKS; the MPS is not yet completed, but published components of it are included separately; studies of genetic effects (since no human heritable risks have been shown); studies of tissue reactions (because these are generally not believed to be LNT).

[e]The dosimetry used in the Preston et al. (2016) study of breast cancer, based on the Simon et al. (2014) dosimetry, is significantly improved and would be rated "2" compared with the dosimetry that was used in other published epidemiologic analyses of this cohort. However, since little other epidemiology has been published using the new dosimetry, for the purposes of this Commentary, these studies are limited in their support for LNT.

[f]Considered "weak" support or "inconclusive" primarily because of weaknesses in the epidemiology, dosimetry or statistical risk modeling. The other studies scored as 1 (no support) had reasonable methodologies but provided little or no support for the LNT model because their risk coefficients were essentially zero or negative.

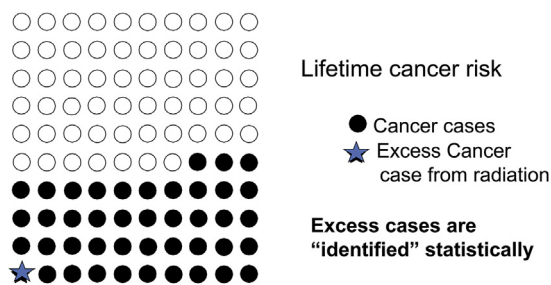
[g]Fallout studies were included as a group (they mostly had little or poor dosimetry and many were studies of aggregates rather than individuals, however, the Hanford ^{131}I fallout study was of better quality, so was identified separately).


FIGURE 42.15   Linear, no-threshold exposure—response model; Science or Policy?

death of the individuals because cancer treatment in general is not highly effective, although it can extend the life span of some of the treated individual.

In my opinion, the NRC committee grossly understated the uncertainties in their estimates. Yes, the number of background cancer cases can be estimated, indeed, extrapolated from past experience with reasonable certainty. However, in my opinion, the extra case estimated from the baseline cancer rate and a highly uncertain estimate of the potency of radiation for projecting an ERR for single 100 mSv exposures of the population is a highly uncertain! Nonetheless, let us use the BEIR VII Committee results as a basis for considering where future investments in cancer and biomarkers research might yield the greatest benefits to Society-at-large.

It is obvious that any increase in knowledge that will aid in earlier diagnosis and treatment of the baseline cancer cases, irrespective of their etiology, will yield a positive net benefit to Society. By comparison, the development and use of any potential biomarkers to diagnose and treat cancers, the relatively rare cancers uniquely caused by radiation exposures below 0.1 mSv will have a trivial benefit to Society. The radiation-attributable cancer is only one of 43 cancers in the example. I expressed the view earlier that much of the radiation-related biomarker research had been spurred by "radiation phobia." The impact of "radiation phobia" including that generated by the BEIR VII report may have negative impacts if it discourages the use of medical procedures that involve exposure to ionizing radiation resulting in less effective medical care. I conclude that it is important for Society-at-large to focus scientific and financial resources on developing and using "biomarkers" for all cancers whose early diagnosis and treatment will yield the greatest benefit to Society.

A paper by Cohen et al. (2018) offers promise for development of useful "biomarkers" for early diagnose and treatment of cancer. Their large team reported a new single blood test, Cancer SEEK, that screens for cancers in the ovary, liver, stomach, pancreas, esophagus, colorectum, lung, or breast. Consideration of the occurrence of cancer in different organs in the A-Bomb

survivors indicates that if this test can be validated by large population studies, it could be very useful. A large portion of the cancers in the A-Bomb survivors were in the eight organs studied by the Cohen team, see Fig. 42.11. Recalling the size and duration of the LSS cohort study helps one understand the challenge of validating Cancer SEEK, it will require the study of a very large population over a number of years.

At this juncture, let me note that starting in 1998, the US Department of Energy initiated a low dose radiation research program that continued for just over a decade. The origin of the program, its etiology, research content, and major findings have recently been reviewed by Brooks (2018), who served as Chief Scientist for the program. At its initiation, a decision was made to focus on doses of less than 0.1 Gy of low-LET ionizing radiation. Early in the program, a decision was made to focus on the use of recent advances in modern molecular biology. To a large extent, the research program consisted of individual investigator—originated research efforts on adaptive responses, genomic instability, and bystander effects in cells. Very few of the research projects include direct linkages to observations of cancer in humans or laboratory animals. The program generated many findings reported in peer-reviewed publications. Some of the observations made clearly qualify as biomarkers of radiation exposure and response. It is not clear if the collective findings have had significant impact on the central issue of the relationship between low doses of radiation, typically given over short periods of time, and the occurrence of excess cancer, over and above background incidence.

A survey of many of the papers cited by Brooks (2018) and the earlier radiation biomarker chapter by Ray et al. (2014) reveals that most of the past research, to better understand early markers of radiation-induced disease, has used experimental designs and related statistical approaches useful for "deterministic" or threshold dose—response relationships. The approaches, appropriate for stochastic responses, routinely used in epidemiological investigations, have rarely been used in the experimental studies. There appear to be a substantial "disconnect" between the experimental studies and the "stochastic" end point of primary concern—cancer in humans.

In designing future biomarker studies, it is important to recall that health end points, like cancer, occur in a time and dose-dependent manner following brief or protracted radiation exposure. There are many reasons to anticipate that biomarkers of intermediate events leading to cancer will also have time and dose-dependent relationships. Future studies need to be designed to identify these relationships. Studies of biomarkers of effects that utilize single doses and only a few observational times are unlikely to yield very

much useful information. Unfortunately, in the past many studies have been conducted without taking account of these considerations.

One approach to bridging this gap may be increased use of biologically based models of carcinogenesis as pioneered by S. H. Moolgavkar (Moolgavkar, 2016, 1977, 1978, 1986, 1990, 1994, 2004; Moolgavkar and Knudson, 1981; Moolgavkar et al., 1999; Little et al., 2008). Such models allow the integration of multiple kinds of data in a quantitative manner with linkages to the end point of concern—cancer as it occurs in age-related fashion over the lifetime of individuals in populations. The world of experimental observations needs to be merged with the real world of epidemiological findings on human populations!

Although this chapter specifically addresses ionizing radiation, the lessons learned from experience with radiation should also be applied to chemical agents. Some individuals might argue that both radiation and chemicals may provide model systems for development of biomarkers of cancer. I find that argument unconvincing if it focuses on cancers produced by high dose exposures to either radiation or chemicals. These are the cancers that are most likely to have unique characteristics related to radiation and chemical exposure compared with cancers of unknown etiology.

We need to collectively develop a new strategic approach to planning and conduct of our biomarker research. With a very few exceptions, it is clear that today's science is not adequate to identify the etiology of the vast majority of cancers observed in populations in countries with well-developed economies such as the United States with populations that have long life spans which allow a large portion of the population to develop cancer. In my opinion, focusing research on radiation and chemical caused cancer is unlikely to help understand the real major factors that cause the cancers diagnosed in about 40% of the population over their lifetime.

Biomonitoring Exposures to Carcinogens

Sofia Pavanello, Marcello Lotti

Dipartimento di Scienze Cardio-Toraco-Vascolari e Sanità Pubblica, Università degli Studi Padova, Padova, Italy

INTRODUCTION

A wide array of analytical tools exists to assess biological parameters, referred to as biomarkers, which are used in clinical medicine as indicators of normal or pathological processes and pharmacological responses (Biomarkers Definitions Working Group, 2001). However, in environmental and occupational health the term biomarker is used somehow differently, indicating signaling events in biological systems or samples (NRC, 1987) that are aimed at preventing adverse effects of exposures (Angerer et al., 2007). A procedure known as human biomonitoring measures the size of human exposures to chemicals (Angerer et al., 2011), their biochemical effects (Mateuca et al., 2012), and individual susceptibility (Christiani et al., 2008). Data obtained from this procedure are used for a variety of purposes including risk assessment, the setting and the compliance to occupational and environmental limits of exposure, and in molecular epidemiology.

Biomonitoring of carcinogens, however, requires a unique conceptual framework because cancer is thought to be the long-term result of multiple causal interactions between environmental and genetic/epigenetic factors (Thomas, 2010). Factors involved in cancer causality include both external (pollutants, diet, drugs) and internal (hormones, human, and microbial metabolites) environments, collectively known as the exposome that vary both quantitatively and qualitatively throughout the lifespan (Rappaport and Smith, 2010). Exposome research was thought as a complement to the genome sequencing, but because of its complexity it is at an early stage of development (Dennis et al., 2017). Several genetic/epigenetic players are also involved in cancer initiation and development, and different pathways and sequence of events within variable time frames may be activated even in the same type of cancer (de Vogel et al., 2009). Mutations may occur on different components of a given signaling pathway, each mutation associated with a different cancer (Jakowlew, 2006), and players may even change their role as it occurs when a tumor suppressor gene switches into an oncogene (Abbas and Dutta, 2009) and when autophagy favors or hinders the carcinogenic process (Choi et al., 2013). Consequently, every individual tumor even of the same histopathological subtype as another tumor is distinct with respect to its genetic alterations and development, though the pathways affected in different tumors may be similar (Vogelstein et al., 2013), and the mutation pattern of individual cells may vary even within the same tumor (Gerlinger et al., 2012).

The variety and variability of environmental and genetic/epigenetic factors in the development of cancer may explain the large interindividual differences in susceptibility to the disease, but they also hamper the understanding of the significance of biomarkers used to monitor carcinogen exposures (Pavanello and Lotti, 2012). In fact none of these biomarkers, used either alone or in combination, are able to capture the complex dynamics of both exposures and carcinogenesis (Lahiri, 2011). This chapter summarizes biomarkers currently used for carcinogen biomonitoring and highlights their values and limitations, restricting the examples of exposures to those chemicals classified in groups 1 and 2A by the International Agency for Research on Cancer (IARC, 2011).

ASSESSING EXPOSURES

Chemicals and Metabolites

Current exposures to carcinogens, mainly at work places, are estimated by measuring either the chemical itself or its metabolite(s) in body fluids (Tan et al., 2012). Examples are many folds. Metals such as arsenic, cadmium, lead, and nickel are measured in urine and blood (Becker

et al., 2013; Wilhelm et al., 2004), the hydroxylated metabolites of pyrene, phenanthrene, and naphthalene (Campo et al., 2010; Pesch et al., 2011), and their hydroxyl-nitrated analog such as hydroxy-1-nitropyrene and hydroxy-N-acetyl-1-aminopyrene in urine (Miller-Schulze et al., 2013), dioxin and nondioxin-like polychlorinated biphenyl in plasma (Schettgen et al., 2012) and mother milk (Mannetje et al., 2012) lipids, and benzene in blood, urine, and expired air with its metabolites S-phenylmercapturic and t,t-muconic acids in urine (Egeghy et al., 2003; Weisel, 2010). A broad spectrum of carcinogenic aromatic amines has also been detected in urine samples such as o-toluidine (Kütting et al., 2009; Richter, 2015) and 4-aminobiphenyl (Ward et al., 1996; Riedel et al., 2006). However, these tests have little or no value in assessing the risk of developing cancer. When they have been used for that purpose, as for instance to assess lung cancer risk in smokers and health risk in benzene exposure, results appear either somehow obvious and redundant or difficult to be interpreted. For instance a prospective nested case-control study shows that urinary levels of 4-methylnitrosamino-1-(3-pyridyl)-1-butanol, a metabolite of the tobacco-specific compound 4-methylnitrosamino-1-(3-pyridyl)-1-butanone, and cotinine a metabolite of nicotine were both associated with risk of developing lung cancer in a dose-dependent manner (Yuan et al., 2009). However, individuals of the cohort that developed lung cancer had higher numbers of pack-years of smoking than those remaining cancer free, suggesting that the self-reported smoking history may be enough to assess cancer risk. Even when specific biomarkers of exposure and large amounts of data are available, such as in the case of benzene, the interpretation of biomonitoring data of exposure for human risk assessment presents several problems, as recently outlined (Arnold et al., 2013). These include issues associated with the short half-life of this chemical and gaps in knowledge regarding the relationship between the biomarker and subsequent toxic effects.

Undoubtedly, the ability to detect hazardous substances and their metabolites in body fluids now seems to far exceed our understanding of their biological significance. In this respect the relative role of these biomarkers, as compared with other information, has been defined within a framework for biomonitoring guidance values aimed at assessing risk (Bevan et al., 2012). At present, the body fluid concentrations of chemicals and metabolites may be useful to assess the hygienic conditions and practices at work place and also to comply with reference values and limits of exposure, when available. However, even for these purposes, caution should be exercised because gender differences may blur the picture as shown by urinary t,t-transmuconic acid in female workers, which was higher than that of male workers exposed to benzene at comparable levels of exposure (Moro et al., 2017).

DNA and Protein Adducts

Adduct formation is the result of the covalent binding between reactive electrophilic substances and the nucleophilic sites of DNA and proteins. The preferred sites for adduct formation are guanine with five nucleophilic sites on DNA and the sulfhydryl group of cystein, the nitrogen of histidin, and the N-terminal valine on proteins. DNA adducts, such as those detected with ^{32}P-postlabeling and immunoassay methods, have been measured in lymphocytes of workers with different exposures. However, these adducts are nonspecific because the responsible electrophilic substance cannot be identified. These studies include workers exposed to polycyclic aromatic hydrocarbons (PAHs) in iron foundries (Santella et al., 1993), coke oven plants (Brescia et al., 1999), aluminum plants (van Schooten et al., 1995), garages, car repair shops (Nielsen et al., 1996a), rubber industries (Peters et al., 2008), shipyards (Lee et al., 2003), and incineration facilities (Lee et al., 2002). In this way other exposures to PAHs have been assessed in bus drivers (Nielsen et al., 1996b; Hemminki et al., 1994), asphalt workers (McClean et al., 2007), policemen (Binkova et al., 2007), US army soldiers (Poirier et al., 1998), and dietary exposures as well (Kang et al., 1995).

Further examples of these nonspecific DNA adducts include those measured in subjects occupationally exposed to diesel exhaust (Scheepers et al., 2002), epichlorohydrin (Plna et al., 2000), and benzidine and benzidine-based dyes (Zhou et al., 1997). Another adduct, which is nonspecific because it is a biomarker of endogenous DNA oxidation, is the 8-hydroxy guanidine (Pilger and Rüdiger, 2006) that was measured in individuals exposed to PAHs (Marczynski et al., 2009; Chen et al., 2011; Huang et al., 2012), chromium (Zhang et al., 2011), polychlorinated dibenzodioxins, polychlorinated dibenzofuranes, polychlorinated biphenyls (Wen et al., 2008), and benzene (Yoshioka et al., 2008) and in smokers (Manini et al., 2010).

Other studies adopted chemical-specific methods such as mass spectrometry detection and include measurements of alkyl-DNA adducts such as N7, N2-alkylguanines (Boysen et al., 2009), O-6-methylguanine (Reh et al., 2000), N7-(2-hydroxyethyl)guanine (Huang et al., 2011), and etheno-adducts such as 1,N6-ethenoadenine, 3,N4-ethenocytosine, 1,N2—ethenoguanine, and N2,3-ethenoguanine (Bartsch and Nair, 2000). Examples of chemical-specific DNA adducts that have been measured in lymphocyte DNA and urine

after exposures to benzo(a)pyrene and aflatoxin are reported in Table 43.1.

The major advantage of measuring chemical-specific DNA adducts is to offer an assessment of the dose of carcinogens close to the molecular target. However, it is unclear how accurate this assessment would be because rate and speed of repair of the various DNA adducts are unknown. In addition, because DNA adducts are measured in peripheral blood leukocytes they may not represent those formed at the DNA of target organs.

Adducts to hemoglobin and serum albumin have been measured after exposure to a variety of electrophilic carcinogens and have been recently reviewed (Sabbioni, 2017; Sabbioni and Turesky, 2017). Table 43.2 shows examples of these adducts that have been detected using chemical-specific methods. However, these also include nonspecific adducts because they are formed endogenously such as alkyl-adducts cleaved at the N-terminal valine of hemoglobin and chemical-specific adducts, both quantified by mass spectrometry. Advantages of measuring hemoglobin and serum albumin adducts include the amount of protein present in blood, which is larger than that of

[b]Chemical is released after mild alkaline or acidic hydrolysis.

nuclear DNA, and their stability as opposed to DNA repair capabilities. In the case of hemoglobin adducts, they represent a measure of short-term cumulative exposure, given the long life span of red blood cells (Tornqvist et al., 2002). Nevertheless, it should be made clear that these proteins do not represent the target of carcinogenic substances.

Finally, as for the concentrations of chemicals and their metabolites in body fluids, DNA and protein adducts represent snapshot measurements that are not representative of doses of carcinogens that may cause cancer after prolonged exposures. However, attempts have been recently made to extrapolate lifetime risks from spot biomarkers data sets using a statistical approach (Pleil and Sobus, 2013).

ASSESSING EFFECTS

Chromosomal Aberrations and Sister Chromatid Exchanges

Cytogenetic alterations in cultured peripheral blood lymphocytes, such as chromosomal aberrations (CAs) and sister chromatid exchanges (SCEs), have been used as biomarkers of exposure to and early effects of carcinogens. CAs are structural aberrations including chromosome-type and chromatid-type breaks and rearrangements, usually analyzed by light microscopy from Giemsa-stained metaphase specimens or by fluorescence microscopy using in situ hybridization (Albertini et al., 2000; Norppa, 2004). SCEs are interchanges of DNA replication products between sister chromatids thought to represent homologous recombination repair of DNA double strand breaks (Johnson and Jasin, 2000). SCEs are analyzed by fluorescence microscopy from second division metaphases after bromodeoxyuridine staining (Albertini et al., 2000; Norppa, 2004). Several studies reported increased frequencies of SCE (Miner et al., 1983; Bender et al., 1988; Kalina et al., 1998) and CAs (Bender et al., 1988; Reuterwall et al., 1991; Forni et al., 1996; Kalina et al., 1998) in workers exposed to PAHs. Few studies, where internal exposure to PAHs was quantified, reported rather small increases and high variability of SCE frequencies (Buchet et al., 1995; Popp et al., 1997; Siwińska et al., 2004; van Delft et al., 2001; van Hummelen et al., 1993). In addition, the study of Siwińska et al. (2004) measured CA frequencies but no increases were observed.

Because an increased number of CAs is a marker of genomic instability (Fenech, 2006), an event occurring at early stages of carcinogenesis, a large international prospective study was undertaken. Results show that an increased frequency of CAs (Bonassi et al., 2008),

but not of SCEs (Norppa et al., 2006), in peripheral lymphocytes predicts cancer risk and, in particular, the risk of stomach cancer was associated with increased frequency of ring chromosomes. However, the association was weak and independent from known exposures to carcinogens, such as smoking and occupation. Several reasons might account for this lack of association considering that several confounding factors such as age (Bolognesi et al., 1997), sex (Bonassi et al., 1995), and smoking (Wang et al., 2012a,b) might influence the frequencies of SCE and CA in peripheral blood lymphocytes.

Micronuclei

Micronuclei (MN) are small, extranuclear bodies identifiable by light microscopy arising in cells dividing from fragments (without centromere) or whole chromosomes/chromatids lagging behind in anaphase. MN can result from a large spectrum of mechanisms including misattachment of tubulin, defects in kinetochore proteins or assembly, late replication, epigenetic modifications of histones, nucleoplasmic bridge formation, and gene amplification (Fenech et al., 2011). They may be formed spontaneously as a mechanism to remove extra DNA (Shimizu et al., 2007) or during normal development from progenitor cells (Peterson et al., 2008). They may also result from exposure to clastogens or aneugens. MN frequencies have been analyzed in various cell types (peripheral lymphocytes, erythrocytes, and exfoliated epithelial cells) and used to monitor genetic damage in humans. The cytokinesis-block micronucleus test in cultured human lymphocytes is the preferred method for measuring MN (Fenech et al., 2011). This method can also be used to measure nucleoplasmic bridges, a biomarker of dicentric chromosomes, and nuclear buds, biomarkers of gene amplification. The simplicity of MN assay led to its exponential use worldwide and guidelines are available for its uses in human biomonitoring (Albertini et al., 2000; Fenech, 2007).

MN frequencies are higher in women than men and increase with age (Kirsch-Volders et al., 2011). Examples of the uses of this biomarker assessing PAH and vinyl chloride exposures are given in Table 43.3. Although almost all studies on vinyl chloride workers show increased MN formation (Bolognesi et al., 2017), even after different cumulative exposures, the results on PAHs show that at certain low levels of exposures they are not associated with increased MN frequencies.

Increased MN frequencies in lymphocytes were found to be predictive of cancer risk in one large prospective study (Bonassi et al., 2007). Although the association was weak and independent from exposures

to carcinogens, such as smoking and occupation, this study is worth to be mentioned because it is one of the few that provides a prospective assessment of cancer biomarkers.

Comet Assay

The comet assay is a single-cell gel electrophoresis method for measuring DNA strand breaks in cells. Cells embedded in agarose on a microscope slide are lysed with detergent and high salt to form nucleoids containing supercoiled loops of DNA linked to the nuclear matrix. Subsequent electrophoresis at high pH results in structures resembling comets, observed by fluorescence microscopy. The intensity of the comet tail relative to the head reflects the number of DNA breaks. The likely explanation for comet tail formation is that loops containing a break lose their supercoiling and become free to extend toward the anode (Tice et al., 2000; Collins, 2004). Besides single-strand DNA breaks, alkali labile sites (apurinic/apyrimidic sites), cross-links, and incomplete DNA repair sites in individual cells can be detected. This technique has been further modified to detect specific classes of DNA adducts, e.g., thymidine dimers, oxidative damage by using lesion-specific antibodies and specific DNA repair enzymes (Lorenzo et al., 2013). The comet assay has been used in molecular epidemiology as a biomarker of effects of occupational exposures, and Table 43.4 shows examples of studies on white blood cells of workers with different exposures to carcinogens. Results appear inconsistent. In addition, several studies have been published where the effects of occupational exposures in the production and application of pesticides have been evaluated (Bhalli et al., 2006; Bian et al., 2004; Garaj-Vrhovac and Zeljezic, 2002; Paz-y-Miño et al., 2004), even if the qualitative and quantitative assessments of exposure are often missing. The comet assay can be applied to a broad spectrum of cells such as white blood, buccal, nasal, sperm, and exfoliated cells from urinary tract and lachrymal ducts, although technical variables should be carefully controlled both within and across laboratories. Besides exogenous exposures such as smoking, diet, and drinking habits another confounding factor is the basal level of DNA damage that is influenced by endogenous exposures such as oxidative stress.

Specific Gene Mutations

Mutant forms of the proteins p53 and p21 encoded by p53 tumor suppressor gene and Ki-ras oncogene are detectable in blood serum by specific monoclonal antibodies and have been used to monitor exposures to carcinogens (De Vivo et al., 1994; Trivers et al., 1995). Table 43.5 shows examples of measurements of mutated p53 and p21-ki-ras proteins in serum of workers exposed to vinyl chloride as compared with controls and across different exposures.

Although mutated p53 was found in liver angiosarcomas that rose in workers exposed to vinyl chloride (Hollstein et al., 1994), and 5 out of 15 workers affected by angiosarcoma were positive for serum-mutated p53, only 2 out of 77 exposed individuals were positive before the development of neoplasia. These results raise the question as to whether these are biomarkers of early effect or disease.

In general, the use of these biomarkers to monitor exposures to carcinogens underestimates the complexity of cancer development. Cancer cells acquire their

characteristics using different strategies and players (Hanahan and Weinberg, 2011), and the time for a given gene alteration to occur varies during the development of the same cancer type (Guimaraes and Hainaut, 2002; Letouzé et al., 2017).

Telomere Shortening

Telomeres are DNA repeat sequences (TTAGGG) that, together with associated proteins, form a sheltering complex that caps chromosomal ends and protects their integrity (Chan and Blackburn, 2004). Because of limitation of DNA polymerase (telomerase), chromosomal stability is gradually lost as telomeres shorten with each round of cell division (Harley et al., 1990). Consequently, telomere length shortening is considered a cellular marker of biological aging (Mather et al., 2011).

Epidemiological retrospective (Broberg et al., 2005; Hou et al., 2009; Jang et al., 2008) and prospective (McGrath et al., 2007; Willeit et al., 2010) studies show that individuals with shorter telomeres in peripheral blood leukocytes have a higher risk of cancer.

Telomeres, as triple guanine−containing sequences, are highly sensitive to damage by oxidative stress (von Zglinicki, 2002), alkylation (Petersen et al., 1998), or ultraviolet irradiation (Oikawa et al., 2001). Telomere shortening have been associated with exposures to ionizing radiation (Ilyenko et al., 2011), alcohol (Pavanello et al., 2011), N-nitrosamines (Li et al., 2011a,b), PAHs (Pavanello et al., 2010), benzene (Hoxha et al., 2009), and polychlorinated biphenyls (Ziegler et al., 2017). Although the shortening can be further accelerated by internal stressors such as oxidative stress (von Zglinicki, 2002; Epel et al., 2004), its use is hampered for the assessment of occupational exposure effects.

Epigenetic Changes

The term "epigenetics" literally means "above the genetics," and it is generally used to refer to

modification of gene expression without a change in the DNA sequence. Epigenetic changes include DNA methylation at the carbon-5 position of cytosine in CpG dinucleotides, changes of chromatin by posttranslational histone modifications, and miRNA expression (Pogribny and Rusyn, 2013). Epigenetic signatures can be transmitted through generations, may reflect the prenatal environmental exposure, and may persist when exposure ends.

A variety of environmental pollutant exposures is linked with epigenetic variations in blood leukocytes. These variations induced by human genotoxic carcinogens have been recently reviewed (Marrone et al., 2014; Chappell et al., 2016). Most studies assessed exposures to carcinogenic metals where, for instance, blood arsenic was associated with global hypermethylation (Pilsner et al., 2007), or hypomethylation at higher concentrations (Pilsner et al., 2011; Lambrou et al., 2012). Prenatal lead exposure was associated with increased methylation of long interspersed nuclear element-1 (LINE-1) and short interspersed repeated DNA elements (SINEs). The latter named Alu repeats represent a surrogate measure of global methylation (Pilsner et al., 2012).

Exposure to particulate matter rich in lead, cadmium, and chromium was associated with increased miR-222 and miR-21 expression (Bollati et al., 2010), whereas that rich in nickel and arsenic was positively correlated with both histone 3 lysine 4 dimethylation (H3K4me2) and histone 3 lysine 9 acetylation (H3K9ac) (Cantone et al., 2011). Occupational exposure to nickel was associated with increased histone 3 lysine 4 trimethylation (H3K4me3) and decreased histone 3 lysine 9 dimethylation (H3K9me2) (Arita et al., 2012).

Benzene exposures of gas-station attendants and police officers were associated with reduction of LINE-1 and Alu methylation. Benzene exposure was also associated with hypermethylation of p15 gene and hypomethylation of the melanoma antigen family 1 (MAGE-1), a tumor-associated antigen in hematological malignancies (Bollati et al., 2007). PAH exposures were associated with hypermethylation of LINE1 and Alu (Pavanello et al., 2009) and p53 hypomethylation (Pavanello et al., 2009; Alegría-Torres et al., 2013). An inverse linear relationship between plasma persistent organic pollutants and polychlorinated biphenyls and Alu methylation was observed in Inuit individuals that have the highest reported levels of persistent organic pollutants worldwide (Rusiecki et al., 2008). However, it is not clear how these associations between epigenetic modifications and exposures reflect cancer risk.

ASSESSING SUSCEPTIBILITY

The phenotypic variability of xenobiotic metabolism and DNA repair may confer susceptibility to cancer development. The genetic polymorphism of enzymes involved in these processes accounts for these variabilities. Thus, the polymorphisms of both phase I enzymes involved in bioactivation of carcinogens and phase II enzymes involved in detoxification modulate the size of dose at the target. The polymorphism of enzymes involved in DNA repair mechanisms influences the persistance of DNA damage, but the majority of associations between DNA repair gene variants and cancer risk have not been replicated (Vineis et al., 2009). Table 43.6 shows examples of phases I and II and of DNA repair polymorphic genes that have been used as biomarkers of susceptibility in biomonitoring studies.

These biomarkers of susceptibility have several limitations (Ketelslegers et al., 2008) when considering the multiplicity of metabolic pathways that take place concurrently at different rates. Therefore, by assessing one or fewer metabolic pathways the amount of ultimate carcinogen(s) can hardly be predicted. In addition, the risk conferred by single variants is quite small, as shown in genome-wide association studies (Manolio et al., 2009). Finally, genetic screening in occupational settings is ethically questionable considering that primary prevention should represent the option of choice (Christiani et al., 2008).

NEW SCENARIOS TO ASSESS EXPOSURES AND EFFECTS: THE OMICS APPROACH

Current research on biomarkers aimed at the identification of new ones is focused on no hypothesis-driven studies. Novel high-throughput techniques in combination with advanced biostatistics and bioinformatics tools (Baker, 2013) quantitate global sets of molecules (i.e., polymorphisms, chemicals, RNAs, proteins, etc.) in biological fluids allowing the identification of new biomarkers to be used in biomonitoring studies.

For instance, genome wide association studies (GWAS) explore genetic associations with diseases and successfully identified common single nucleotide polymorphisms (SNPs) for a wide variety of cancers (http://www.genome.gov/26525384). Thus, the results of GWAS may represent the basis for a comeback to a hypothesis driven biomarkers discovery. Similarly, an environment wide association study (EWAS) evaluates multiple environmental factors and their association

with disease (Patel et al., 2010, 2012). The combining of EWAS with GWAS might allow a better understanding of gene–environment interactions in the development of cancer and the identification of biomarkers to monitor such interactions (Patel et al., 2013).

New opportunities may be derived from measuring the results of exposures from all sources both external and internal that occur throughout the life span. This approach named exposome by Wild (2005, 2012) is represented by the set of chemicals derived from sources outside genetic control that include diet, pathogens, microbiome, smoking, psychological stress, drugs, and pollution (Rappaport, 2012).

New technologies are not only opening new scenarios for biomarker discovery but also new challenges, which include the need of repeated measurements of global sets of biomarkers to be collected at different critical life stages. Only in this way can the dynamics of exposures and early and subsequent effects be captured.

Adductomic

The concept of "adductome," which represents all covalent adducts linked to nucleophilic sites of proteins and DNA, has recently paved the way for the characterization of all reactive electrophiles in biological samples (Rappaport et al., 2012; Carlsson and Törnqvist, 2017). Insufficient knowledge of DNA adduct fragmentation patterns and limited availability of DNA adduct standards currently act as the bottleneck for a full characterization of unknown DNA adducts. The research on adductome has mainly focused on hemoglobin and serum albumin adduct detection, because of the greater abundance and lack of damage repair on these proteins. An adductomic approach for the screening of adducts to N-terminal valine in hemoglobin of human blood samples has been developed for detecting exposure to food and endogenous agents in general population (Carlsson et al., 2014, 2015; Carlsson and Törnqvist, 2016). This approach was also applied to school-age children to measure adduct levels, originating from unspecified endogenous processes or exogenous exposure (Carlsson and Törnqvist, 2017). Two pilot studies instead report the analysis of albumin adductome in relation to tobacco smoke (Preston et al., 2017; Li et al., 2011a,b). Serum albumin Cys34 adductome approach was applied to investigate exposure to high levels of indoor combustion products (Lu et al., 2017) and to tobacco smoke (Grigoryan et al., 2016). These pilot studies are still based on few dozen subjects and further research is required to enlarge the spectrum of the adducts to be identified.

Transcriptomics

Transcriptomics has become a powerful tool for studying genome-wide responses to environmental exposures in human populations. Genome-wide approaches, based on microarrays and more recently on next-generation sequencing (NGS), have been used to gain a comprehensive assessment of the gene expression signature associated with exposures. Transcriptome modifications associated with specific exposures have been detected in target (e.g., airway epithelium) and "surrogate" tissues (e.g., cells from peripheral blood leucocytes and umbilical cord blood). Exposures include benzene (McHale et al., 2009, 2010, 2011; Forrest et al., 2005), diesel exhaust (Peretz et al., 2007), welding fumes (Wang et al., 2005), dioxin (McHale et al., 2007), arsenic (Argos et al., 2006), and acrylamide (Hochstenbach et al., 2012). In particular, Wang et al. (2005), in a pre- and post-exposure study changes were detected in the transcriptome of blood leucocytes of welders as soon as 6 h after occupational exposure to heavy metal fumes. The differentially expressed genes mainly involved in processes related to inflammation, oxidative stress, cell signaling, cell cycle, and apoptosis. Particular attention has been paid to the effect of occupational exposure to benzene on the transcriptome of blood leukocytes in groups of shoe factories and refineries (Forrest et al., 2005; McHale et al., 2009, 2010; 2011). The analysis conducted on two microarray platforms (Affimetrix and Illumina) reveals a large number of differently expressed genes linked to immune and inflammatory responses. The transcriptome analysis is also sensitive to low benzene exposures (<10 ppm) (McHale et al., 2011) where a leukemia-associated signature was identified (Li et al., 2014). Several studies have also investigated the impact of tobacco smoke on the transcriptome of peripheral blood leukocytes (Wright et al., 2012; Lampe et al., 2004; van Leeuwen et al., 2007) and airway epithelial cells (Hackett et al., 2012; Beane et al., 2007, 2011; Steiling et al., 2009; Spira et al., 2004; Tilley et al., 2011). Transcriptomic patterns associated with tobacco smoke are frequently related to inflammatory processes and oxidative stress. Similar transcriptomic profiles have also been revealed after occupational exposure to welding and diesel exhaust fumes (Wang et al., 2005; Peretz et al., 2007). Moreover, many overexpressed genes in smokers return to normal expression levels a few weeks after smoking cessation (Beane et al., 2007; Zhang et al., 2008). This suggests that transcriptome changes may be reversible signatures. This, together with experimental problems and difficulties in interpretation of subtle changes of low-dose effects, limits the value of transcriptomics in individual studies and for cross-study comparisons.

Epigenomic

The introduction of Infinium Human Methylation Bead Chip technology (27 and 450K) has allowed the analysis of the DNA methylation status throughout all the genome, which is defined as epigenome-wide analysis. DNA regions, most susceptible to environmental exposures, are the promoter regions in transposable elements of some housekeeping genes that are adjacent to genes with metastable epialleles and the regulatory elements of imprinted genes. In fact, these target regions, rich in CpG dinucleotide sequences, are preferential site of DNA methylation.

Most attention has been paid on exploring the relationship between epigenome-wide changes and smoking exposure in several cross-sectional studies (Zeilinger et al., 2013, Breitling et al., 2011, Hillemacher et al., 2008, Shenker et al., 2013, Joehanes et al., 2016, Lee and Pausova, 2013). In particular, changes in aryl hydrocarbon signaling pathway (AHRR, receptor signaling involved in detoxification of the components of tobacco smoke) have been coherently detected

([Monick et al., 2012; Joubert et al., 2012](#)), but other end points showed inconsistent results.

Cross-sectional studies on birth cohorts examined umbilical cord blood epigenome in relation to lead ([Wu et al., 2017](#)), arsenic ([Green et al., 2016; Cardenas et al., 2015](#)), and mercury exposures ([Cardenas et al., 2017](#)). Epigenome analysis seems to represent more stable signatures of environmental exposure than changes in the transcriptome. However, it is still unclear how these epigenetic modifications are related to the complexity of human exposures and how they may predict cancer risk.

Metabolomic

Metabolomic is an analytical approach that aims to detect and quantify the metabolome, which is the sum of all low molecular weight metabolites (molecules <1 kDa) present in biological samples. About 20,000 metabolites are known in humans ([Wishart et al., 2018](#)). Metabolome can be measured in blood, urine, or tissues ([Holmes et al., 2008](#)).

Over the last years, an increased application of metabolomics, for the identification of disease biomarkers, reveals large interindividual differences in relation to environmental factors, linked to particular time of an individual's life ([Assfalg et al., 2008](#)), different living regions ([Holmes et al., 2008; Saadatian-Elahi et al., 2009](#)), and genetic factors.

The untargeted metabolomic approach is mainly used to identify metabolites over- or underexpressed in individuals with different exposures. In this approach, hundreds to thousands of metabolites are detected in biological samples. Metabolites are then identified using multivariate statistical methods and their chemical structure is determined by comparison with those stored in large metabolite databases ([Dunn et al., 2011](#)).

Metabolomics have been used to characterize the effect of occupational and smoking exposures. In particular, alterations of amino acid and lipid metabolism, subsequent to occupational exposure to welding fumes ([Kuo et al., 2012; Wei et al., 2013; Wang et al., 2012a](#)), polyvinyl chloride ([Guardiola et al., 2016](#)), smelter fumes rich in arsenic, lead, and chromium ([Dudka et al., 2014](#)), and environmental exposures to dioxin ([Saberi Hosnijeh et al., 2013; Jeanneret et al., 2014](#)) and tobacco smoke ([Wang-Sattler et al., 2008](#)) have been reported.

Metabolomic techniques appear to be the most omics-versatile approach in which metabolic profiles from samples collected under diverse conditions (e.g., different exposures, treatments, or physiologic states) may be systematically compared. However, there are still many uncertainties in terms of experimental design for larger scale analysis and computational methods for characterization of metabolites that hinder the identification to what extent such metabolic changes associate with a given individual exposure.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

The practice of biomonitoring carcinogen exposures appears to have limited value. Certainly, the clinical significance of exposure and effect of biomonitoring is unknown because these tests are not predictive of cancer development. As far as their preventive uses, these are largely postulated given the paucity of prospective validation studies. However, tests to assess the size of exposures may be used to monitor hygienic conditions at work place. Difficult and also questionable in some respect is the use of biomonitoring data for risk assessment. Finally, interventions of primary prevention as opposed to biomonitoring individual susceptibility should be preferred, in particular in occupational settings. Indeed, a new era for biomarker discovery may result from the application of new technologies.

INTRODUCTION

Genetic toxicology elucidates the effects of chemical and physical agents on genetic material or deoxyribonucleic acid (DNA) causing alteration(s) in the structural integrity of the genome. Evaluation of genetic damage by using a combination of in silico, in vitro, and in vivo assays would enable us to utilize a weight of evidence approach in reaching a conclusion regarding the mutagenic or carcinogenic potential of a chemical. Genetic damage is a natural phenomenon occurring endogenously in the cells as a result of oxidative respiration and metabolism, but this damage is continually being repaired by a variety of DNA repair processes present in all cells. However, when the genetic damage becomes overwhelming for the cellular machinery to handle, genetic lesions accumulate that could lead to a wide variety of adverse outcomes, including apoptosis, altered cell division or proliferation, and DNA replication and mutagenesis that may result in carcinogenesis. Carcinogenesis is a multistep process, but broadly it is a three-step process, consisting of initiation, promotion, and progression. DNA damage plays an important role in the initiation step of carcinogenesis, where a carcinogen or its activated metabolite covalently binds to DNA forming a DNA adduct, which may be repaired or, following cell division, may be fixed as a mutation, leading to a heritable alteration in the DNA sequence.

Genetic toxicology encompasses the study of a wide variety of DNA damage end points, including, but not limited to mutagenicity, clastogenicity, and aneugenicity. Mutagenicity refers to the ability of an agent to alter the nucleotide sequence of DNA. Mutations are categorized as base-pair substitutions, frameshifts, additions, and deletions of nucleotide base(s) or chromosomes. Mutations are heritable and hence may have a permanent or long-lasting adverse effect on the health of an organism. Although mutations naturally arise during evolution or DNA replication, most of them occur in areas of DNA that do not exert any harmful effects to the organism. However, if mutations occur in the coding regions (e.g., genes) or in the noncoding (e.g., regulatory regions of genes), then they may lead to adverse effects due to altered gene expression patterns or formation of nonfunctional

[c] The views expressed in this chapter are those of the author and do not necessarily reflect the views or policies of the U.S. Environmental Protection Agency

or altered proteins and enzymes, thus impacting the functional activities of the cells. Not all mutations in the coding region lead to adverse effects. In the case of silent mutations, the base substitution in a codon will either not result in a change of the amino acid the codon codes for or even if it results in an amino acid change, it will not affect the functionality of the protein product.

Clastogenicity refers to the ability of an agent to cause disruptions or breakages of chromosomes that lead to sections of the chromosome being rearranged, deleted, or added (i.e., structural alteration of chromosome). Aneugenicity reflects the ability of an agent to give rise to a daughter cell that has an abnormal number of chromosomes (i.e., numerical alteration of chromosome). It occurs due to errors in chromosomal segregation, altered tubulin polymerization, and spindle apparatus instability. Aneugenicity may result in polysomy or monosomy. In polysomy, the organism has at least one more chromosome than normal. Polysomy is found in many diseases such as Down syndrome (trisomy of chromosome 21) and Cat eye syndrome (the short arm and a small section of the long arm are present either three [trisomy] or four [tetrasomy] times). In monosomy, either only one chromosome from a pair is present or only a portion of the chromosome has one pair and the rest has two (partial monosomy). Sufferers of Turner syndrome completely or partially miss one of the X chromosomes.

A wide variety of in silico, in vitro, and in vivo assays are used to predict the three common types of genotoxic damage: mutagenicity, clastogenicity, and aneugenicity. In vitro assays in general are designed to achieve high sensitivity in detecting DNA damage caused by chemicals or agents. High sensitivity of these in vitro assays often leads to decreased specificity in predicting the carcinogenic potential of chemicals. In vivo genotoxic assays on the other hand have high specificity, but tend to exhibit low sensitivity in predicting the carcinogenic potential of chemicals. Therefore, to increase the specificity and sensitivity of detecting DNA damage, a combination of in vitro and in vivo genotoxicity assays is used, commonly referred to as the "battery approach," for predicting the carcinogenicity potential of a test article in humans. The use of a genotoxic battery approach has been proven to have high sensitivity and specificity ($\sim$85%$-$90%) (Kirkland et al., 2005).

The main emphasis of this chapter has been placed on providing a general overview of currently available genotoxic biomarkers. It is beyond the scope of this chapter to discuss carcinogenesis and relevant predictors/assays, but these are covered elsewhere in other chapters of this textbook. Here we discuss the genotoxicity assays that can be used to monitor and measure biomarkers of DNA damage. In addition, the mechanisms of different types of DNA damage, and the molecular basis of genetic variability and susceptibility are also elaborated with examples. Comprehensive details on the conduct of commonly used genetic toxicology assays can be reviewed by accessing the Organization for Economic Cooperation and Development (OECD) guidelines (http://www.oecd.org/chemicalsafety/testing/).

GENOTOXIC BIOMARKER DETECTION METHODS

In Silico Approaches

As indicated earlier and discussed next in this chapter, there are several in vitro and in vivo genotoxicity testing assays that are available to aid in identifying genotoxic damage. However, the global call for reduced animal usage with emphasis on the three Rs (Reduce, Refine, and Replace) and the phasing out of animal testing has led to rapid expansion and evolution of a myriad of in vitro and in silico genetic toxicology screening assays. The objective of in silico screening techniques is to apply mathematical, statistical, chemical, and computational tools to the existing genetic toxicology data from the literature and to develop efficient and effective genotoxicity predictive models. These predictive models can be used to screen large numbers of untested new chemicals to predict their genotoxic potential. In silico genotoxicity screening methods offer a fast, reliable, and economical solution for preliminary screening of large numbers of chemicals. The in silico modeling has its roots in Structure$-$Activity Relationship (SAR). The earliest examples of SAR were the Ashby$-$Tennant alerts, which associated certain chemical structures with mutation, based on the expert knowledge and experience of these scientists. Others have continued to expand the list of structural alerts associated with DNA reactivity based on known chemical reactivity and expert knowledge. Later, an alternative approach was used based on quantifying structure$-$activity relationships or QSARs using statistical correlation and quantum chemical properties. QSAR models use linear free energy relationships to describe reaction rates and equilibrium. There are a wide variety of in silico tools that have been packaged into software programs capable of predicting a variety of genotoxic end points, but the best validated are models predicting bacterial mutagenicity end points. These in silico tools can be divided into three main categories: databases, virtual screening programs, and prediction systems.

The primary step in in silico assessment of a chemical is to perform a search in public databases to determine if any genotoxicity data exist for the chemical under investigation. The databases collect and store genotoxicity data obtained from multiple sources, including published literature, public data sources, and proprietary in-house historical data from within a testing laboratory obtained over the years of conducting genotoxicity testing. The databases are either open to public use free of cost or available commercially, where the users pay service charges to

access them. Some examples of free databases are the Toxicology Data Network of the US National Library of Medicine, the Aggregated Computational Toxicology Online Resource of the Environmental Protection Agency, the Carcinogenic Potency Database, and the National Toxicology Program of the US Department of Health and Human Services. Examples of commercial databases include PharmaPendium, SciFinder, and STN (See Table 44.1 and Box 44.1 for additional database information.). There are some tools that serve the dual purpose of a database and prediction system; examples include Derek Nexus, Vitic Nexus, Leadscope, and so forth.

Prediction systems are software programs that enable us to make predictions of species and assay-specific end points, such as in vivo mouse micronucleus test and in vitro chromosome aberration test, mouse lymphoma assay, and micronucleus (MN) test in several species. These software programs use different types of algorithms to compute the propensity of a specific chemical to induce genotoxicity. The algorithms for these systems can be divided into three main categories: knowledge-based, statistical methods, and read-across systems. Knowledge-based predictive systems focus on organizing relevant experimental genotoxicity data as knowledge guidelines or rules in a computer program. The in silico software compares the structure of the chemical of interest/investigation with the chemicals in the knowledge library of the database. For example, one of the widely used commercial knowledge-based predictive systems is Deductive Estimation of Risk from Existing Knowledge (Derek); version 14 comprises 82 rules or alerts for mutagenicity. The Derek rules are written and maintained by experts from the nonprofit organization Lhasa Limited (www.lhasalimited.org). There are also several free open-source knowledge-based in silico predicting software packages, such as ToxTree (http://toxtree.sourceforge.net/), Bioclipse-DS (www.bioclipse.net), and OncoLogic (https://www.epa.gov/tsca-screening-tools/oncologictm-computer-system-evaluate-carcinogenic-potential-chemicals) (Table 44.1).

A structural fragment statistically related to the biological activity is called a *biophore*. Biophores of known genotoxic chemicals are compared in databases through biological activity or QSAR modeling. For example, presence of the N−N=O (nitrosamine) fragment is strongly statistically correlated with mutagenicity of both aromatic and aliphatic chemicals. Biophores or structure moieties that are related to toxic or therapeutic end points are referred to as "toxicophore" and "pharmacophore", respectively. If a biophore is present, then the software predicts the chemical as active, and if no biophore is found, the software predicts the chemical as inactive (Klopman et al., 1985; Rosenkranz and Klopman, 1990). Based on the distribution of a biophore and its correlation to toxicity, the statistical systems give a statistical value or predictive value of the biophore. For example, if the database contains 50 nitrosamines, and all of these are active, then presence of the N−N=O biophore is a very strong predictor of toxicity. On the other hand, if only half of the nitrosamines in the database are active and half are inactive, then the confidence that chemicals containing N−N=O are active will be only 50%. The term "structural alert" has also been applied in computational toxicology, meaning a chemical moiety that serves as an indicator of toxic outcome (Klopmann et al., 1985; Rosenkranz and Klopman, 1990). The two widely used commercial statistically fragment-based in silico systems are Leadscope (www.leadscope.com), whose QSAR models were developed by Informatics and Computational Safety Analysis Staff (ICSAS) of the Food and Drug Administration, and MultiCASE (www.multicase.com), whose QSAR models were based on proprietary statistical algorithms developed by Klopman and Rosenkranz (1984). There are also several free open source statistically fragment-based in silico predicting software packages, such as ToxTree (http://toxtree.sourceforge.net/) and Bioclipse-DS (www.bioclipse.net). In read-across systems, the end point result of one chemical is used to predict the end point of a structurally similar chemical. The QSAR toolbox (http://www.oecd.

BOX 44.1

FREELY AVAILABLE DATABASES WITH GENOTOXICITY AND CARCINOGENICITY INFORMATION

- ACToR (Environmental Protection Agency's [EPA] Aggregated Computational Toxicology Online Resource) (https://actor.epa.gov/actor/home.xhtml): Aggregates toxicity data from thousands of public sources on over 500,000 chemicals. It is also the warehouse for EPA web applications that can be used to explore and visualize complex computational toxicology information.
- NTP (National Toxicology Program) (https://ntp.niehs.nih.gov/): Contains data on subchronic, chronic, and in vitro and in vivo genotoxicity assays and carcinogenicity studies.
- CCRIS (Chemical Carcinogenesis Research Information System) (https://toxnet.nlm.nih.gov/newtoxnet/ccris.htm): Contains chemical records with carcinogenicity, mutagenicity, tumor promotion, and tumor inhibition test results.
- CPDB (Carcinogenicity Potency Database) (https://toxnet.nlm.nih.gov/cpdb/cpdb.html): Contains information on carcinogenicity studies on 1547 chemicals.
- GENE-TOX (Genetic Toxicology Databank) (https://toxnet.nlm.nih.gov/newtoxnet/genetox.htm): Provides genetic toxicology test data for more than 3000 chemicals from EPA.
- HSDB (Hazardous Substances databank) (https://toxnet.nlm.nih.gov/newtoxnet/hsdb.htm): It is a toxicology database containing over 5800 individual chemical records. Available data include genotoxicity and carcinogenicity test results.
- IRIS (Integrated Risk Information System, EPA) (https://cfpub.epa.gov/ncea/iris/search/basic/index.cfm): Contains descriptive and quantitative information related to human cancer and noncancer health effects that may result from exposure to 511 substances in the environment.
- TOXNET (Toxicology Data Network) (http://toxnet.nlm.nih.gov): It is a group of databases such as CCRIS, CPDB, GENE-TOX, HSDB, IRIS, etc.

- HPVIS (High Production Volume Information System, EPA) (https://ofmext.epa.gov/hpvis/HPVISlogon): Provides access to genetic toxicity, carcinogenicity, and other information on chemicals that are manufactured in exceptionally large amounts.
- EURL ECVAM (European Union Reference Laboratory for Alternatives to Animal Testing (https://eurl-ecvam.jrc.ec.europa.eu/databases/genotoxicity-carcinogenicity-db): A structured master database that compiles available genotoxicity and carcinogenicity data for Ames positive chemicals originating from different sources.
- ATSDR (Agency for Toxic Substances and Registry (https://www.atsdr.cdc.gov/toxprofiles/index.asp): Contains toxicological profiles, including mutagenicity, and carcinogenicity data, for hazardous substances.
- ECHA (European Chemicals Agency) (https://echa.europa.eu/information-on-chemicals): Contains information, including genotoxicity and carcinogenicity, on chemicals manufactured and imported in Europe.
- Tox Benchmark (http://doc.ml.tu-berlin.de/toxbenchmark/): Ames mutagenicity data set for 6512 chemicals.
- PharmaPendium (www.pharmapendium.com): Offers searchable Food and Drug Administration and European Medical Agency approval packages with excerpted preclinical, clinical, and postmarketing safety data into a single longitudinal database.
- INCHEM (International Programme on Chemical Safety) (http://www.inchem.org/): Consolidates information from a number of intergovernmental organizations on chemicals commonly used throughout the world, which may also occur as contaminants in the environment and food.

---

org/chemicalsafety/risk-assessment/oecd-qsar-toolbox.htm) and Analog Identification Method (https://www.epa.gov/tsca-screening-tools/analog-identification-methodology-aim-tool) are examples of in silico tools that can be used to find structurally similar chemicals.

Although the in silico systems provide an economical, faster, and easier screening of a large set of chemicals, they are far from being replacements of in vitro and in vivo genetic toxicology screening assays, due to lack of strong correlation between the in silico predictions and experimental outcomes. However, currently they serve as powerful tools for early genetic toxicology screening of chemicals, impurities, and degradants.

IN VITRO AND IN VIVO BIOMARKERS OF GENOTOXICITY

Gene Mutations in Prokaryotes

Assays for gene mutations can detect either reversion or forward mutation. Reversions are back mutations that restore gene function in a mutant (i.e., bring about a return to the wild type phenotype). In contrast, forward mutations are mutations in a wild-type gene. Bacterial forward mutation assays are less commonly used than reversion assays. The Ames test is an assay that measures bacterial revertant colony formation. The test was named to honor Bruce Ames, who first identified and reported the utility of this assay in detecting mutations in 1974 (Ames, 1974). Ames created a series of genetically modified strains of *Salmonella typhimurium* with mutations in the histidine gene such that these strains require histidine for growth. In the Ames assay, auxotrophic bacteria that require the amino acid histidine for growth are treated with a test chemical or vehicle or positive control on an agar plate consisting of growth media that lacks histidine. Therefore, only bacteria that have reverted back to wild type histidine locus are now capable of growth and formation of colonies. Increased numbers of revertant colonies in test chemical treated plates compared to concurrent untreated or vehicle control plates is an indication of the mutagenic potential of the test chemical (Fig. 44.1). As bacteria lack or have limited metabolic activation potential, the Ames assay is almost always carried out with and without exogenous metabolic activation to help distinguish chemicals that require metabolic activation for genotoxicity from those that have intrinsic genotoxic potential.

The Ames assay is the most commonly used assay to predict mutagenic potential of a test compound across several scientific disciplines and industries, because historically those chemicals shown to be positive in the Ames assay have also been shown to be positive in the in vivo rodent bioassay (∼65% concordance), used to measure carcinogenic potential of a test chemical. The Ames assay is considered a gold standard assay to predict human carcinogenic potential of a chemical, by health regulatory authorities globally (Kirkland et al., 2005). The bacterial reversion assay is commonly carried out using several bacterial strains. Both *S. typhimurium* and *Escherichia coli* strains can detect base-pair substitution and frameshift mutations. These strains are genetically manipulated to increase their sensitivity to detect mutation frequency. A list of commonly used bacterial strains employed to detect reverse gene mutations and detailed assay guidelines can be obtained in OECD test 471 guideline (OECD 471, 1997; Mortelmans and Zeiger, 2000).

Micronucleus Formation

Increased incidence of micronuclei formation serves as a good biomarker for genotoxic damage. A MN, also known as Howell—Jolly body, is often a broken chromatid/chromosome fragment or rarely a whole chromatid/chromosome that remains outside the nucleus after cell division. Micronuclei formed can be of various sizes, but typically they vary from 1/10th to 1/100th the size of the original nucleus (see Fig. 44.2). Acentric chromatid/chromosome fragments are usually the result of unrepaired or misrepaired DNA breaks. An MN consisting of an entire chromatid(s)/chromosome(s) arises due to deficiency in chromosome segregation. For a thorough review of the mechanisms behind MN formation, see the review by Luzhna et al. (2013).

Ames Bacterial Plates

FIGURE 44.2 Image showing the micronuclei formation in hepatocytes. *Images courtesy of Rie Takashima, Mitsubishi Chemical Medience Corporation, Japan.*

The formation of MN can be readily measured both in vitro in different cell types (in vitro MN assay) and in vivo samples (in vivo MN assay) including peripheral blood, bone marrow, and tissues of rodents and other species using MN assay. Although in principle the in vitro MN assay can be performed in any cell type (primary or immortalized cells), the most commonly used cell types are Chinese hamster ovary (CHO) strain -K1 and -WBL cells, Chinese hamster V79 lung epithelial cells, L5178Y mouse lymphoma cells, TK6 human lymphoblastoid cells, and primary human lymphocytes. The in vitro MN assay is typically carried out with and without exogenous metabolic activation. For the in vivo MN assay, bone marrow or peripheral blood samples from rodents treated with multiple doses of test compound, vehicle, and appropriate positive control are analyzed for the formation of MN. Cell division (one mitosis) is required for the formation of micronuclei, and use of cytochalasin B (CytoB) blocks the cells in the binucleated stage with micronuclei; hence this is called the cytochalasin-blocked micronucleus assay. Cells treated with CytoB undergo karyokinesis but not cytokinesis, resulting in binucleated cells, so by evaluating binucleated cells only those cells that have undergone one cell replication are evaluated. MN formation can be due to either a clastogenic and/or an aneugenic DNA damaging event. However, MN formed by clastogens lack centromeres, whereas those micronuclei resulting from loss of an entire chromatid or chromosome (aneugenic event) contain a centromere. Hence, by centromere staining using various methods, such as fluorescence in situ hybridization (FISH) or other immunofluorescence methods, one can determine if micronuclei are a result of clastogenic or aneugenic events (Degrassi and Tanzarella, 1988; Miller and Adler, 1990; De Stoppelaar et al., 1997). Although yet debated, the size of MN can also serve as an indicator of an aneugenic or a clastogenic event, as the size of MN formed due to aneugenic events is generally larger than that resulting from a clastogenic event (Hashimoto et al., 2010). Advanced and high throughput MN detection technologies, such as flow cytometry and imaging-based technologies, make this a popular biomarker to measure genotoxic damage. More details on the conduct, analysis, and interpretation of in vitro and in vivo MN assays can be obtained in the OECD test guidelines 487 and 474, respectively (Krishna and Hayashi, 2000; Hayashi et al., 2000; Kirsch-Volders et al., 2003; Lorge et al., 2006; OECD Test 487, 2016g; OECD Test 474, 2016b).

Chromosomal Aberrations

One of the traditional and direct cytogenetic methods to detect genotoxic damage is based on a direct observation of the changes in the chromosomes after exposure to a chemical insult in cell populations under a microscope. Chromosomal aberrations (CAs) can be measured by the CA assay, which is commonly used in both clinical and nonclinical settings. Different types of CA are accumulated due to genotoxic damage such as insertions, deletions, translocations, endoreduplication, polyploidy, chromatid aberrations, and chromosomal gain and chromosomal loss. Depending on the relative abundance of a particular type of CA in comparison with other types of aberrations occurring due to treatment with a chemical, it is possible to understand the mechanism of action of the test chemical; for example, an abnormal number of chromosomes suggests aneuploidy, rather than clastogenicity. Although numerical changes can be observed in the CA assay, the MN assay is far more sensitive to chemicals inducing this type of DNA damage. CA studies can be carried out in both in vitro and in vivo test models. In vitro CA studies may be conducted with primary or immortalized cells, but regardless of cells used all require addition of an exogenous S9 liver metabolic fraction to enable detection of chemicals requiring metabolism to the ultimate genotoxicant. For in vivo CA studies, bone marrow or peripheral blood samples from rodents are commonly used. The main advantage of treating intact animals is that they include mammalian metabolism and DNA repair.

CA are usually studied in cell populations at the metaphase stage of the cell division, as chromosomes are condensed and damage is easily visualized at this stage. The cell populations can be arrested in metaphase by treatment with chemicals such as colcemid. Similar to MN detection, in principle the CA assay can be performed in any cell type. However, CHO cells are most commonly used in the in vitro studies because of the large size of chromosomes, fewer chromosomal numbers, a stable and well-defined karyotype, and a relatively shorter cell division interval (Fig. 44.3). Detection of the CA assay is a direct subjective method of measuring genotoxicity levels, not amenable to automation, and requires skilled cytogeneticists to analyze and score the CA. Invention of new technologies, such as fluorescence in situ hybridization (FISH) and chromosome painting, allows scientists to identify CA with relative ease and also to determine insertions and translocations more precisely, which is not possible with traditional CA assay. More details on the conduct, analysis, and interpretation of the CA assay data can be inferred from Bignold (2009) and OECD tests 473 (2016a, in vitro mammalian CA) and 475 (2016c, in vivo mammalian CA).

Comet Formation

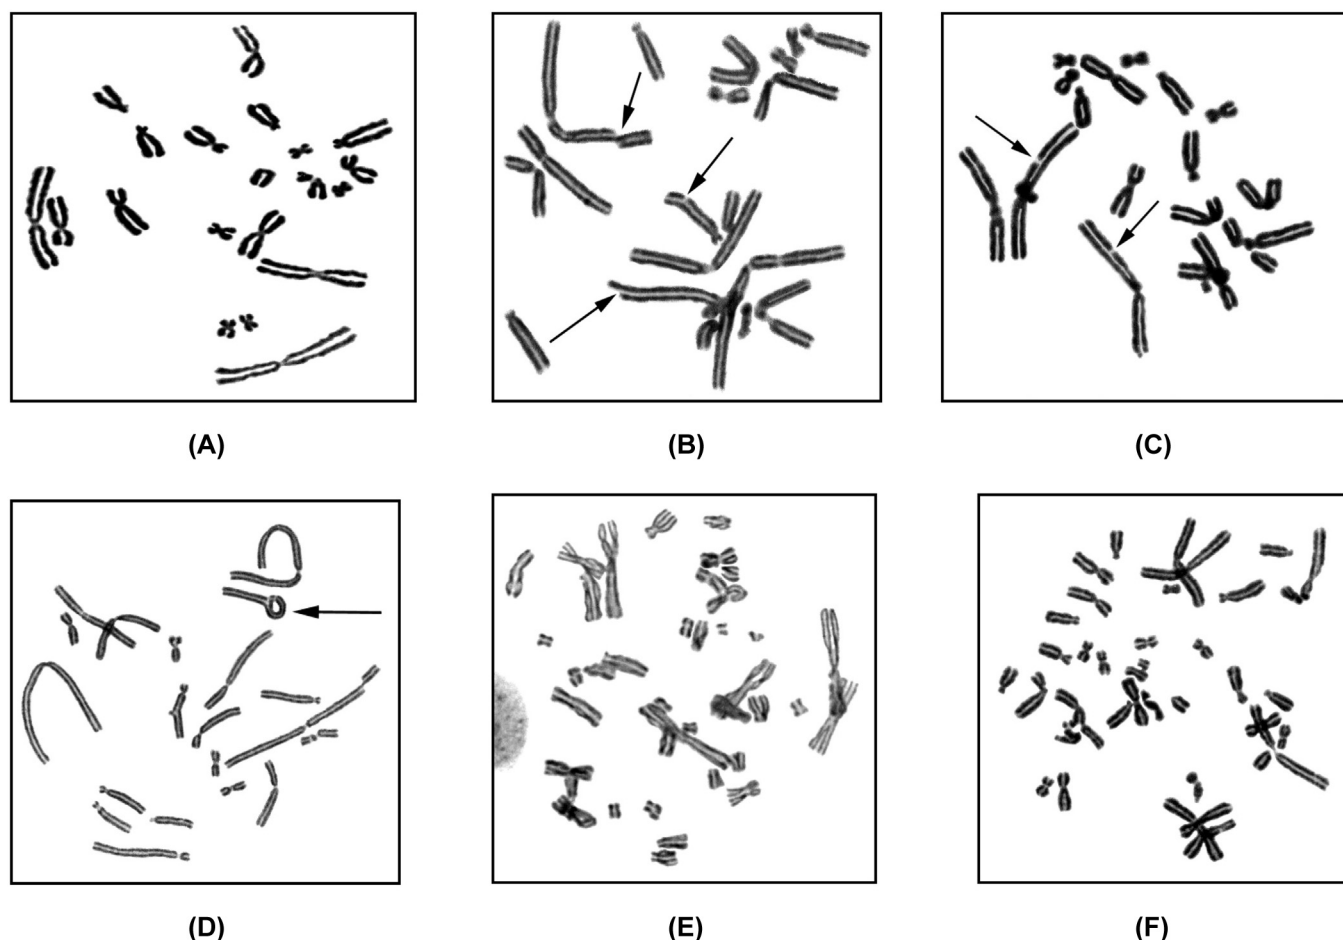
The Comet assay, also known as the single cell gel electrophoresis assay, detects single or double strand breaks measured at the individual cell level. This assay


FIGURE 44.3 Images showing different chromosomal aberrations in CHO cells: normal (A), chromatid breaks (B), chromatid gaps (C), chromosome intrachange (D), endoreduplication (E), and polyploidy (F). *Images courtesy of James Wojciechowski and Louis Nimzroff, Bristol Myers Squibb, NJ, USA.*

was first developed by Ostling and Johansson in 1984 and was later revised by Singh et al. in 1988. With the advent of recent technological innovations such as fluorescent DNA stains and automated comet scoring for analysis, comet assay has emerged as a popular assay to detect DNA damage. Unlike the other assays described above, the comet assay measures transient genetic damage that is not a fixed change to the DNA. Strand breaks may be repaired, hence the requirement for very short time intervals between the final treatment and damage evaluation. The comet assay may be conducted in vitro using single cells from immortalized cell lines or in vivo for any tissue that can be dispersed to a single cell suspension.

At the molecular level, the formation of "comets" in the DNA of cells on genotoxic insult can be visualized through the method of gel electrophoresis and indicates DNA strand breaks, as the damaged DNA migrates at a different rate than nondamaged DNA during electrophoresis. In the comet assay, when a damaged DNA—containing single cell suspension embedded in low

melting agarose is electrophoresed, the damaged DNA migrates away from the undamaged DNA—containing nucleoid body, resembling the structure of a comet, hence the name comet assay. In the comet structure, the undamaged DNA nucleoid part is referred to as the "head" and the trailing damaged DNA streak is referred to as the "tail" (Fig. 44.4). The percentage of DNA in the tail is directly proportional to the percentage of DNA damage that has occurred in a particular cell. Thus, by counting a representative sample of ∼100−300 cells per tissue, it is possible to arrive at the average percentage of DNA damage accumulated in a particular tissue due to genotoxic stress.

The in vitro comet assay can be performed in any rodent or human cancer cell lines and human lymphocytes. It is typically carried out with and without exogenous metabolic activation, usually by supplementing with induced rat liver S9 fraction as indicated in other assays detailed earlier in this chapter. Although in principle any tissue can be used for in vivo comet assay analysis, high blood circulating organs such as
FIGURE 44.4   Image showing the comet formation comprising the head (undamaged DNA) and tail (damaged DNA). *Images courtesy of James Wojciechowski and Dan Roberts, Bristol Myers Squibb, NJ, USA.*

liver, kidney, and spleen are the target organ tissues that are analyzed. Also, if the route of administration is oral, then the site of contact or exposed tissue such as stomach mucosal cells are commonly used for comet analyses. More details on the conduct, analysis, and interpretation of the comet assay data can be inferred from Tice et al. (2000), Azqueta et al. (2011), Burlinson (2012), and OECD test 489 (2016h).

Toxicogenomic Signatures

Toxicogenomic studies in relation to genetic toxicology utilize the comprehensive gene expression data to identify gene expression signatures that strongly correlate with genetic toxicity. The use of these approaches has a long history and due to rapid development in gene expression technologies such as microarrays, real-time PCR, RNA sequencing, and other bioinformatics tools, the field of toxicogenomics has emerged as an area that may have immense potential for genotoxicity testing. In toxicogenomic studies, changes in gene expression patterns in response to genotoxic stress are most commonly studied, but changes in protein expression or metabolite formation can also be investigated. In addition, toxicogenomic approaches have the potential to overcome some of the limitations posed by traditional genotoxicity testing approaches, such as use of a limited number of animals, especially when changes in a limited set of genes are being investigated. Also, toxicogenomic approaches are more amenable for high throughput and high content screening than are traditional methods, thus aiding in reducing the costs associated with genetic toxicity screening and risk assessment.

Several investigators to date have reported different toxicogenomic signatures both in vitro using rodent and human cancer cell lines and in vivo in rodent models, to predict carcinogenicity in rodents and/or in humans and to distinguish genotoxic and nongenotoxic agents (Thybaud et al., 2007; Ellinger-Ziegelbauer et al., 2009; Fielden et al., 2011; Thomas and Waters, 2016; Li et al., 2015, 2017). Although toxicogenomic signatures have been proposed to differentiate genotoxins versus nongenotoxins, aneugens versus clastogens, carcinogens versus noncarcinogens, genotoxic carcinogens versus nongenotoxic carcinogens, etc., no general consensus exists on their usage in genetic toxicology testing. This is primarily because of diverse test models and gene expression analysis and bioinformatics technologies used to arrive at these toxicogenomic signatures, independently by different groups. Public repositories of gene expression studies include the Gene Expression Omnibus of the National Center for Biotechnology Information (https://www.ncbi.nlm.nih.gov/geo/) and the ArrayExpress of the European Bioinformatics Institute (https://www.ebi.ac.uk/arrayexpress/). Additionally, TOXsIgN (TOXicogenomic sIgNature) serves as a free cross-species repository for toxicogenomic signatures (http://toxsign.genouest.org/app/#/). The Comparative Toxicogenomics Database (CTD) is a public website that is maintained by the Department of Biological Sciences at North Carolina State University (http://ctdbase.org/). One of the aims of CTD is to advance the understanding of toxicogenomics and contains data on chemical—gene interactions and chemical—disease, gene—disease, and chemical—phenotype associations.

Other Genotoxic Biomarker Detection Methods

Other genotoxic biomarker detection methods include in vitro mammalian cell gene mutation assays (OECD test 476, 2016d), in vivo transgenic rodent somatic and germ cell gene mutation assays (OECD test 488, 2013), in vivo mammalian spermatogonial chromosome aberration test (OECD test 483, 2016f), in vivo mouse heritable translocation assay (OECD test 485, 1986), and the in vivo rodent dominant lethal test (OECD test 478, 2016e). Guidelines for performing these assays can be found in the above OECD test guidelines along with other genetic toxicology test guidelines (https://www.oecd-ilibrary.org/).

BIOMARKERS AND MECHANISM OF ACTION

Biomarkers of exposure are considered measures of internal dose. The genetic toxicology assays elaborated on in the previous sections of this chapter provide a general standard battery of genotoxic biomarkers available for the evaluation of functional cellular and molecular

alterations on chemical exposure. Because changes in cellular molecules are thought to precede toxic outcomes, appropriate changes serve as early, sensitive indicators of potential genotoxicity (inclusive of mutagenicity and clastogenicity). Therefore, application of genetic techniques and biomarkers to provide an understanding of the effects of chemicals on cellular alterations is crucial. In this section, we will elaborate on how genotoxic biomarkers would facilitate better understanding of gene mutations, structural, and numerical chromosome changes that induce changes to genetic material (DNA).

Gene Mutations and Their Mechanism of Action

Mutation by definition refers to a permanent change in the nucleotide sequence of the genome of an organism. Mutation can be beneficial or detrimental to the cell. In this section, detrimental mutations are reviewed. Mutations in the DNA sequence may trigger a cascade of reactions that can adversely impact cellular events such as replication, transcription, or translation, possibly eventually resulting in cell death. Mutations can be classified into two main types: acquired (or somatic) and hereditary (or germline mutation). Acquired mutations occur in certain, but not all, cells of an organism as a result of DNA damage due to environmental agents such as nuclear radiation, UV exposure, chemical exposure (exogenous or endogenous), or errors during the DNA replication or transcription process. Elegant repair mechanisms exist to revert DNA damage caused by various mutagens and to repair errors that occur during replication or transcription; however, these repair mechanisms have their limitations and are not able to sufficiently restore the damage that is caused by potent mutagens. Acquired mutations in somatic cells cannot be passed down to the next generation. When a mutation is present in the germ cells (eggs or sperm), it can be passed down to the next generation. This type of mutation will be present in every cell of the offspring and is called a hereditary mutation.

Gene mutation refers to a permanent alteration in the DNA sequence of a gene. This change can range in size from a base to a large segment of the DNA that spans across multiple genes. The DNA sequence of a gene can be altered by missense mutation, nonsense mutation, insertion, deletion, frameshift mutation, and repeat expansion.

Chemical mutagens induce mutagenicity through various mechanisms. For example, 2-amino purine has a structure that is similar to that of the nitrogenous base adenine and, during the DNA replication, it forms a base analog. Then there are other mutagens that function as intercalating agents. An intercalating agent inserts itself between the strands of dsDNA and causes the DNA to unwind, thereby inhibiting mechanisms involved in replication and transcription.

The first step in identifying the genotoxic and carcinogenic potential of various agents is the conduction of genotoxicity assays. Among the various assays, as alluded to earlier in this chapter, the Ames test is the very first assay used as the point of detection to eliminate potential mutagenic/carcinogenic chemicals. All chemicals identified as mutagens in an Ames test may not necessarily test positive for carcinogenicity (Eastmond et al., 2009; Claxton et al., 2010). For example, chemicals that contain the nitrate functional group may test positive in the Ames test because nitrate compounds may generate the signaling molecule nitric oxide. It is important to understand, as described earlier in this chapter, that in an Ames test, the tester strains that are used are mutated and are unable to grow without histidine. Mutagenic chemicals would revert these mutated strains back to the wild type and enable them to grow in absence of histidine. Sodium azide is used as a positive control for *S. typhimurium* strains TA100 and TA1535 in absence of S9. Strains TA1535 and TA100 carry a *hisG46* marker that results from the substitution of amino acid leucine (GAG/CTC) by a proline (GGG/CCC). Sodium azide reverts the mutation to the wild-type by inducing point mutations at the GC base pair sites (Mortelmans and Zeiger, 2000). In bacteria, sodium azide is converted to the mutagenic compound azidoalanine by the bacterial enzyme *O*-acetylserine(thio)lyase. However, in a rodent carcinogenicity assay, sodium azide is determined to be negative. Hence, the mutagenic effects observed in *S. typhimurium* or *E. coli* are irrelevant for evaluation of the genotoxicity in humans. This is an interesting example of a chemical that induces strong mutagenic response in the Ames test, but is negative in the in vivo rodent carcinogenicity assay.

2-Nitrofluorene is used as positive control for *S. typhimurium* strains TA98 and TA1538 in absence of S9. 2-Nitrofluorene is converted to N-hydroxy-2-aminofluorene by nitroreductase activity. During this conversion, hydroxylamine intermediates form, which results in esterification to electrophiles and formation of DNA adducts. The mutagenic potency of nitrated fluorenes increases on addition of nitro groups (McCoy et al., 1981). Strains TA1538 and TA98 carry a frameshift mutation that affects the reading frame near the —C—G—C—G—C—G—C—G— sequence. 2-Nitrofluorene induces frameshift mutations and reverts these strains to the wild-type state (Mortelmans and Zeiger, 2000). Various aromatic nitroso derivatives such as 4-nitro-*o*-phenylenediamine also induce frameshift mutation in a similar manner. Hence, 4-nitro-*o*-phenylenediamine is often used as a positive control for strains TA98 and TA1538.

Most often, chemicals would cause a mutagenic effect only in the presence of metabolic factors (S9) because the presence of metabolic factors could result in the formation of mutagenic metabolites. For this reason, 2-aminoanthracene, an aromatic amine, is commonly used as a positive control in the Ames assay for all the bacterial strains only in presence of metabolic factors.

Chromosomal Aberrations and Their Mechanisms of Action

There is accumulating evidence that MN and CAs can independently aid in the prediction of risk of cancer development (Hagmar et al., 1998a; b; 2004; Bonassi et al., 2000; Boffetta et al., 2006; Bonassi et al., 2007). Often, in addition to gene mutations, these genotoxicity end points aid in the interpretation of chemical exposures and cancer risk. Hence, genotoxicity biomonitoring studies using MN or CA formation are widely undertaken. Recently, MN and nuclear abnormalities tests were used as biomarkers in the fish *Oreochromis niloticus* from a polluted pond in winter, spring, and summer, wherein fish collected at the polluted pond exhibited higher rates of DNA damage, as indicated by increased rates of MN and numerical aberrations in erythrocytes when compared to the negative control (Seriani et al., 2012). To provide comprehensive coverage of the mutagenic potential of a chemical, it is important to generate information on three types of genetic damage, namely gene mutation, changes to chromosome structure (i.e., clastogenicity), and number (i.e., aneuploidy) to provide comprehensive coverage of the mutagenic potential of a chemical. A clastogen is a chemical that can cause breaks in chromosomes, leading to sections of the chromosome being deleted, added, or rearranged. Known clastogens include acridine yellow, benzene, ethylene oxide, arsenic, phosphine mimosine, vincristine, etc. An aneugenic agent, on the other hand, is a chemical that promotes aneuploidy in cells by affecting normal cell division and migration of chromosomes during mitosis (or meiosis). Thus, aneuploidy is defined as an abnormal number of chromosomes in any given homologous pair of chromosomes. A few known examples of chemicals that are aneugenic are vinblastine, griseofulvin, colcemid, and mitomycin C. In general, several in vitro and in vivo mammalian cell assays described earlier can be performed to assess the potential of a chemical to cause chromosomal damage. Elaborated below are genotoxicity biomarkers and their mechanism of action, with a few examples.

Most of the mechanisms of CAs involve the concepts of clastogens directly acting on DNA to produce strand breaks, and subsequently, the survival of these directly caused DNA strand breaks—or misrepairs of them—to metaphase when they appear as chromosomal "breaks" or translocations. Chemicals such as mitomycin C, cadmium chloride, and 5-fluorouracil that are direct-acting clastogens have been shown to be positive in the MN assay (Shi et al., 2009) in addition to other known indirect clastogens, such as benzo[a]pyrene, cyclophosphamide, and 2-aminoanthracene. Many cytotoxic cancer therapies, such as cyclophosphamide, are positive in the in vivo MN assay by their mechanism of action. The main effect of cyclophosphamide is due to its metabolite phosphoramide mustard. This metabolite is only formed in cells that have low levels of aldehyde dehydrogenase. Phosphoramide mustard forms DNA crosslinks both between and within DNA strands at guanine N-7 positions (known as interstrand and intrastrand cross linkages, respectively). This, being irreversible, leads to cell death.

Induction of MN in vivo could occur by non–DNA-damaging mechanisms and the identification of a structurally diverse class of compounds that appear to bind noncovalently to DNA and that could enhance the DNA nicking activity, resulting in micronuclei induction, has been reviewed in Snyder (2010). A classic example of the mechanism of noncovalent DNA binding would be topoisomerase inhibitors such as etoposide. Etoposide is a chemotherapeutic drug that forms a ternary complex with DNA and the topoisomerase II enzyme (which aids in DNA unwinding), prevents religation of the DNA strands, and by doing so induces DNA strand breaks that cause errors in DNA synthesis and promote apoptosis of the cancer cell (Hande, 1998). Other examples are drugs that induce hypothermia (morphine, chlorpromazine), hyperthermia, or increased erythropoiesis following bone marrow toxicity or direct stimulation of precursor cells to divide.

Aneugens such as vinblastine, vincristine, colchicine, and nocodazole have been shown to induce micronuclei in the MN assay. Studies reviewed indicate that these chemicals interact with a number of cell components and processes such as synthesis and functioning of the spindle fibers, the activity of the centrosome, and modification of centromeres, resulting in the production of aneuploid progeny cells (Parry et al., 2002). A well-studied example of a chemical that induces aneuploidy is vincristine. It is a dimeric alkaloid, a mitotic inhibitor, and is used in cancer chemotherapy. Vincristine binds to tubulin dimers, inhibiting assembly of microtubule structures. Disruption of the microtubules arrests mitosis in metaphase, therefore affecting all rapidly dividing cell types including cancer cells; it has been used widely to treat pediatric leukemias. The genotoxicity and cytogenetic effects of vincristine at different genetic end points have been demonstrated using biomarkers such as the comet assay and MN assay,

and a gene mutation assay in occupational exposure settings (Hongping et al., 2006).

Taken together, both the in vitro and in vivo genetic toxicology assays have proven invaluable in understanding the mechanism of action in a biological system and serve as essential biomarkers of genotoxicity.

MOLECULAR BASIS OF GENETIC VARIABILITY AND SUSCEPTIBILITY

Genotype is the sum total of all the genetic information of an individual. In a population, individuals differ from one another with regard to their genotypes. These differences in the genetic traits are often referred to as genetic variability. Although the variation between individuals constitutes genetic variability, the variability within the population is genetic diversity. Genetic variability or variation in genetic traits in response to the genetic and environmental influences determines the susceptibility of the individual or the population to toxicant injury or disease. Genetic susceptibility represents an increased likelihood of developing a disease, otherwise known as genetic predisposition.

Genetic Variability

Genetic variability represents the genetic differences within or between populations. Several possible factors, including gene flow due to population migration, homologous recombination or crossing over during meiosis, polyploidy, and mutations, might contribute to the genetic variability in the population. Of these possibilities, mutations make the primary source for genetic variation. Mutations affecting a single nucleotide (point mutation), whereby new alleles (alternative forms of the same gene or locus) are formed, constitute a common source of genetic variation. On the other hand, chromosomal mutations move the alleles around, either on to different loci on the same chromosome or a different chromosome by homologous recombination or translocation resulting in genetic variation, but this form is less common.

Gene mutations and epimutations (those that affect gene expression, but do not alter gene sequence) are also markers of genetic variability, which may have an impact on the population in different ways. A positive impact may enhance the well-being of the individual, and it is likely to be propagated in the population through the natural selection process, whereas the negative impact may be concealed if the mutation is lethal; the neutral mutations will not cause an impact. Both endogenous and exogenous factors contribute to genetic variations. Endogenous sources of genetic variations include heritable traits, life stage, and aging, whereas exogenous factors include preexisting health conditions, coexposure to chemicals, and dietary and psychosocial stress factors.

Examples of common genetic alterations or variants include Short Tandem Repeats (STRs), Single Nucleotide Polymorphisms (SNPs), and Copy Number Variants (CNVs). The STRs are also referred to as microsatellites or simple sequence repeats, and there are 1–6 or more base pairs of repetitive DNA sequences that are considered molecular markers of genetic variation. STR or microsatellite scans could help researchers in identifying the candidate genes involved in genetic susceptibility to a particular disease. Minisatellites are 10–60 or more base pairs of repetitive DNA sequences. Microsatellites and minisatellites together are classified as variable number of tandem repeats. CNV is a structural variation wherein an abnormal number of copies of a gene or a fragment of the gene occurs in the genome of an individual as a result of either duplication or deletion of a part of genome. Inherently, the human genome shows interindividual variability in the copy number of DNA sequences. Two types of CNVs exist in the human population; they are either inherited or arise de novo in the genome of an individual. CNVs play an important role not only in population diversity but also in human disease. CNVs have been associated with neuropsychiatric diseases such as autism, schizophrenia, and Prader–Willi in addition to a wide variety of other diseases such as Crohn's disease, psoriasis, and systemic lupus erythematosus (Girirajan et al., 2011; Thapar and Cooper, 2013; Ionita-Laza et al., 2009).

Genetic alterations or variations commonly occur in organisms due to two reasons: allelic variations and CAs. Allelic variations represent mutations in a given gene locus, whereas CAs represent structural damage to chromosomes or chromatids affecting multiple genes or loci. Exposure to environmental agents and drugs or pharmaceuticals can cause genetic alterations, which can affect both somatic and germ cells in the form of somatic and germline mutations, respectively. In somatic cells, genetic alterations can induce immediate effects, such as cell death or a slow transformation of cells into cancer cells. Usually these hazardous cellular events are preceded by accumulation of genotoxic or cytogenetic damage that can be monitored or detected using biomarkers such as mutations, MN formation, sister chromatid exchanges, CAs, and DNA repair. In contrast, heritable germline mutations occur in germ cells that are passed on to the offspring, such as chromosome aberrations, leading to birth defects and genetic diseases.

Genotoxic effects such as mutations in somatic cells precede the genetic changes following exposure to environmental agents. Several biomarkers of exposure and genotoxic effect have been reported from somatic cells

in a number of studies due to their relative abundance in number compared to germ cells (Bickham et al., 2000). However, when the mutations occur in germ cells, those mutations are more detrimental than somatic mutations, as they can be inherited, thus making the investigation or studying of heritable mutations more critical for hazard identification and risk assessment. Biomarkers such as chromosomal rearrangements or abnormal number of chromosomes (e.g., trisomy, monosomy) are often associated with certain birth defects and genetic diseases that could be used for the prediction of certain disease outcomes by screening pregnant women. In this context, the affected population is likely to have low viability, life expectancy, and fertility because the induced heritable mutations are likely to cause several medical complications in the organisms harboring these genetic mutations. Also, the influence of genetic and environmental factors affecting the spontaneous formation of cytogenetic biomarkers of genotoxicity in humans can be measured. For example, in twins of different age groups, spontaneous micronuclei formation has been shown to be increased with age, particularly in females.

Epigenetic changes or modifications involve modifying DNA base pairs or proteins rather than changing the genome sequence itself, as is the case in mutations. Epigenetic changes include both heritable and nonheritable changes. Most common epigenetic mechanisms include DNA methylation, histone protein modifications (methylation, phosphorylation, acetylation, ubiquitylation, and sumoylation), and noncoding RNAs (miRNAs, picoRNAs, etc.). Epigenetic mechanisms regulate or modulate gene expression both in transient and permanent manners in response to endogenous and exogenous environmental stress factors (Hernandez and Singleton, 2012). Epigenetic mechanisms are highly dynamic in nature, thus facilitating modulation of gene and protein expression and are greatly influenced by environmental, dietary, race, gender, and age factors of the organism under study. DNA damage or genotoxic stress is shown to induce the miRNA family miR34 through the p53 pathway, which includes three miR-NAs: miRNA-34a, miRNA-34b, and miRNA-34c (He et al., 2007). Also, miR-125b and miR-504 are shown to negatively regulate p53 expression, a key regulator of the genotoxic damage response pathway (Le et al., 2009; Hu et al., 2010). A few more examples of direct regulation of cytochrome P450 (CYP) enzymes by miR-NAs that affect the toxicokinetics of drugs include miR-27b for CYP1B1 and CYP3A4 and miR-378 for CYP2E1. SNPs in miRNAs are another regulatory possibility affecting the toxicokinetics of drugs. Other sources of genetic variability include homologous recombination, translocation, and polyploidy.

With the completion of the Human Genome Project in 2003, common genetic variants that contribute to the susceptibility and progression of disease and the variability in the response to treatment have been mapped using state-of-the-art methods in genotyping and sequencing (Abramowicz, 2003). High-throughput screening techniques, such as next-generation DNA sequencing (NGS) and other wide-range genetic screening technologies, will facilitate identification of sources for genetic variability among populations. Understanding the relationship between genetic variation and biological function is essential for unraveling the critical aspects of the biology, evolution, and pathophysiology of humans. In terms of disease susceptibility, two kinds of genetic variants are known. The first one is the rare variants that drastically affect simple traits (e.g., cystic fibrosis), whereas the second variant is a common one having mild impact on complex traits (e.g., diabetes). However, there are a great many unknowns between these two categories that are yet to be identified by the scientific community. To investigate the data gaps and explore the association between phenotype and genotype, the 1000 genomes project was initiated in 2008. This is an international research effort aimed at measuring the human genetic variations in 1000 unrelated individuals, by performing genome-wide sequencing of 1000 individual genomes using NGS platforms (1000 Genomes Project Consortium, 2010). In a pilot study of the 1000 genomes project, they identified 250–300 loss-of-function variants in annotated genes. Also, the genes related to human disease susceptibility were compiled in the HapMap (Haplotype Map) project, which was coordinated by a group of countries including the United States, United Kingdom, China, Canada, Japan, and Nigeria. From a limited set of DNA samples, the HapMap project together with the Human Genome Project and the SNP Consortium identified 10 million common SNPs. Information on the linkage disequilibrium patterns of these SNPs was employed in conducting genome-wide association studies (GWAS); thereby several hundreds of genomic loci affecting human diseases were identified (Buchanan et al., 2012).

Susceptibility

Susceptibility involves an increased likelihood of developing a given disease due to heritable changes such as gene mutations; it is also referred to as genetic predisposition. Genetic polymorphisms in drug-metabolizing enzymes play an important role in the susceptibility or sensitivity of individuals to environmental chemicals. Genetic markers such as SNPs are correlated with genetic variation in a population. The SNPs are inherited as a cluster, which is referred to as a haplotype. Influence of genetic variation on response to

pharmaceutical agents or drugs, determined by SNPs or gene expression, is referred to as pharmacogenomics. Based on their location in the genome, the SNPs are classified into three types: (1) SNPs within the coding region of the genes that are referred to as coding SNPs (cSNPs), which may or may not cause changes in amino acids; (2) SNPs in noncoding sequences that are upstream of regulatory regions and introns of the genes, referred to as perigenic SNPs (pSNPs) and which may not be functional; and (3) SNPs in intergenic (between genes) sequences that are referred to as coding intergenic SNPs (iSNPs). In general, cSNPs are more detrimental to organisms than pSNPs or iSNPs. However, the cSNPs may not always have a detrimental impact because single nucleotide change may not always result in a change in amino acid due to the degenerative nature of the genetic code. Variations in the SNPs in the population can be related to the differences in susceptibility of individuals to diseases, pathogens, or toxicant exposure. SNPs have been used as high-resolution markers in genetic mapping using GWAS, a concept in which several genetic variants are examined to see whether they have an association with a particular trait. SNPs differ at a single nucleotide and often have two alleles in the population. The linkage disequilibrium pattern, i.e., a nonrandom association of two alleles at two or more loci, determines the number of SNPs required (Christiani et al., 2008).

Susceptibility of individuals to genotoxic environmental pollutant or toxicant exposures could also be affected by polymorphisms in phase I and phase II xenobiotic metabolizing enzymes. As reviewed recently by Zanger and Schwab (2013), the impact of genomic markers on cytochrome P450 enzymes has been in the order of CYP2D6>CYP2C19∼CYP2A6>CYP2B6 >CYP2C9>CYP3A4/5 and this study focused on common variants, but not rare variants. In addition, DNA repair enzymes belonging to different repair pathways, such as base excision repair, nucleotide excision repair, mismatch repair, and recombination repair, may also contribute to the genetic variation and susceptibility of individuals towards DNA damage and carcinogenesis. Many of these sets of enzymes act by forming protein—protein interactions leading to large enzyme complexes, and the fidelity and functional ability of these enzymes can be affected by polymorphisms that might result in altered ability of the repair enzymes to form a functional enzyme complex (Miller et al., 2001).

Similarly to the case of genetic variability, genetic effects and epigenetic mechanisms also play a significant role in regulating the genetic susceptibility of an individual or organism. For example, CYP1A1 gene promoter methylation in the human lung tissue of nonsmokers is higher compared to that in heavy smokers (Anttila et al., 2003). Environmental factors can also influence CYP polymorphism in smokers and nonsmokers.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

Screening for genotoxic damage using several in silico, in vitro, and in vivo screening assays is an important part of pharmaceutical and chemical safety testing across a wide range of industries. Existing genotoxic battery testing that investigates and monitors biomarkers of genotoxic damage, such as increased bacterial revertant colonies, MN formation, comet formation, and CAs, are of tremendous help in genotoxic hazard identification and risk assessment. However, currently there are no sensitive and specific short term in vivo assays to evaluate carcinogenicity of chemicals caused via nongenotoxic or epigenetic mechanisms and only a limited number of sensitive in vitro assays. In vitro assays to assess both genotoxic and nongenotoxic carcinogens include Syrian Hamster Embryo cell transformation assay (SHE CTA) and Bhas 42 CTA (OECD Guidance Document, 2015; OECD Draft Guidance Document, 2015). The 2-year in vivo rodent bioassay that is used currently to evaluate carcinogenicity of chemicals is extremely time-consuming and cost prohibitive for screening a plethora of potential genotoxic chemicals. In this regard, cutting-edge technologies such as toxicogenomics, high content imaging, FISH, and high throughput approaches, such as NGS technologies, would be valuable to gain insights into genotoxic, nongenotoxic, and epigenetic mechanisms that play an important role in carcinogenesis, genetic variability, and susceptibility.

Epigenetic Biomarkers in Toxicology

Anirudh J. Chintalapati, Frank A. Barile

St. John's University, College of Pharmacy and Health Sciences, Department of Pharmaceutical Sciences, Toxicology Division, New York, United States

INTRODUCTION

Epigenetics was first coined in 1942 by Conrad Hal Waddington, who used it to describe how genes and their products interact to produce diversity of phenotypes (Jablonka and Lamb, 2002). Since then, the definition has evolved to signify heritable changes in gene expression, which do not involve alterations in DNA sequence (Roloff and Nuber, 2005). Major epigenetic (EG) mechanisms include DNA methylation, covalent posttranslational modifications (PTMs) of histone proteins, and noncoding RNAs (ncRNAs). These mechanisms mediate transcriptional alterations to orchestrate processes necessary to maintain chromatin structure and differential patterns of gene expression. DNA methylation is covalent addition of methyl groups to cytosine of CpG dinucleotides (cytosine-5′—phosphate bond—guanine), which is implicated in gene silencing. PTMs of histone proteins, including acetylation, methylation, phosphorylation, ubiquitination, and sumoylation, create dynamic states of chromatin that influence gene expression (Gadhia and Barile, 2014). NcRNAs are associated with nonprotein coding segments of the mammalian genome, which regulates and influences several EG modifications in addition to regulation of developmental processes, such as embryogenesis and tissue morphogenesis (Sauvageau et al., 2013; Grotece et al., 2013). These and other accompanying EG modifications play important roles in processes of cellular development, imprinting, cellular differentiation, X-chromosome inactivation, and transposon silencing (Barile, 2013). Furthermore, tracing subcellular EG mechanistic changes provide novel biomarkers for drug classification, disease diagnosis, and/or prognosis and endow viable therapeutic targets. For example, endocrine disruptors vinclozolin and methoxychlor induce alterations in DNA methylation pattern in germline and are classified as EG reproductive/developmental toxicants (Anway et al., 2005; Autrup et al., 2015).

Although it is well established that the science of genetics modulates etiology of disease, especially cancer, awareness of EG etiology of disease states has more recently been the subject of increasing scrutiny. The Basis of diseases that are implicated to involve EG causes includes mechanisms that do not require genetic mutations. These EG mechanisms incorporate aberrations in DNA methylation and/or improper histone modifications, ostensibly resulting in abnormal gene expression and malfunction of normal EG progression (Feinberg, 2007). Such alterations are mainly conveyed through either loss of function or gain of function of EG modifiers, resulting in an abnormal phenotype. The following discussion describes critical functions of EG regulators and consequences of their malfunction.

DNA METHYLATION

DNA methylation refers to the covalent addition of a methyl group donated by cofactor *S*-adenosyl methionine (SAM) to carbon-5 of cytosine of CpG dinucleotides, catalyzed via action of DNA methyltransferases. Product of this reaction, 5-methylcytosine (5-mc), is capable of pairing with guanine without compromising DNA integrity (Goodman and Watson, 2002). Termed as a "chemically improbable reaction" (Chen et al., 1991), DNA methylation is only possible by base flipping, or *eversion*, of target cytosine away from the inner helix (Klimasauskas et al., 1994; Cheng and Roberts, 2001; Goll and Bestor, 2005). As a stable, highly conserved, but reversible modification, DNA methylation is most notably involved in repression of genomic activity, although some examples of genetic activation

are noted. For instance, CpG island methylation at gene promoter region of FoxA2, a transcriptional factor responsible for endodermal development and pancreatic beta-cell gene expression, resulted in transcriptional activation of FoxA2 gene expression (Halpern et al., 2014). In addition, DNA methylation also has fundamental roles in processes of X-chromosome inactivation, imprinting, embryogenesis, and silencing of transposons. Loss of conserved patterns, resulting in either hypo- or hypermethylation, results in abnormal gene expression whose consequences are implicated in carcinogenesis.

Pathways of DNA Methylation

Two modes of DNA methylation are now widely accepted: *de novo* and maintenance methylation. *De novo* methylation occurs when new patterns of DNA methylation are established, whereas maintenance methylation involves conservation of existing patterns during DNA replication. How *de novo* methylation is prompted is incompletely understood. However, Klose and Bird (2006) postulate that *de novo* methyltransferases target their substrates via transcriptional repressors or other factors that aim at specific sequences of DNA. Alternatively, maintenance methylation relies on compliment of each methylated parent strand formed during replication; cytosine, however, as opposed to 5-mc, is incorporated into regions that should be methylated, resulting in hemimethylated DNA (Goodman and Watson, 2002). DNA methyltransferases then transfer methyl groups to cytosine of newly formed compliment strands, thus conserving the methylation pattern and completing replication processes (Goodman and Watson, 2002).

Demethylation is a biological method by which methyl groups are removed from cytosine residues, generally resulting in gene reactivity. Since there are no known active demethylases, demethylation is proposed to occur by both **passive** and **active** reactions (Ooi and Bestor, 2008). **Passive** DNA methylation is described as failure to methylate DNA following its replication as a function of deficit or malfunction of DNA methyltransferase 1 (DNMT1). Alternatively, **active** demethylation occurs by two different mechanisms. Hydrolytic deamination of 5-mc in DNA to thymine is suggested as one mechanism. This base substitution, when repaired properly, is replaced by an unmethylated cytosine. Conversion of 5-mc to 5-hydroxymethylcytosine (5-hmC), 5-formylcytosine, and 5-carboxylcytosine by ten-eleven translocation enzymes (TET) is a second pathway for demethylation (Tammen et al., 2012). Both passive and active reactions result in loss of DNA methylation patterns.

TABLE 45.1 DNA Methyltransferases (DNMTs)

Name	Description
DNMT1	Preference for hemimethylated DNA; maintenance methyltransferase; some de novo methylation activity
DNMT3a	De novo methyltransferase
DNMT3b	De novo methyltransferase
DNMT3L	Catalytically inactive; required cofactor for DNMT3a and DNMT3b activity
DNMT1o	Oocyte-specific form of DNMT1
DNMT2	Not required for either de novo or maintenance methylation

DNA Methyltransferases

Several forms of DNA methyltransferases have been identified and are outlined in Table 45.1. The First purified and cloned eukaryotic DNA methyltransferase was DNA (cytosine-5)-methyltransferase (Bestor et al., 1988), later termed DNMT1. DNMT1 is usually referred to as maintenance methyltransferase as it has a higher preference for hemimethylated DNA (Pradhan et al., 1999; Hermann et al., 2004). DNMT1 is targeted to replication fork by specific factors, such as UHRF1 (ubiquitin-like, containing PHD and RING finger domains protein 1), which recognize hemimethylated DNA (Bostick et al., 2007; Sharif et al., 2007). DNMT1o is an oocyte-specific truncated form of DNMT1 found in very high levels in oocytes (Goll and Bestor, 2005). Other DNA methyltransferases include DNMT3a and DNMT3b, predominant *de novo* methyltransferases (Okano et al., 1999). Their activity is linked with DNMT3-like protein (DNMT3L), an inactive regulatory cofactor that enhances *de novo* methylation (Suetake et al., 2004). DNMT3b is also responsible for methylation of satellite DNA and pericentromeric regions of chromosomes (Okano et al., 1999). For most of the last three decades, biochemical analyses of DNMT2 enzymes that contain motifs similar to DNA methyltransferases demonstrated very weak, albeit no specific, DNA methyltransferase activity (Okano et al., 1998a,b). More recent data confirm RNA methylation activity of DNMT2 at cytosine38 (C38) of tRNAAsp^{GTC} in mice, *Drosophila melanogaster* and *Arabidopsis thaliana*. Current advances in sequence alignment analysis of methyltransferase catalytic domains suggest that eukaryotic DNMT1, DNMT2, and DNMT3 probably evolved from common ancestral DNMT2-like RNA methyltransferases. Progressive evolution steered DNMT1 and -3 to shift DNA to RNA, while action of DNMT2 remained conserved (Goll et al., 2006; Jeltsch et al., 2017).

Transcriptional Repression and DNA Methyl-Binding Proteins

Transcriptional silencing elicited by DNA methylation occurs by two different mechanisms—through "removal of a permissive environment" or by "acquisition of a repressive environment" (Prokhortchouk and Defossez, 2008).

In the "removal of a permissive environment," a protruding methyl group is oriented away from the major groove of DNA, thus interfering with transcription factor (TF) binding (Klose and Bird, 2006; Perera and Herbstman, 2011). In a second mechanism, "acquisition of a repressive environment" involves transcriptional repressors that recognize methylated DNA. The repressors, or DNA methyl-binding proteins (MBPs), bind and prevent accessibility to DNA, thus obscuring these areas from TFs. In addition, DNA MBPs recruit transcriptional corepressors that create repressive chromatin, thus solidifying gene suppression (Robertson and Jones, 2000; Klose and Bird, 2006). In the latter environment, DNA methylation is viewed as initiator of process, while activity of repressors and corepressors facilitates transcriptional silencing (Jones and Baylin, 2002). Active genes, however, can also be methylated, but the degree of methylation is an important consideration (Zemach et al., 2010).

Table 45.2 lists three families of DNA MBPs: (1) methyl-CpG-binding domain (MBD)–containing family; (2) zinc finger proteins; and (3) SET and RING finger associated (SRA) domain-containing proteins (Prokhortchouk and Defossez, 2008; Sasai and Defossez, 2009). MBDs prevent binding of TFs and associate with corepressor complexes to enhance gene repression; for example, MeCP2 (MBD-containing protein 2) associates with histone deacetylase (HDAC)–containing corepressor SIN3 (Jones et al., 1998; Nan et al., 1998). Similar to MBDs, zinc finger protein Kaiso mediates gene silencing by linking with another deacetylase-containing corepressor complex, N-CoR (Yoon et al., 2003). Other zinc finger proteins (ZBTB4 and ZBTB38) are capable of binding to single CpG dinucleotides to mediate transcriptional repression (Filion et al., 2006). SRA domain-containing proteins UHRF1 (ICBP90) and UHRF2 (NIRF) recognize and join with hemimethylated DNA (Mori et al., 2012). Interestingly, UHRF1 is essential for maintenance methylation (Bostick et al., 2007; Sharif et al., 2007).

HISTONE MODIFICATIONS

Within the beukaryotic nucleus, DNA is packaged by histones; i.e., proteins, which together with DNA, form the nucleosome (Barile, 2013). Nucleosome is a fundamental repeat unit of chromatin and consists of a 147-base pair DNA wrapped around two of each of core histones—H2A, H2B, H3, and H4—at a rate of 1.8 turns. Together with DNA, core histones thus comprise the histone octamer structure. Linker histone, H1, along with a string of DNA, connects neighboring nucleosomes (Luger et al., 1997). Core histones contain protruding N-terminal tails that participate in PTMs, including acetylation, methylation, phosphorylation, ubiquitination, and sumoylation, and are summarized in Table 45.3.

PTMs affect histone/DNA, histone/histone, and histone/protein interactions, all of which influence chromatin structure and activity. According to the "histone code" hypothesis, cross talk between varying PTMs orchestrates DNA functions, such as gene transcription, replication, and repair (Strahl and Allis, 2000). Different PTMs activate or repress these functions depending on location and type of modification and presence of adjacent modifications (Kouzarides, 2007). PTMs are also site-specific, interdependent, and contribute to organization of chromatin (Lachner and Jenuwein, 2002).

Chromatin is found in two distinct forms in eukaryotic cells: heterochromatin and euchromatin. Heterochromatin, or condensed, closed form of chromatin, is transcriptionally silent, whereas euchromatin is opened, less condensed form, which allows for both active and silent

TABLE 45.2 DNA Methyl-Binding Proteins

Family	Members	Description
MBD	MBD1, MBD2, MBD4, MeCP2	Methyl-CpG-binding domain-containing; associate with corepressor complexes; involved in transcriptional repression[a,b]
Zinc finger	Kaiso, ZBTB4, ZBTB38	Zinc finger domain-containing; associate with corepressor complexes; involved in transcriptional repression[c]
SRA	UHRF1 (ICBP90), UHRF2 (NIRF)	SRA domain-containing; preference for hemimethylated DNA[d]

MBD, methyl-binding domain; MeCP2, methyl-CpG-binding protein 2; SRA, SET and RING finger associated domain; UHRF, ubiquitin-like, containing PHD and RING finger domains; ZBTB, zinc finger and BTB domain. Alternate acronyms are provided in parenthesis.
[a]Jones et al. (1998).
[b]Nan et al. (1998).
[c]Yoon et al. (2003).
[d]Mori et al. (2012).

TABLE 45.3　Posttranslational Histone Modifications

Type of Modification	Key Mediators	Required Cofactor/Substrate	Antagonizers (Erasers)
Acetylation	Histone acetyltransferases	Acetyl coenzyme A	Histone deacetylases
Methylation (arginine)	Protein arginine methyltransferases	S-Adenosyl methionine (SAM)	JMJD6; demethylimination
Methylation (lysine)	Histone lysine methyltransferases	SAM	Lysine demethylases
Phosphorylation	Serine/threonine and tyrosine kinases	ATP	Phosphatases
Ubiquitination	E1-activating, E2-conjugating, E3-ligating ubiquitin enzymes	Ubiquitin	Deubiquitinases
Sumoylation	E1-activating, E2-conjugating, E3-ligating SUMO enzymes	SUMO1, SUMO2, SUMO3	SUMO-cleaving isopeptidases

ATP, adenosine triphosphate; *SUMO*, small ubiquitin-related modifier.

gene transcription. This accounts for an important role of euchromatin in DNA repair and replication (Roloff and Nuber, 2005; Kouzarides, 2007). In general, heterochromatin is associated with low levels of histone acetylation but high levels of histone methylation (Kouzarides, 2007). Active transcription within euchromatin is supported by high levels of histone acetylation and trimethylation, whereas transcriptionally inactive euchromatin associates with low levels of histone acetylation, methylation, and phosphorylation (Kouzarides, 2007).

Histone Acetylation

Acetylation occurs in part through counterbalancing activities of histone acetyltransferases (HATs) and HDACs. HATs are generally accepted as transcriptional activators as their activity weakens interactions between histones and DNA (Robertson and Jones, 2000). HAT activity promotes hyperacetylation, thus stimulating an open chromatin accompanied by increased transcriptional movement (Roth et al., 2001). Conversely, HDACs are transcriptional repressors that reverse HAT activity, consequently restoring histone/DNA interactions that support repressive chromatin (Robertson and Jones, 2000). Most importantly, acetylation not only disrupts histone/DNA interactions but also initiates histone/histone and histone/regulatory protein exchanges, all of which have weighty effects on DNA transcription (Roth et al., 2001). Both HATs and HDACs often exist within multiprotein complexes (Bannister and Kouzarides, 2011).

Using acetyl coenzyme A as a cofactor, HAT catalyzes transfer of an acetyl group to lysine (K) side chains, neutralizing lysine's positive charge (Bannister and Kouzarides, 2011). HAT exerts its modifications to weaken interaction between histones and DNA, essentially by disrupting electrostatic interactions, namely between positive charge of lysine residues and negative charge of DNA (Sterner and Berger, 2000; Bannister and Kouzarides, 2011). The outcome is the production of a relaxed, open state of chromatin that is permissive to TF binding and transcriptional activation. Two major classes of HATs are categorized: type-A and type-B. Originally, HATs were defined by location—nuclear HATs were designated type-A, while cytoplasmic HATs were assigned to type-B (Roth et al., 2001). However, increasing evidence suggests that HATs are not confined to one or other compartment (Parthun, 2007). Only known type-B HAT is HAT1, which performs acetylation of newly synthesized histones required for nuclear transport and deposition (Parthun, 2007; Shahbazian and Grunstein, 2007). Type-A HATs include *CBP/p300*, *GNAT*, and *MYST* families, which are classified and listed in Table 45.4, and are

TABLE 45.4　Histone Acetyltransferases

based on sequence homology and structure (Bannister and Kouzarides, 2011).

HDACs, in contrast, remove acetyl groups from lysine residues, restoring lysine's positive charge. Deacetylation is characterized by transcriptional repression. Four major classes of HDACs account for most of enzymatic action: class I, class II, class III (more commonly referred to as "sirtuins"), and class IV HDACs (Table 45.5). Class I, II, and IV HDACs require Zn^{2+} to catalyze removal of acetyl group, while sirtuins necessitate NAD^+ as a cofactor (Saunders and Verdin, 2007; Witt et al., 2009). Enzymes are involved in many chromatin repressive complexes (De Ruijter et al., 2003; Kouzarides, 2007). For instance, HDAC1 (class I) is associated with Sin3 corepressor complex, which is recruited to methylated DNA by DNA MBP MeCP2, the product of which is formation of hypoacetylated chromatin and gene repression (Jones et al., 1998; Nan et al., 1998).

Histone Methylation

Histone methylation occurs on lysine (mono-, di-, or trimethylation) or arginine (mono- or symmetric/asymmetric dimethylation) residues. Depending on site and degree of methylation, lysine methylation either activates or represses transcription, whereas arginine methylation is generally an activating mark (Kouzarides, 2002; Völkel and Angrand, 2007). Three major protein families are responsible for histone methylation: protein arginine methyltransferases (PRMTs), SET domain-containing subfamilies, and Dot1/DOT1L (Völkel and Angrand, 2007).

Table 45.6 assembles histone PRMTs as type I or type II enzymes, based on their ability to perform monomethylation and asymmetric (type I) or symmetric (type II) dimethylation (Kouzarides, 2002; Bedford and Clarke, 2009; Bannister and Kouzarides, 2011). Addition of methyl group(s) from donor (SAM) by PRMTs to ω-guanidino moiety of arginine (R) residues disrupts hydrogen bond formation between arginine and nearby acceptors, while increasing residue's affinity for aromatic rings (Chen et al., 1999). Common arginine methylation sites include R2, R17, and R26 of H3 and R3 of H4, resulting in transcriptional activation or repression, depending on site of methylation (Di Lorenzo and Bedford, 2011).

Jumonji C (JmjC) domain-containing iron- and 2-oxoglutarate-dependent dioxygenase (JMJD6) is the only known arginine demethylase (Chang et al., 2007). It reverses dimethyl H3R2 (H3R2me2) and mono- and dimethyl H4R3 marks (H4R3me1 and H4R3me2), respectively (Chang et al., 2007). Other mechanisms of demethylation involve demethylimination; i.e., conversion of arginine and monomethyl-arginine to citrulline by enzymatic activity of PADI4/PAD4 (peptidylarginine deiminase 4), which prevents or reverses arginine methylation and, hence, transcriptional activation (Kouzarides, 2007; Völkel and Angrand, 2007).

Using SAM as a methyl donor, histone lysine methyltransferases (HKMTs) introduce methyl groups to ε-amino group of lysine (K), resulting in enhanced or repressed transcription (Bannister and Kouzarides, 2011). Unlike acetylation, methylation does not result in any change to oxidation states; instead it increases hydrophobic properties (Rice and Allis, 2001). Most HKMTs are generally site specific, modifying corresponding lysine residues on specific histones (Kouzarides, 2007). All HKMTs contain catalytically active SET domain, except for Dot1/DOT1L (Völkel and

TABLE 45.7 Histone Lysine Methyltransferases

Family	Structural Features	Representative Members	Target Residues

Angrand, 2007; Bannister and Kouzarides, 2011). SET domain, or *Su(var)3-9, enhancer of zeste (E(z)), and trithorax (trx)* domain, is required for functional histone lysine methylation.

Table 45.7 summarizes properties of HKMT families, including SUV39 family, whose members, SUV39H1 and SUV39H2, were the first mammalian HKMTs identified (Völkel and Angrand, 2007). Additional HKMTs consist of SET1, SET2, EZH, SMYD, and PRDM families, as well as other SET-containing proteins, such as SET7/9 and SET8 (PR-SET7), and non−SET-containing protein, Dot1/DOT1L (Völkel and Angrand, 2007). Lysine methylation occurs on residues K4, K9, K27, K36, and K79 of H3 and K20 of H4; H3K9, H3K27, and H4K20 methylation results in transcriptional repression, while H3K4, H3K36, and H3K79 methylation causes transcriptional activation (Table 45.8) (Gadhia *et al.*, 2012; Lachner and Jenuwein, 2002; Völkel and Angrand, 2007).

Table 45.9 illustrates families of histone lysine methylases and demethylases whose activities are antagonistic.

Of these, lysine-specific demethylase 1 (LSD1) was the first to be discovered (amine oxidase). When combined with repressor, Co-REST, the complex activates demethylation of both H3K4me1 and -me2, which results in transcriptional repression (Kouzarides, 2007; Völkel and Angrand, 2007). Mechanism of LSD1 demethylation involves oxidation of an amine to form an unstable imine intermediate that ultimately regenerates unmethylated lysine residues (Völkel and Angrand, 2007). LSD1 also demethylates H3K27me1 and -me2, during interactions with androgen receptor, which is presumably the basis for transcriptional activation of androgen-responsive genes (Kouzarides, 2007; Völkel and Angrand, 2007). Other lysine demethylases include *JmjC* domain-containing families, hydroxylases *JHDM1*, *JHDM2*, and *JHDM3*, which require *JmjC* domains for their catalytic activity (Klose *et al.*, 2006).

Histone Phosphorylation

Important for transcription and cell cycle progression, phosphorylation is dependent on upstream signal transduction cascades (Baek, 2011). When activated, these signaling pathways regulate gene transcription and alter chromatin states. This is accomplished by stimulating phosphorylation of histones, TFs, and transcriptional coregulators (Baek, 2011). Phosphorylation involves activity of kinases that transfer phosphate groups from ATP to hydroxyl groups of target residue,

resulting in net formation of negative charges (Bannister and Kouzarides, 2011). As presented in Table 45.10, kinases modify histone serine and threonine residues (serine/threonine kinases), as well as tyrosine residues (tyrosine kinases), generally leading to transcriptional activation or chromatin condensation (Baek, 2011). For example, phosphorylation of H3S10 by a variety of serine/threonine kinases (RSK2, MSK1/2, protein kinase B [PKB] [ATK]) is a frontrunner for transcriptional activation (Baek, 2011). Alternatively, during mitosis,

chromatin condensation is facilitated by phosphorylation of H3S10 and H3S28 by *Aurora B*, a process necessary for cell cycle progression (Sugiyama et al., 2002; Bhaumik et al., 2007; Baek, 2011).

In addition to specific TFs, kinases directly or indirectly target other histone modifiers, such as HATs (CREB, CBP, and GCN5), HDACs (SIRT1 and HDAC5), and HKMTs (EZH2), thus modulating their activity (Baek, 2011). For instance, direct phosphorylation of EZH2 by PKB (AKT) inhibits lysine methyltransferase activity, producing a decrease in H3K27 trimethylation (Baek, 2011). In addition, GCN5 is indirectly recruited following phosphorylation of H3T11, establishing acetylation of neighboring H3K9 and H3K14 residues (Shimada et al., 2008); phosphorylation of H3S10, however, has a contrasting effect, causing hypoacetylation of same residues (Edmondson et al., 2002). Activity of kinases is reversed by phosphatases, such as effects of serine/threonine phosphatases, PP1 and PP2A, the net reaction of which is dephosphorylation necessary for firm control of chromatin condensation (Sugiyama et al., 2002).

Histone Ubiquitination and Sumoylation

In addition to mediating protein degradation, protein trafficking, stress responses, and cell cycle progression, ubiquitination also regulates gene transcription via histones (Pickart, 2001; Zhang, 2003). Ubiquitination of histones, unlike other proteins, is not linked to degradation; instead it dictates transcription in a site-specific manner by impacting higher-order chromatin structure (it is a bulky modification) (Zhang, 2003; Bhaumik et al., 2007). Consequently the pathway is capable of recruiting other regulatory molecules that control transcription, thus enhancing or interfering with other neighboring histone modifications (Zhang, 2003).

Ubiquitination is the covalent addition of ubiquitin (Ub) via an isopeptide bond between C-terminal glycine of Ub and ε-amino group of lysine of either target proteins (i.e., histones) or other Ub molecules (Pickart, 2001; Zhang, 2003). Furthermore, ubiquitination is likely to occur by presence of multiple lysine residues found within Ub, allowing for formation of poly-Ub proteins (Zhang, 2003). Target residues include H2AK119 (mono- or poly-Ub), a biomarker associated with transcriptional repression, and H2BK120 (mono-Ub), a biomarker required for initiation and elongation of transcription (Zhang, 2003; Kouzarides, 2007).

Ubiquitination is performed by sequential activity of one E1-activating enzyme, varying E2-conjugating enzymes, and target-specific, RING finger domain-containing E3 ligases (Pickart, 2001; Zhang, 2003; Bhaumik et al., 2007). For example, RING1, a polycomb group (PcG) protein, is an E3 ligase that performs

monoubiquitination of H2AK119 during gene silencing (Bhaumik *et al.*, 2007; Kouzarides, 2007). Deubiquitination, or removal of ubiquitin groups, occurs via activity of deubiquitinases (isopeptidases), such as 2A-DUB, which mediates deubiquitination of H2AK119 (Zhang, 2003; Bhaumik *et al.*, 2007).

Sumoylation, like ubiquitination, is covalent addition of a small protein (SUMO) to lysine of a target protein via an isopeptide bond. SUMO, or "small ubiquitin-related modifier," is an ubiquitin-like protein distantly related to ubiquitin (Melchior, 2000). Members of SUMO family include SUMO1 (sentrin), SUMO2 (SMT3a; sentrin-3), and SUMO3 (SMT3b; sentrin-2), which are conjugated to target proteins by sequential activity of SUMO-activating enzyme (E1), -conjugating enzyme (E2), and -ligase (E3) (Johnson, 2004). Sumoylation is a reversible process, where removal of SUMO groups is performed by a group of isopeptidases—i.e., Ulp domain-containing SUMO-cleaving enzymes, such as *SENP1* (Johnson, 2004).

SUMO modifications regulate transcriptional processes and nuclear transport, as well as promote assembly of multiprotein complexes (Johnson, 2004). In addition, SUMO, which conjugates same lysine targets as ubiquitin, competes with and blocks ubiquitin binding at these sites (Johnson, 2004). Many targets of SUMO are involved in regulation of gene transcription, including transcriptional activators, coactivators, repressors, and corepressors, where sumoylation generally induces transcriptional repression (Johnson, 2004). For instance, SUMO1 is required for repressive activity of HDAC1, HDAC4, and p300 (David *et al.*, 2002; Kirsh *et al.*, 2002; Girdwood *et al.*, 2003).

POLYCOMB AND TRITHORAX PROTEINS

PcG and trithorax group (TrxG) proteins are evolutionarily conserved multiprotein complexes that regulate chromatin states in an opposing manner (Mills, 2010). More specifically, Table 45.11 outlines activities of PcG protein complexes that result in transcriptional repression, whereas those of TrxG promote transcriptional activation (Schuettengruber *et al.*, 2007; Mills, 2010). Both PcG and TrxG protein complexes are recruited to chromatin by DNA regulatory elements, where they form covalent modifications of histones (Mills, 2010; Tammen *et al.*, 2012).

Two main PcG protein complexes are reported: polycomb repressor complexes 2 (PRC2) and 1 (PRC1). Catalytic activity of PRC2 resides in its SET domain-containing subunit, EZH2 (Schuettengruber et al., 2007; Mills, 2010). Like other SET enzymes, EZH2 is responsible for histone lysine methylation; more specifically, it causes trimethylation of H3K27, a repressive mark

TABLE 45.11 Chromatin Remodeling: Polycomb and Trithorax Group Complexes

[c]Mills (2010).

(Schuettengruber *et al.*, 2007; Mills, 2010). EZH2 activity is dependent on the presence of other PRC2 subunits, such as EED and SUZ12 (Mills, 2010). Conversely, PRC1 recognizes H3K27me3 mark, leading to further PcG-dependent chromatin silencing through monoubiquitination of H2AK119. This activity is supported through action of its RING1 subunit (Kouzarides, 2007; Tammen *et al.*, 2012), a mark of which prevents RNA polymerase activity, thus halting gene transcription (Tammen *et al.*, 2012).

TrxG protein complexes are involved in several histone-modifying reactions. Mixed lineage leukemia (MLL) complex or mixed lineage leukemia (Tables 45.7 and 45.11) is one possible pathway, while ATP-dependent chromatin remodeling, such as execution by switch/sucrose nonfermentable (SWI/SNF), ISWI (protein **ISWI** or **imitation SWI** of *drosophila melanogaster*), and CHD (Chromodomain Helicase DNA-binding family of proteins)complexes (Mills, 2010), is another. Histone-modifying activity of MLL complexes is dependent on catalytic activity of SET domain-containing MLL subunit (MLL, MLL2, MLL3, or MLL5; Table 45.11), which results in trimethylation of H3K4 and subsequent transcriptional activation (Mills, 2010). Interestingly, as acetylation is an activating mark and prevents H3K27 trimethylation, MLL complex also recruits HATs, such as MYST1 (Dou et al., 2005), further promoting its transcription-enhancing activity (Mills, 2010).

NONCODING RNA

The significance of mRNA, tRNA, and rRNA in transcription of DNA, followed by translation and protein synthesis, and their associated molecular machinery, has been well established for several decades. Remarkably, genome-wide analysis in eukaryotes reveals that only 1%–2% of a transcribed genome is required to be functionally active and to encode protein; the transcribed, nonprotein coding segment of DNA is referred to as "junk DNA," and its nontranslatable product is labeled ncRNA (Frith *et al.*, 2005; Kaikkonen *et al.*, 2011). Exploration of the biological significance of both junk DNA and ncRNAs started in early 1990s leading to the discovery of several types of ncRNAs, which are primarily categorized according to the variable lengths formed by their constituent nucleotides. Although microRNAs (miRNAs) are the most studied variants among ncRNAs, other representatives such as small nucleolar RNAs, transcribed ultraconserved regions, PIWI-interacting RNAs (piRNAs), and a diverse group of long noncoding RNAs (lncRNAs) have been discovered and are known for their differential modulatory effects on genomic transcription and translation (Kaikkonen *et al.*, 2011). Table 45.12 outlines the variety of ncRNAs, as well as their length and frequency of occurrence in the human genome.

The biological reputation of miRNAs is attributed to their ability to specifically target mRNA, the basis of which leads to posttranscriptional gene silencing and suppression of translation. Biogenesis of miRNAs is mediated by transcription of miRNA genes by pol II promoter to produce a primary transcript of miRNA (Khandelwal *et al.*, 2015). The primary transcript produced is the precursor of miRNA constituting several thousands of nucleotides in length, which, when cleaved by nuclear Drosha/DGCR8 complex, forms long precursor miRNA (pre-miRNA) spanning hundreds of nucleotides. Pre-miRNA is then exported to the cytoplasm via Ran-GTP/exportin-5 complex and is further cleaved by Dicer/TRBP (TAR RNA-binding protein) complex to form mature miRNA, with a final length of 19–24 nucleotides. Mature miRNA combines with Argonaute proteins, which materializes into RNA-induced silencing complex. The completely formed complex recognizes and targets mRNA eventually causing transcriptional repression (He and Hannon, 2004). In contrast, biogenesis of piRNAs is Dicer-independent and is functionally involved in maintenance of genomic stability in germline cells. PiRNAs form complexes with PIWI proteins and suppress transposable element expression by either cleavage or progressive DNA methylation, rendering gene silencing (Aravin *et al.*, 2007).

TABLE 45.12   Classification of Noncoding RNAs

Type	Length (nt)	Function	Number in Humans	Example
tiRNAs	17–18	Transcription regulation	>5000	CAP1 gene and cAMP pathway
miRNAs	19–24	Target and inactivate mRNA causing transcriptional repression	>1500	miR-34b/c, miR-200
piRNAs	26–31	DNA methylation and transposon repression	∼23,000	Targeting LINE1 and IAP elements
TSSa RNAs	20–90	Transcription regulation	>10,000	RNF12 and CCDC52 gene regulation
PASRs	22–200	Gene promoter region alterations	>10,000	Associated with protein coding genes
PROMPTs	<200	Transcription regulation	Unknown	EXT1 and RBM 39 gene processing
snoRNAs	60–300	rRNA alterations	>300	SNORD
T-UCRs	>200	mRNA and transcriptional regulation	>350	uc.338, uc.160+
NATs	>200	Gene expression regulation; RNA editing/stability	Unknown	p15-NAT
eRNAs	>200	Enhance gene transcription	Unknown	P53 derived eRNAs

CAP1, adenylyl cyclase-associated protein 1; *CCDC52*, coiled-coil domain containing 52; *eRNAs*, enhancer-derived RNAs; *EXT*, exostosin 1; *HOTAIR*, homebox transcript antisense RNA; *HOTTIP*, HOXA distal transcript antisense RNA; *lincRNAs*, large intergenic noncoding RNAs; *LINE1*, long interspersed element 1; *miRNAs*, microRNAs; *NATs*, natural antisense transcripts; *PASRs*, promoter-associated small RNAs; *piRNAs*, PIWI-interacting RNAs; *PROMPTS*, promoter upstream transcripts; *RBM 39*, RNA-binding motif protein 39; *RNF12*, ring finger protein 12; *snoRNAa*, small nucleolar RNAs; SNORD, C/D box snoRNAs; *tiRNAs*, transcription initiation RNAs; *TSSa RNAs*, transcription start site–associated RNAs; *T-UCRs*, transcribed ultraconserved regions.
Adapted and modified from Esteller, M., 2011. Non-coding RNAs in human disease. Nat. Rev. Genet. 12(12), 861.

LncRNAs are diverse within the class with more than 200 bp length, accompanied by an ability to inhibit transcriptional regulation during gene expression using multiple mechanisms. From an EG perspective, lncRNAs are postulated to recruit chromatin remodeling complexes to specific gene loci resulting in progressive transcriptional manipulations (Gupta *et al.*, 2010). Furthermore, analysis of lncRNAs as a function of its gene and associated EG modifications indicated that the effects of these alterations are similar to those of protein encoding genes. Case in point—the presence of the transcriptionally active biomarker modifications, H3K4me3 and H3K36me3, in genes encoding lncRNAs resulted in their own overexpression, a situation analogous to genes that encode proteins (Sati *et al.*, 2012). However, limited evidence suggests an inverse relationship of EG modifications in lncRNAs coding genes contrary to mRNA coding genes. This phenomenon is embodied in a study displaying hypermethylation (transcriptional repressor) of the transcription start site of lncRNA coding genes having no significant effect on their expression levels (Sati *et al.*, 2012).

EPIGENETICS AND DISEASE

The field of EGs is now associated with an abundance of biomarkers, and the mechanisms of numerous diseases have been correlated with it. Consequently, biomarkers offer significant opportunities to understand the progression of pathologies and disease states. The role of biomarkers thus encourages appreciation of the mechanisms associated with the disease state, aids in the diagnoses of pathologies, and is involved in identifying interactions of therapeutic modalities with pathological consequences. In addition, biomarkers are involved in aberrations associated with DNA methylation, disruption of chromatin structure, or defects in "gain- or loss of function" of histone-modifying enzymes, all of which adversely affect gene expression (Feinberg, 2007). Thus, EG dysfunction results in loss of imprinting (LOI), DNA hypo- and hypermethylation, abnormal histone modifications, and generation of ncRNAs, frequently resulting in inactivation, or overexpression, of specific genomic loci (Herceg and Hainaut, 2007). Accordingly, EG dysregulation is implicated in generation or development of cancer, autoimmune diseases, and metabolic disorders (Calabro *et al.*, 2008).

Abnormalities of DNA Methylation

Abnormal regulation of DNA methylation is implicated in the origin of many genetic diseases, presumably a result of mutations in genes whose protein products have essential functions in DNA methylation and recognition. As such they are noted in immunodeficiency and centromere instability, including facial anomalies syndrome (ICF) and Rett syndrome, respectively. ICF is a rare autosomal recessive disorder characterized by hypomethylation of pericentromeric repeats. Its origin is a point mutation in the gene encoding DNMT3b, resulting in abnormal methylation (Xu *et al.*, 1999). The mutation adversely affects function of PWWP domain, responsible for normal chromatin binding (Klose and Bird, 2006). Alternatively, DNA methylation occurs normally in Rett syndrome, but the characteristic EG predicament is displayed by a defect in the ability to recognize methyl marks (Bienvenu and Chelly, 2006; Feinberg, 2007). This neurodegenerative disease is triggered by mutations in DNA MBD and transcription repression domain of the gene that encodes MeCP2, thus interfering with its proper functioning (Amir *et al.*, 1999).

Aberrations in DNA methylation patterns, such as in those required for imprinting, are also implicated in a variety of diseases. Regulated by EG processes during normal development, imprinting or silencing of either maternal or paternal alleles of particular genes is critical for proper cell functioning. When imprinting fails, the result is biallelic expression of certain monoallelic genes, initiating abnormal gene overexpression (Herceg and Hainaut, 2007). Diseases attributable to imprinting failure include Beckwith—Wiedemann syndrome (characterized by Wilms' tumors), Prader—Willi syndrome, and Angelman syndrome (Feinberg, 2007). In addition, LOI, i.e., either activation of a normally silent imprinted allele or silencing of a typically expressed imprinted allele, is implicated in cancer development, such as neuroblastoma and invasive breast cancer (Pedersen *et al.*, 1999; Astuti *et al.*, 2005; Feinberg, 2007).

As observed in LOI, DNA hypo- or hypermethylation results in aberrant gene expression and its pathological consequences. Hypomethylation occurs when established methylation patterns are lost through demethylation. Conversely, hypermethylation results from introduction of new methylation patterns where previously there may have not been an impact. Global hypomethylation is a general hallmark of cancer and is associated with aberrant activation of protooncogenes and chromosome instability (Jones and Baylin, 2002; Gopalakrishnan *et al.*, 2008; Herceg and Hainaut, 2007). Gene-specific hypermethylation is also a characteristic of many cancers, frequently occurring within promoter regions of tumor suppressor genes (Jones and Baylin, 2002; Feinberg, 2007).

Abnormalities in Histone Modifications

Abnormalities in histone modifications result from either loss-of-function or gain-of-function mutations in

regulators. For instance, Rubinstein—Taybi syndrome is instigated through microdeletions, translocations, and point mutations in the gene that encodes for acetyltransferase coactivator CBP (Petrij *et al.*, 1995). Other examples of disorders resulting from histone methyltransferase malfunction include Sotos syndrome and Wolf—Hirschhorn syndrome, represented by mutations in genes encoding NSD1 and NSD2, respectively (Bergemann *et al.*, 2005; Feinberg, 2007). Sotos syndrome is characterized by a triad of Wilms' tumor, leukemia, and tissue overgrowth, while Wolf—Hirschhorn syndrome presents with mental retardation, epilepsy, and cranio-facial dysgenesis (Bergemann *et al.*, 2005; Feinberg, 2007).

As increasing evidence of EG mechanistic changes in multiple disease conditions is discovered, selected examples of cancer and autoimmune diseases, such as systemic lupus erythematosus (SLE), type 1 diabetes mellitus (T1-DM), and metabolic syndrome (MS), are further discussed in this context.

Epigenetics and Cancer

Cancer cells exploit innate metabolic pathways for their survival and hyperproliferation. This metabolic dysregulation associated with tumor microenvironment leads to an anomalous EG regulation pattern that subsequently disrupts cellular homeostasis (Shen and Laird, 2013). A pathological hallmark of cancer, consequentially, is disruption of genetic mechanisms by an assortment of mutations, copy number alterations, and impairment of DNA repair mechanisms, which ultimately result in extensive microsatellite instability throughout the genome (Hanahan and Weinberg, 2011). Mutations in EG regulators include writers—DNA methyltransferases, histone methyltransferases, HATs; readers—bromodomain, chromodomain, tudor protein; erasers—HDACs, histone demethylases; and chromatin remodelers—SWI/SNF complex; all of which result in abnormal processing patterns of the genetic code (Simó-Riudalbas and Esteller, 2014; Soshnev *et al.*, 2016).

Approximately 40% of CpG islands occur at promoter regions of human genes spanning at the 5'-end of their regulatory regions (Goll and Bestor, 2005; Gopalakrishnan *et al.*, 2008). Genome-wide analysis of several cancers has demonstrated a 10% increase in progressive methylation of normally unmethylated promoter CpG of tumor suppressor genes rendering them silenced (Simó-Riudalbas and Esteller, 2014). This phenomenon of methylation associated with underexpression of demethylation enzymes, such as TET methylcytosine dioxygenase family, activation-induced cytidine deaminase, and thymine DNA glycosylase, results in perpetual inactivation of tumor suppressor genes. Hypermethylation of promoter region CpG islands of tumor suppressor genes and subsequent gene silencing leads to the inability to regulate DNA repair and cell cycle progression (Mulero-Navarro and Esteller, 2008). Examples of gene-specific hypermethylation of tumor suppressor genes include *RB* in retinoblastoma, $p15^{INK4B}$, in particular forms of leukemia, and *BRAC1* in breast and ovarian cancer (Sakai *et al.*, 1991; Herman *et al.*, 1996; Esteller *et al.*, 2000). In addition, it is important to note that 5-mc, a methyl mark, is an endogenous mutagen. During spontaneous deamination, 5-mc is converted to thymine, a substitution that is more difficult to detect by DNA repair mechanisms as compared with deamination of cytosine, to form uracil (Robertson and Jones, 2000). This process has been implicated in mutagenesis of tumor suppressor genes, such as *TP53*, the gene that encodes p53. Point mutations in locations of known methylated cytosines in *TP53* result in amino acid surrogates in its protein product, affecting abnormal function and disease (Rideout III *et al.*, 1990).

Substantial variability in the genome and epigenome exists between and within specific cancer types. For instance, one of the challenges in breast cancer therapeutics is the high degree of heterogeneity exhibited by different breast tumors. Notably, a higher frequency of DNA methylation is observed in luminal (ER+) breast tumors compared with nonluminal (ER−) subtypes. (Interestingly, breast cancers are ER+ in the initial stages of the disease and later progress to more aggressive ER− breast cancers.) Hypermethylation of genes that encode ER has been proposed as a mechanism of silencing initially overexpressed ER receptors, which then progress to ER− breast cancer (Benevolenskaya *et al.*, 2016). Table 45.13 summarizes a selected list of drugs which exploit EG modifications as their therapeutic targets in cancer treatment.

HATs are also linked to fusion proteins caused by chromosomal translocations (Herceg and Hainaut, 2007). As an illustration, in acute myeloid leukemia, CBP was found to form fusion protein with MOZ, which causes global loss of acetylation (Borrow *et al.*, 1996; Fraga *et al.*, 2005). Another leukemia-related fusion protein, MORF-CBP, also results in a loss of acetylation (Fraga *et al.*, 2005). Mutations in genes encoding CBP coactivator, p300, result in truncated forms of protein and are also coupled to colorectal and breast cancers (Gayther *et al.*, 2000). MLL is implicated in human lymphoid and myeloid leukemias and in myelodysplastic syndrome (Varier and Timmers, 2011). Chromosomal aberrations of gene encoding MLL result in over 50 different types of translocations (Varier and Timmers, 2011). In addition, overexpression of EZH2, whose consequences are responsible for increased gene repression, is a hallmark of metastatic prostate cancer (Feinberg,

TABLE 45.13 Epigenetic Classification of Drugs in Cancer Therapeutics

Epigenetic Class of Drug	Compound	Target; Subclass	Clinical Stage of Development; Sponsor	Indication
DNA methylation inhibitors	5-Azacytidine	DNMT1	Approved; Celgene	MDS
	Decitabine	DNMT1	Approved; Otsuka, Janssen	MDS
Histone methyltransferase inhibitors	EPZ-5676	DOT1L	Clinical trials; Epizyme Inc.	Hematological malignancy
	EPZ-6438	EZH2	Clinical trials; Epizyme Inc.	Lymphoma and solid tumors
Histone demethylase inhibitors	Tranylcypromine analog	HDM	Clinical trials; Oryzon genomics	Leukemia
Histone acetyltransferase inhibitors	C646	p300	Preclinical trails; John Hopkins University	Multiple tumor types
Histone deacetylase inhibitors	Vorinostat	HDACs	Approved; Merck	CTCL
	Pracinostat	HDACs	Approved; MEI pharma	AML
	Panobinostat	HDACs; Hydroxamic acid derivatives	Approved; Novartis	Multiple myeloma
	Romidepsin	HDACs; Cyclic peptides	Approved; Gloucester pharmaceuticals	CTCL, PTCL

AML, acute myeloid leukemia; *CTCL*, cutaneous T cell lymphoma; *DOT1L*, disruptor of telomeric silencing 1-like histone H3K79 methyltransferase; *EZH2*, enhancer of zeste homolog 2; *MDS*, myelodysplastic syndrome; *p300*, E1A-binding protein; *PTCL*, peripheral T cell lymphoma.
Adapted from Biswas, S., Rao, C.M., 2017. Epigenetics in cancer: fundamentals and beyond. Pharmacol. Ther. 173, 118–134; Bennett, R.L., Licht, J.D., 2018. Targeting epigenetics in cancer. Ann. Rev. Pharmacol. Toxicol. 58, 187–207.

2007). Another overexpressed polycomb-related factor, BMI1, is observed in colorectal and liver carcinomas, non-small cell lung cancer, and mantle cell lymphoma (Valk-Lingbeek *et al.*, 2004).

Epigenetically altered genes and their expression can be modified by partial to complete reversal of undesired aberrant EG modifications, which makes them ideal targets for cancer therapeutics.

Epigenetics and Autoimmune Disease

Systemic Lupus Erythemosus

Historically, evidence has accumulated demonstrating the involvement of EG alterations in pathogenesis of autoimmune diseases. Richardson (1986) first demonstrated activation of autologous macrophages resulting in development of an autoimmune lupus-like condition when the patient was treated with the demethylation agent, 5-azacytidine (Richardson, *et al.*, 2004). Table 45.14 summarizes characteristic EG marks associated with several genes regulating immunity.

SLE is a chronic, systemic, autoimmune disease with diverse clinical manifestations affecting multiple organs. Pathological manifestations of SLE are mediated by production of autoantibodies that activate the complement cascade and trigger cytotoxic hypersensitivity in systemic circulation. Clinical evidence suggests that CD4+ T cells are globally hypomethylated in SLE and inhibitors of DNA methylation, such as procainamide and hydralazine, and induce lupus-like disease in mice (Cornacchia *et al.*, 1988). Furthermore, patients treated with high-dose hydralazine for longer durations exhibited lupus-like symptoms that waned on termination of the drug. This phenomenon of hydralazine-induced T cell hypomethylation in SLE is caused by inhibition of extracellular signal–regulated kinase pathway (Gorelik and Richardson, 2010). Promoter region hypomethylation and hence overexpression of select genes in T cells, including perforin, CD70, and CD11a, are linked with SLE. The results lead to CD4+ T cell–induced monocyte death, hyperstimulation of B cells, and disease-induced flares (Lu *et al.*, 2002; Richardson *et al.*, 2004; Kaplan *et al.*, 2004). In addition, elevation in global 5-hmC levels and increased expression of TET2 and TET3, which collectively convert methylcytosine to hydroxymethylcytosine in CD4+ T cells, is associated with active transcription and overexpression of select immune-related genes, notably, SOCS1, NR2F6, and IL15RA. The results lead to hyperstimulation of the immune system (Zhao *et al.*, 2016). Inactivation of HAT affected severe lupus-like disease in mice, progressing to glomerulonephritis and premature death (Forster *et al.*, 2007). In vivo studies demonstrate global histone H3 and H4 hypoacetylation and H3K9 hypomethylation

TABLE 45.14 Epigenetic Marks Associated With Genes Regulating Immune Cells

Type of Cell	Gene	Function	Characteristic Epigenetic Modification
T cell	CD3d[a]	T cell development	Active, H3 acetylation
	Bcl11b[a]	T cell development	
	Hhex[a]	Hematopoietic progenitor differentiation	Repressive, H3K27me3
	Lmo2[a]	Hematopoietic progenitor differentiation	
	Tbet[b]	Transcriptional regulator of Th1 subset of CD4+ T cells	**Naive state** - Hypermethylation with associated repressive histone modifications
	Gata3[b]	Transcriptional regulator of Th2 subset of CD4+ T cells	**Immune-activated state** - Hypomethylation and loss of histone repressive marks
	Rorgt[b]	Transcriptional regulator of Th17 subset of CD4+ T cells	
	FOXP3[c]	Transcription factor (TF) of immunosuppressive Treg	DNA hypomethylation
Macrophages	Pu. 1[d]	TF for macrophage lineage determination	Recruitment of TFs favoring open chromatin structure
Dendritic cells	CD209[e]	Essential factor for dendritic cell trafficking	Active, H3K9ac in CD209 gene; loss of histone repressive marks; Promoter region hypomethylation
B cells	PAX5[a]	Early B cell development	Hypomethylation before development of B cells; Hypermethylation upon development and maturation of B cells
	Pu. 1[d]		
	MB1[e]		
	Blimp-1[f]	Regulation of plasma cell differentiation	Variable histone active and repressive marks

Bcl11b, B cell lymphoma/leukemia 11B; *Blimp-1*, B-lymphocyte–induced maturation protein 1; *CD209*, dendritic cell–specific intracellular adhesion molecules-3 grabbing nonintegrin; *CD3d*, T cell surface glycoprotein CD3 delta chain; *FOXP3*, forkhead box protein P3; *Gata3*, GATA binding protein 3; *Hhex*, hematopoietically expressed homeobox; *Lmo2*, LIM domain only protein 2; *MB1*, membrane bound immunoglobulin associated protein; *PAX5*, paired box homeotic gene 5; *Pu. 1*, Spi-1 protooncogene; *Rorgt*, RAR related orphan receptor gamma; *H3*, Histone 3; *H3K27me3*, histone 3 lysine 27 trimethyl modification; *H3K9ac*, histone 3 lysine 9 acetyl modification.

in lupus-prone mice (Hu et al., 2008). Additionally, significant improvement in glomerulonephritis and splenomegaly was observed in lupus-prone mice when treated with HDAC inhibitors, including trichostatin A or suberoylanilide hydroxamic acid (Mishra et al., 2003; Reilly et al., 2011).

Type 1 Diabetes Mellitus

T1-DM, traditionally identified with insulin-dependent diabetes, is characterized by autoimmune destruction of insulin producing β cells in islets of Langerhans in the pancreas. The outcome results in deficiency of insulin in systemic circulation, leading to hyperglycemia, ketoacidosis, and other micro/macrovascular complications (Eisenbarth, 2005). The autoimmune reaction involved is elicited by hyperproliferation of B cells, CD4+ and CD8+ T cells, and autoantibodies against β cells causing their progressive destruction (Eisenbarth, 2005). T1-DM—mediated microvascular complications, such as retinopathy and neuropathy, are associated with concomitant elevation of H3K9ac levels at the promoter region of proinflammatory signaling molecule NF-kB (Miao et al., 2014). Furthermore, genome-wide analysis of DNA methylation in T1-DM patients identified differential global methylation levels that can serve as a prospective biomarker for diabetic complications (Gautier et al., 2015).

Epigenetics and Metabolic Syndrome

Studies concerning metabolic diseases and associated changes in variable regions of the mammalian epigenome, compared with healthy controls, demonstrated several alterations of EG fingerprints. MS is a classic example of metabolic disease characterized by a varied combination of multiple etiologies such as hypertension, dyslipidemia, obesity, and type 2 diabetes mellitus (Kaur, 2014). Increased expression of suppressor of cytokine signaling 3 (SOCS3) gene is linked to elevated risk of MS; DNA methylation analyses of obese subjects demonstrate hypomethylation and subsequent overexpression of SOCS3 gene (Ali et al., 2016). MiRNAs miR-33, -34a, and -22 are considered biologically significant in regulating lipid metabolism and are proposed to serve as valuable EG biomarkers to monitor MS (Yang et al., 2015).

CONCLUDING REMARKS AND FUTURE DIRECTIONS

EG mechanisms, such as DNA methylation, covalent PTMs of histones, and ncRNAs, play important roles in normal cellular processes. Dysfunction of such mechanisms, in the absence of induced mutations, results in abnormal gene expression and progression of pathologies. As EG changes typically occur early in a disease process, aberrant EG regulators are ideal targets for disease identification, diagnosis, monitoring, and follow-up treatment (Herceg and Hainaut, 2007). These regulators also act as valuable biomarkers in global public health risk assessment in the detection and prevention of diseases, notwithstanding the benefit of calculating treatment response (Mulero-Navarro and Esteller, 2008).

Risk Factors as Biomarkers of Susceptibility in Breast Cancer

Carolina Negrei[1], Bianca Galateanu[2]

[1]Departament of Toxicology, Faculty of Pharmacy, "Carol Davila" University of Medicine and Pharmacy, Bucharest,
Romania; [2]Department of Biochemistry and Molecular Biology, University of Bucharest, Bucharest, Romania

INTRODUCTION

Epidemiology

Over the entire span of their lives women, and postmenopausal women especially, have an 11% risk of developing breast cancer, making this the most widespread malignancy among women. The current worldwide trend in incidence rate is higher in developed countries, but changes in lifestyle may lead to increases in less developed countries as well (Tao et al., 2015).

Pathology

Adenocarcinomas are the most type of common cancer, almost excluding lymphoma and sarcoma pathology. Both noninvasive and invasive breast tumors usually originate in the lobules and ducts, and their specific morphology becomes evident via microscopic examination, which provides decisive histological data to distinguish lobular from ductal carcinomas. According to present evidence, the site of origin for both types is considered to be the terminal duct lobuloalveolar unit (Russo and Russo, 1999).

Usually determined by mammography (Ernster et al., 2002), atypical ductal hyperplasia leading to in situ breast carcinomas do not pervade the basement membrane but may be considered as early precursors of invasive types (Kuerer et al., 2009). This has been successfully shown in a number of progression models for normal breast tissue.

Between ductal and lobular invasive types, the histological category most commonly diagnosed (approximately 80% of all cases) is ductal carcinoma. Invasive lobular carcinoma occurs much less often (Li et al., 2003), mostly in elderly women and, despite a specific metastatic pattern, it has a similar prognosis for other ages (Arpino et al., 2004). Other well-defined morphologic but more infrequent subtypes providing better prognosis may include Paget and adenoid cystic, papillary, medullary, tubular, and mucinous carcinomas.

Risk Factors

Among the most significant risk factors for developing breast cancer, inherent predisposing factors have to be taken into account. Factors such as gender, age, and history of benign or malignant breast disease in both patients and their family (more significantly in a first-degree relative) may be broad predictors. Although gender would seem irrelevant as a breast cancer risk factor, because of the difference between males and females in exposure to hormones, male breast cancer cases used to be very rare, but they are becoming more frequent of late. The risk of developing breast cancer is mainly age dependent as a consequence of genetic and epigenetic changes (Fraga et al., 2007). Thus, there is low risk but more aggressive progression before the age of 25, and the risk increases significantly in the third decade. Diagnosis is largely established prior to menopause, possibly indicative of a hormonal status association (Tao et al., 2015).

Several more specific predisposing factors stand out, the most important of which are hormonal and reproductive particulars related to estrogen exposure (age at first period, first pregnancy and menopause, high levels of endogenous sex steroid hormone, lifetime use of hormonal drugs), breast density, and genetic and epigenetic alterations. Breast density relates to the amount of mammary gland stromal and epithelial cells, and higher density arises from more extensive fibrous and glandular

tissue as opposed to adipose tissue. This is a significant (four times higher than average) risk for both breast cancer occurrence and more aggressive tumors.

Further factors of individual risk are proliferative breast lesions with an excessive number of cells, some of which display morphological abnormalities. At the same time, behavioral and lifestyle factors (weight, diet, exercise, and use of alcohol) should not be overlooked (Veronesi et al., 2005). Risk factors have a cumulative effect on overall risk.

Life Stage–Related Risks

In addition to genetic and environmental risks, there is a certain increased vulnerability to cancer depending on the person's development of life phase, when the tissue is more susceptible to the occurrence of alterations under the influence of epigenetic factors. These factors are likely to trigger changes in the underlying body structure and functions as well as cellular modifications. For breast development, important stages include the fetal stage, puberty with its marked growth, and late pregnancy with its precipitated preparation for breastfeeding. In the fetal phase, the more pronounced vulnerability is the result of the immaturity of most protection fostering mechanisms such as DNA repair, functioning of the immune system, enzymes and liver metabolism, and incomplete formation of the blood–brain barrier (BBB) to ensure protection against external aggression (Fenton et al., 2012). Developmental stage–related susceptibility may be determined by biomarkers as well, and recent research has focused on rodent models to offer evidence of potential epigenetic or underlying genetic risk factors. Thus, the following have been deemed of significance and they have been presented in order of relevant life stage importance.

Gestation and Development of the Fetus

Summarized in the theory of "fetal basis of adult disease," the first 3 months of pregnancy in particular and the entire pre-birth period are characterized by quick cellular division and growth, susceptible to the influence of environmental toxicity or modified hormone (such as estrogen) action (Birnbaum and Fenton, 2003), which can alter underlying tissue structure, function, and programming (Fenton et al., 2012).

The risk of cancer later in life has been suggested to be influenced by endogenous factors, such as altered hormonal exposure as indicated by weight at birth, gestational age, birth order, twins and maternal age, and preeclampsia (Park et al., 2008). The influence of elevated estrogen levels during pregnancy on cancer risk later on is also apparent from exposure during pregnancy to exogenous agents capable of endocrinal disruption (such as diethylstilbestrol or phytoestrogens) (Hoover et al., 2011).

Puberty

As a period of rapid and substantial growth, puberty is the second life stage with an increased susceptibility to breast cancer. On an intrinsic level, puberty is normally governed by two endocrine processes: first, development of the hypothalamic–pituitary–gonadal axis (gonadarche) and secondly, maturation of the hypothalamic–pituitary–adrenal axis and the ability to produce and secrete androgens (adrenarche) (Fenton et al., 2012; Wan et al., 2012). This accounts for the capacity of disturbances in either or both axes to determine modified pubertal timing.

The onset of puberty is indicated by physical markers such as breast development, the so-called "growth spurt," growth of pubic hair, and the first menstrual cycle and its development towards regularity (Fenton et al., 2012). Breast, bone, and brain development are under the control of estrogens (reviewed in Fenton et al., 2012). However, early onset of puberty may be the result of disruptions with major effects on cancer risk.

Precocious puberty may be determined by hormonal profiling and the appearance of sudden breast development or pubic hair growth (Carel et al., 2004), together with an assessment of bone age and performance of pelvic ultrasound checks. This is usually identified in girls under 8 years of age. Elevated breast density is a very relevant risk factor for breast cancer (higher breast tissue density means five times more likely to develop cancer) (IBCERCC, 2013). Early breast development and increased numbers of terminal duct lobular units increase vulnerability to exposure to carcinogenic factors (Fenton, 2006; Biro et al., 2010).

Precocious onset of menarche is also a risk factor for breast cancer (D'Aloisio et al., 2013), so much so that a woman's risk is approximately 10% lower for each year of menarche delay (Biro et al., 2010). According to recent studies, an association has been established between early onset of menarche and vitamin D deficiency [defined as 25-hydroxyvitamin D [25(OH)D] blood level<20 ng/mL (IOM, 2011)], which makes vitamin D deficiency an important factor in breast cancer risk. Other intrinsic factors include height and obesity. In a pubertal pattern of growth, height is in direct relation to estrogen as well as a sex steroid–dependent increase in growth hormone and production of insulin-like growth factor-I (Carel et al., 2004), making it a definite risk factor for breast cancer. Obesity, on the other hand, as indicated by body mass index (BMI) is a risk factor for breast cancer in young girls, as associated with precocious breast development (Biro et al., 2003; Wan et al., 2012) triggered by increased body fat (Biro et al., 2003), and women after menopause. Exogenous agents, such as exposure to radiation and environmental compounds, directly determine DNA mutation, subsequently altered mammary gland

environment, and deregulation of the mammary stem cell (IBCERCC, 2013).

Susceptible stages in adulthood are pregnancy and lactation because hormonal developments and changes in the morphology of terminal duct lobular units (Kobayashi et al., 2012; Faupel-Badger et al., 2013) may also increase cancer risk.

Pregnancy

In epidemiological studies, pregnancy has been shown to generally lower the breast cancer risk for the longer term, despite its transitory short-term effect of increasing post-birth risk due to the stimulation of malignant cell transformation. Thus, multiple births are a strong protective factor for breast cancer risk (Faupel-Badger et al., 2013).

Lactation and Breastfeeding

Milk secretion and breastfeeding involve all developments turning the mammary epithelium into a mature milk-producing gland (Faupel-Badger et al., 2013) after birth (Neville et al., 2001). According to research, breastfeeding and particularly sustained lactation can be a protective factor as far as breast cancer is concerned (Bernier et al., 2000; Kobayashi et al., 2012), possibly due to a decrease in estrogen exposure resulting from fewer menstrual cycles.

Family History

A family history of breast cancer is a predictor of likely disease, even though if present in first- or second-degree relatives. When diagnosis of the relative in question occurs at age 50 or in case of multiple relatives affected by the disease (Pharoah et al., 1997).

Genetic Modifications

Despite the fact that testing for different genetic biomarkers is comparatively easy to perform, the challenge lies in the ability to consider these biomarkers in their context, making efforts toward predictive genetic testing while not overlooking the medical, social, and psychological implications of results, whether positive, negative, or pending (Walsh et al., 2016).

History of Benign Conditions

A personal history of nonproliferative benign conditions such as fibroadenomas and cysts is not a marker of high breast cancer risk (Page et al., 2003; Dupont et al., 1993). However, the risk rises by 1.5−1.9 with proliferative benign conditions, such as papilloma, hyperplasia, or radial scar, and 4−6 times for atypical lobular or ductal hyperplasia.

Prognostic Factors

Although not thoroughly clarified and therefore not formally endorsed for overall clinical use, criteria such as the stage (extent) of the disease, tumor grade, expression of estrogen receptors, expression of progesterone receptors, and human epidermal receptor-2/neu are among the prognostic factors used to determine the likely progression of the disease (Harris et al., 2007; Bast et al., 2001). Given its importance among prognostic factors, staging is currently achieved based on the TNM system (Singletary et al., 2002), as it focuses on indicators of clinical importance such as the size of the tumor (T), involvement level of lymph nodes (N), and presence of distant metastases (M).

Although not predictive of response to therapy, the above characteristics are strong individual predictors of future progress of the disease, with tumor size indicating death independently from the other criteria. Generally, poorer prognosis is evidenced by larger tumor size, greater number of affected lymph nodes (Cianfrocca and Goldstein, 2004), and presence of distant metastasis (with 2 years median overall survival time) (Giordano et al., 2004). Another prognosis factor, tumor grade, is established as high, moderate, or low, with high-grade disease characterized by faster progression and extreme potential for spreading.

Currently, grading is mainly achieved using the Nottingham histological grade system (Elston and Ellis, 1991), based on criteria referring to glandular formation and cell-related aspects such as size, shape, proliferation rate, and pattern. As far as disease markers are concerned, the most important to examine as far as prognosis are the expressions of the estrogen and progesterone receptors, both belonging to the steroid hormone receptor group.

Generally, expression of the estrogen and/or the progesterone receptors is predictive of improved response to hormonal therapy and better survival. Expression of both receptor types indicates up to 80% effective response. Expression of the estrogen receptor only predicts 30% responsiveness, whereas absence of either receptor expressions indicates nonresponsiveness to estrogen receptor modulator therapy (Lapidus et al., 1998).

An additional marker to examine is the human epidermal growth factor receptor 2 (HER2/neu) of the HER receptor tyrosine kinases. This is overexpressed in 30% of breast cancers, which are more aggressive and show poor prognosis. The drug of choice for the treatment of HER2/neu overexpressing breast cancer cases is trastuzumab (Menard et al., 2003).

Other gene expression profiles have recently been researched to help predict responsiveness to therapy and the likelihood of recurrence and response to

treatment (e.g., assays such as Oncotype DX, the Mam-maPrint test, the Rotterdam Signature, and the Breast Cancer Gene Expression Ratio) (Harris et al., 2007).

Detection and Screening

The current means used for breast cancer detection and screening are physical examination combined with imaging tools such as ultrasonography, mammography, magnetic resonance imaging (MRI), and positron emission tomography, as well as analysis of tumor markers.

Tumor Marker Analysis

The term "tumor marker" refers to features distinguishing the tumor from normal tissue, which are measurable and/or visible outcomes of tumourigenesis (Levenson, 2007).

Biomarkers' efficacy depends directly on the degree of their clinical sensitivity (the ratio of subjects with confirmed disease with positive test results) and specificity (the ratio of healthy control subjects with negative test results) (Pepe et al., 2001).

The main characteristics of effective detection biomarkers include: (1) none or minimal invasive, (2) use of only small specimen amounts, (3) site-specificity expressed in the ability to discern between nonmalignant and malignant events at the level of the same tissue/organ, (4) enhanced specificity allowing for limitation of false-positive results, (5) ease of performance, (6) cost-effectiveness, and (7) independence from the observer (Levenson, 2007).

In relation to breast cancer, researchers have examined a range of analytes of biological molecules with the potential to act as biomarkers for the disease. Therefore, various carbohydrates, lipids, polyamines, proteins, DNA, and RNA have been studied in breast tissue, plasma, serum, and ductal lavage fluid or nipple aspirate fluid (Levenson, 2007). The study of proteins as biomarkers (proteomics) applies biochemical analysis to proteins and focuses on the function of expressed genes. Thus, proteomics is able to render an accurate and dynamic account not only of the cell intrinsic genetic program but also of the impact of its proximal environment. This ability of proteomics to relate gene sequence to cellular physiology suggests the usefulness of biomarker discovery for complementing the genome with the proteome.

In addition, with the aid of recent techniques such as matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) and surface-enhanced laser desorption/ionization (SELDI-TOF MS), high-throughput analysis of the proteome has become feasible. However, the tumor marker value of proteins remains to be clarified through comprehensive prospective clinical studies, and the only cancer biomarker with proven effectiveness is the prostate-specific antigen screening for prostate cancer (Lane et al., 2010).

Among proteins with a substantial value for breast cancer diagnosis, prognosis, or prediction, one should mention CA27-29 and CA15-3 (Gast et al., 2009; Duffy, 2006) or the extracellular mucin 1 (MUC1) protein (antigens for MUC1). MUC1 overexpression and aberrant glycosylation are markers for several cancer types. Recent studies have focused on the capacity of autoantibodies to aberrant O-glycoforms of MUC1 to operate as diagnostic biomarkers. Further sensitive biomarkers for effective early detection of breast cancer have been found in cancer-associated immunoglobulin G autoantibodies in breast cancer patients' serum against various aberrant O-glycopeptide epitopes derived from MUC1 (Wandall et al., 2010).

The technique of measuring gene expression from available sequence information (genomics) allows for determination of an expression profile representing cell function and phenotype (transcriptome). Such molecular signatures of potential biomarker value for early detection have recently come within reach by means of such technologies as multiplex polymerase chain reaction (PCR) (Srinivas et al., 2001) and cDNA oligonucleotide arrays.

In addition, according to certain studies, it seems that plasma mRNA may be used as a highly sensitive tumor marker thus allowing earlier cancer detection (Silva et al., 2002). However, research needs to be continued to resolve the problem of RNA stability in the bloodstream, more so in the presence of high serum ribonuclease levels found in cancer patients (Levenson, 2007).

Testing for Genetic and Molecular Changes

Genetic testing for mutations in breast cancer susceptibility genes such as BRCA1, BRCA2 (conducted so far in over one million individuals), and other genes is one prototype for the incorporation of genomics into personalized medicine practice. It has proved effective for both improvement of specific strategies for screening and prevention and use as a marker in targeted therapy. However, close compliance with the principles of genetic counseling has become even more important with the increasingly rapid development of molecular sequencing for the purposes of successful targeting of therapies. At the same time, it is key to establish whether genomic analysis is conducted to determine inherited susceptibilities or whether its primary purpose is genomic analysis of the tumor.

Approximately 30% of high-risk breast cancer families and around 15% of breast cancer familial relative risk (i.e., the disease risk for an affected individual's relative/the disease risk for the general population) may be attributed to pathogenic mutations (King, 2014;

Bahcall, 2013; Antoniou et al., 2008; Rebbeck et al., 2011). However, the difficulty arises to contextualize the risk of disease of inherited mutations and sequence variants in BRCA1/BRCA2.

Syndromes Predisposing to Breast Cancer

Hereditary Breast and Ovarian Syndrome

Given the numerous cases of worldwide breast cancer obviously developed as the result of an inherited predisposition, the identification of mutated genes as genetic risk biomarkers markedly increases in relevance. Thus, genetic testing becomes all the more important and worthwhile, so much so as early detection results in a more than 90% cure rate. In that respect, as highlighted above, BRCA1 and BRCA2 predominate among breast cancer susceptibility genes. BRCA1 is a large gene, consisting of 24 exons, out of which 22 are coding; the remaining two are noncoding. The location of BRCA1 is chromosome 17.

BRCA2 consists of 27 exons and is located on chromosome 13 (genenames.org).

Both genes are involved in DNA response to damage and in homologous recombination (Venkitaraman, 220).

Families with a history of both male and female breast cancers show higher pretest probability for BRCA2 testing, whereas families with both ovarian and breast cancers present higher pretest probability for BRCA1 testing (Frank et al., 2002). According to epidemiologic studies, mutations in BRCA1 determine a 70% lifetime breast cancer risk by age 70 (Whittemore et al., 1997; Claus et al., 1991, 1993, 1996) and even 90% for certain families with frequent early onset of ovarian or breast cancers (Ford et al., 1994).

High Penetrance Genes Predisposing to Breast Cancer

Actual development of cancer depends on the contribution of factors such as the particular type of constitutional aberration in BRCA1 or BRCA2, occurrence of modifying genomic alterations, and influence of the environment. Susceptibility, however, exists mostly as the result of genomic aberrations consisting of premature truncations of the BRCA1 and BRCA2 proteins by frameshift or nonsense mutations.

Among the more than 2000 distinct rare variants of BRCA1 and BRCA2, there are missense mutations, intronic changes, and small in-frame deletions and insertions that have been reported (Breast Cancer Information Core; www.research.nhgri.nih.gov/bic). BRCA1 main domains are located in the RING finger, and BRCT domains and their involvement are key for DNA repair function.

The location of pathogenic, highly penetrant missense mutations in BRCA2 involves the DNA binding domain in particular (Guidugli et al., 2013, 2014). In BRCA1 and BRCA2 there occur extensive genomic structural variations or rearrangements, representing 14% of mutations and 2.6% of mutations, respectively. The difference in the volume of structural variations between BRCA1 and BRCA2 may be attributed to the numerous Alu repeats characterizing the genomic region of BRCA1 gene location (Judkins et al., 2012).

In relation to BRCA1 and BRCA2, "founder" (population specific) mutations have been identified, among which the mutations occurring in the eastern European Jewish population have been well studied and documented. Thus, BRCA1 is the site of two mutations (5382insC and 185delG) and BRCA2 undergoes one mutation (6174delT) and up to 3% of this population are carriers of such a founder mutation (Offit et al., 1996; Szabo and King, 1997; Thorlacius et al., 1997). Given that 5% of all mutations in BRCA1 and BRCA2 in breast cancer patients belonging to this population group display nonfounder mutations, reflex full gene sequencing may be necessary in the case of negative results (Szabo and King, 1997; Thorlacius et al., 1997).

Carriers identified from population studies show a lower degree of disease penetrance as compared with carriers evidenced by means of kindred-based studies.

Because of an almost 60% breast cancer risk and a 40% ovarian cancer likelihood by age 70, identified BRCA1 mutation carriers are encouraged to be regularly screened. On the other hand, the likelihood of developing the disease by the same age in carriers of the BRCA2 mutation is 49% for breast cancer and 18% for ovarian cancer (Chen and Parmigiani, 2007). However, a certain degree of risk variability has been observed between the two types of cancer, explained in part, in respect to the risk for ovarian cancer, of genotype—phenotype correlations suggested by statistical data, highlighting a connection between specific phenotypes and the location of BRCA1/BRCA2 mutations. This has prompted the assumption that frameshift- and nonsense-type mutations occurring in each distal and proximal genomic region associate with lower ovarian cancer risk compared to analogous mutations by the center of either coding sequence (also known as "ovarian cancer cluster regions") (Gayther et al., 1996, 1997). From the perspective of the mutation location, statistic cohort data gathered from BRCA1/BRCA2 mutation carriers in the records of the CIMBA group (Consortium of Investigators of Modifiers of BRCA1/BRCA2) highlight relative decreases in breast cancer risk and increases in ovarian cancer risk concerning mutations in each gene central region. At the same time, there seems to be a higher breast cancer risk concerning mutations in the 3′ and 5′ regions in each gene.

An additional clarification for this risk variability comes from genome-wide association studies, which have prompted for the action of common genetic modifiers of ovarian and breast cancer risks in BRCA1/BRCA2 mutation carriers (Antoniou et al., 2010; Gaudet et al., 2010; Rebbeck et al., 2011; Wang et al., 2010).

The risk derived from the genomic location of BRCA1/BRCA2 mutations combined with that triggered by modifier genes differentiates between BRCA1 mutation carriers and BRCA2 mutation carriers at highest risk; thus, by age 80, the likelihood in the former carrier group to develop breast cancer is >81% and for ovarian cancer it is >63% (Gaudet et al., 2013).

If considered in the context of further risk-modifying variables observed in carriers of the BRCA1/BRCA2 mutation, mutation location and modifier genes are currently emerging as significant genomic biomarkers, whose worth may reside in their prospective capacity to better estimate the risk itself and to provide improved prognosis of disease behavior. An additional value may lie in profiling the phenotype of hereditary disease (such as the estrogen receptor status). This has been suggested by the observed tendency of tumors in BRCA1 mutation carrier breast cancer patients toward more aggressive disease features (Bignon et al., 1995; Jacquemier et al., 1995; Johannsson et al., 1997; Robson et al., 1998). However, accurate interpretation of genetic biomarkers for inherited risk needs to also take note of variants of unknown significance (e.g., small in-frame deletion/insertion variants, as well as intronic and missense ones).

Classification of these variants in all genes as neutral/low effect (Lindor et al., 2012) or pathogenic is a difficult task in clinical genetic testing. In the absence of an established database, such classification used animal or in silico models in an attempt to as nearly as possible infer the behavior of the disease in humans from patterns of development profiled in animals is difficult. It is also challenging to predict the functional influence of encountered variants on the foundation of the structure and/or conservation of amino acids. More recently, efforts have converged toward initiation of a database, which is designed for organization and oversight of clinical information on such variants (Clinvar—www.ncbi.nlm.nih.gov/clinvar).

Consistent work by the International Evidence-Based Network for the Interpretation of Germline Mutant Alleles (ENIGMA) Consortium has focused on BRCA1 and BRCA2, furthered by the Global Alliance for Genomics and with the aim of establishing an international database of BRCA1/BRCA2 variants. In addition to the database of variants of unknown significance as a tool for more accurate interpretation of genetic biomarkers, research has also endeavored to design quantitative risk prediction methods as necessary algorithms for assessment of such variants'

likelihood for pathogenicity. Thus, for each variant envisaged, work involves measurement of family disease history, conservation, the pathology of the tumor and RNA splicing effects (Guidugli et al., 2013; Spurdle et al., 2012; Iversen et al., 2011; Lindor et al., 2012), and combined evolutionary sequence conservation (Guidugli et al., 2013, 2014; Lindor et al., 2012, Tavtigian et al., 2008, Goldgar et al., 2004). However, the need to compensate for the lack of statistical power concerning individual or rare variants has prompted development and use of high-throughput quantitative cell-based in vitro assays, aimed at providing a reliable estimate of their outcome in relation to BRCA1 and BRCA2 protein functions. Specificity and sensitivity for the variant specific biomarker VUS (Guidugli et al., 2013) or variants of unknown significance are assessed with acknowledged controls of normal versus pathogenic mutations.

Hypomorphic mutations preserve protein activity to some extent, but they also present particular difficulties in gene variant interpretation. Identification and clinical validation of variants or biomarkers in genes predisposing to breast cancer, which feature more moderate risk, allow for the design of increasingly personalized strategies for surveillance and prevention of disease.

Therapeutic Implications of Genetic Biomarkers

Clinical management of individuals with BRCA1 and BRCA2 mutation has been adjusted from the perspective of genetic testing. Genetic testing is a valuable source of information for evidence-based medical decisions. Identification of BRCA mutations requires constant surveillance of the breast, achieved by means of the carrier's self-examination, accompanied by clinical examination, and sustained and validated by mammography, sonography, or MRI (Burke et al., 1997; Kriege et al., 2004; Morris et al., 2003), which should be performed annually as early as the age of 25 in women at hereditary risk (Mettler et al., 1996).

Mammography and MRI, however, show different levels of sensitivity in the case of BRCA mutation carriers, with the former missing as many as 29% of new tumors thus making MRI the standard one. Breast cancer risk for BRCA1 and BRCA 2 mutation carriers may also be significantly (>90%) decreased by mastectomy, but this is comparatively infrequent. Chemoprevention is a further means of breast cancer risk reduction in BRCA1 and BRCA2 mutation carriers as well, and studies are underway to develop more advanced options than tamoxifen.

The standard current means to reduce risk in such mutation carriers is salpingo-oophorectomy, with effectiveness rates between 80% and 96% for ovarian cancer (Kauff et al., 2002; Rebbeck et al., 2002; Finch et al.,

2006) and approximately 50% for breast cancer. This is most likely due to its capacity to induce menopause (Kauff et al., 2002; Rebbeck et al., 2002; Eisen et al., 2005), resulting in a 60% reduction of overall mortality in these patients (Domchek et al., 2010). Several drugs have proven effectiveness against BRCA1 and BRCA2 cancers, such as platinum chemotherapy and poly(-ADP-ribose) polymerase inhibitors.

Other Highly Penetrant Breast Cancer Predisposing Genes

One important outcome of the development of sequencing technologies is the discovery of further predisposing genes, such as TP53 and CDH1. Although rare, genomic alterations in the TP53 gene encoding the tumor suppressor protein p. TP53 is involved in Li-Fraumeni syndrome and a comparatively increased risk of breast cancer (Hisada et al., 1998). Negative/Indeterminate results in tests for BRCA1 and BRCA2 mutations testing and a marked history of cancer in the family require testing for TP53 mutation. In addition to the diffuse gastric cancer risk, CDH1 mutation carriers also face a 40%–50% risk of lobular breast cancer (http://www.nccn.org/professionals/physician_gls/pdf/genetics_screening.pdf). Further, highly penetrant breast cancer predisposing genes PTEN and STK11 determine overt phenotypes such as PTEN hamartoma tumor syndromes and the Peutz-Jeghers syndrome in respective patients of marked breast cancer risk (Amos et al., 2004; Boardman et al., 1998, 2000a; b).

Moderate Penetrance Breast Cancer Genes

Carriers of moderately penetrant breast cancer predisposing genes such as CHEK2, ATM, PALB2, BRIP1, RAD51C, RAD51D, BARD1 should be subjected to screening in line with the patient's family and personal histories.

Low Penetrance Breast Cancer Polygenes

Breast cancer risk may also be weakly increased by common genetic variants (e.g., TGFBR2, MYC, TET2) identified in genome-wide association studies in 76 loci (Couch et al., 2014; Michailidou et al., 2013; Maxwell and Nathanson, 2013). Although still unclear for the most part, one of their mechanisms of action is via gene transcription. Among relevant signatures, single nucleotide polymorphisms, microsatellite instability, and epigenetic changes (e.g., changes in DNA methylation) should be mentioned.

Epigenetic changes such as DNA methylation involve markers regulating gene expression, but these do not modify the original DNA sequence. Such markers may undergo modifications themselves and may be inherited. As a gene expression regulator, DNA methylation can silence genes for tumor suppression and thus bear significant influence on tumorigenesis.

The value of biomarkers for DNA methylation relies on the similarity of primary tumor and blood plasma methylation patterns (Hoque et al., 2006) in the very incipient stages of breast tumor progression (van Hoesel et al., 2013; Radpour et al., 2011; Fabian et al., 2005; Wong et al., 2011; Yan et al., 2006). The proven high sensitivity (>90%) of plasma measurement of DNA methylation of certain genes renders it an effective prospective means for screening.

DNA Methylation, Definitions, and Measurement Methods

Altered gene expression is mainly triggered by microRNA expression, DNA methylation levels, and histone modifications. Epigenetic phenomena for which DNA methylation is key are cell development and differentiation, genomic imprinting and silencing of transposable elements, and inactivation of the X-chromosome. As representative of DNA methylation, methylated cytosine 5-methylcytosine (5mC), found in approximately 4% of cytosines, is an outcome of adding a methyl group to the 5′ position of cytosine mainly in CpG sequences. As a result of hypomethylation, total 5mC levels are known to be lower in tumors compared with neighboring tissues (reviewed in Robertson, 2005). This DNA loss of methylation occurs mainly in repetitive DNA elements, resulting in their reactivation and enhanced aberrant recombination, rendering them genomically unstable.

Gene-specific hypomethylation is also possible and leads to repeated expression of affected genes. Hypomethylation is a modification occurring early in cancer. The opposite phenomenon, gene-specific increase in epigenetic methylation (hypermethylation), more commonly occurs in the CpG island promoters. Its capacity to lead to gene inactivation is relevant for cancer as it also affects tumor suppressor genes, as well as mutation. Numerous genes feature hypermethylated CpG island promoters in breast cancer, which are involved in regulation of the cell cycle, in DNA repair, in the remodeling of chromatin, in cell signaling, and in transcription and tumor cell invasion and apoptosis.

An additional important type of methylated cytosine is 5-hydroxymethylcytosine (5hmC), even if at significantly lower levels. The 5hmC cytosine results from oxidation of 5mC by Tet enzymes (Kohli and Zhang, 2013). This pathway of oxidation can continue, rendering 5-carboxylcytosine and 5-formylcytosine, as substrates for the DNA repair enzyme thymidine–DNA

glycosylase, emerging as one mechanism for methyl group removal from cytosine.

IMPACT OF METHYLATION BIOMARKERS

DNA Methylation Markers and Primary Prevention

In the context of increasing research efforts for cancer prevention, studies have also been directed toward assessment of the potential of DNA methylation as a biomarker for cancer risk evaluation. From the various studies conducted, some have aimed to examine the correlation between breast cancer risk and DNA methylation, both gene specific and global (reviewed in Terry et al., 2011; Brennan and Flanagan, 2012).

For instance, risk assessment studies were performed on white blood cell DNA, concluding on significant association of both hyper- and hypo-global methylation with breast cancer, highlighting the potential as a biomarker for breast cancer risk global DNA methylation.

However, there are certain limitations at this time to the approach of DNA methylation as cancer risk predictor, such as a certain degree of uncertainty derived from the potential for resulting data to be in fact an outcome of differences in cell populations or a response to underlying disease. In addition, DNA methylation can be influenced by other factors as well, such as genetics and age, to which lifestyle and environmental factors may be added (e.g., diet, smoking, air pollution, heavy metals, stress) (Terry et al., 2011; Bakulski and Fallin, 2014). Therefore, evaluation of the value of DNA methylation as a predictor for cancer requires larger population studies, allowing for extended follow-up, as well as serial blood collections (Pepe et al., 2001).

DNA Methylation Markers for Secondary Prevention and Early Detection

Screening tools for diagnosis and to determine treatment and prognosis are proposed as secondary preventive means. Despite its proven practical usefulness in effectively reducing breast cancer mortality for women at medium risk, regular screening by mammography (Mandelblatt et al., 2009; Webb et al., 2014) is generally not entirely satisfactory in specificity and sensitivity and even more limited in the case of younger females or those with dense breasts (Elmore et al., 1998; Alagaratnam and Wong, 1985; Moss, 2004; Qaseem et al., 2007). Such limitations as well as the complexity of the disease make a single-marker approach insufficient

for effective early detection. The basic principle underlying the current general strategy in the management of cancer is to improve screening sensitivity and specificity by actively promoting the use of multiple various markers combined with different risk factors, adjusted for by reliable and validated statistical models (Wald et al., 1999).

Therefore, more effective early detection requires both discovery of additional markers and more precise assessment and stratification of risk. In that respect, biomarkers as additional screening means for early detection are useful for high-risk groups, as they have the ability to identify the disease in the absence of symptoms as well as in cases with normal results by mammography and breast examination (Evron et al., 2001). One such tool consists of plasma/serum cancer screening biomarkers such as the CA-125 for ovarian cancer.

A screening tool not used very often for secondary prevention is the category of blood biomarkers such as circulating cell-free DNA in the plasma, released from apoptotic and necrotic cells in the tumor. A number of studies have concluded that circulating DNA levels are higher in the presence of cancer. The potential usefulness of this blood-based biomarker has been further supported by the fact that, though initially examined for mutations, methylation patterns were discovered in circulating DNA that were similar to those of primary tumor ones (Gormally et al., 2007; Wang et al., 2010; Van De Voorde et al., 2012; Suijkerbuijk et al., 2011).

Methylation of plasma DNA has been found to possess early detection marker potential (van Hoesel et al., 2013) resulting from studies showing DNA hypermethylation of certain biomarkers (e.g., RARβ2, RASSF1A) in early breast cancer stages. Several specific characteristics support the biomarker potential of DNA methylation. Thus, promoter hypermethylation is more frequent than mutations and occurs early in breast tumorigenesis (Hoque et al., 2009; Lewis et al., 2005; Pasquali et al., 2007). In addition, aberrant DNA methylation in malignant cells also occurs in the immediate tissue. There are also technical aspects contributing to the usefulness of DNA methylation as a biomarker. Given its stability and as such the possibility for PCR amplification, analysis of aberrations only requires small amounts of DNA in comparison to gene expression profiling (Sidransky, 1997). Moreover, hypermethylated sequences are easier to detect compared to genetic alterations due to the positive signal they form against an unmethylated background. Furthermore, current research is being conducted on multiple genes such as RASSF1A, CDH1, BRCA1, APC, GSTP1, RARβ (reviewed in Ma et al., 2013, Van De Voorde et al., 2012, Suijkerbuijk et al., 2011).

For adequate sensitivity and specificity in the detection of breast cancer, a range of epigenetic markers should be used (Van De Voorde et al., 2012).

Results from research showing the presence of aberrant promoter hypermethylation in serum or plasma DNA in high-risk cases for a substantial amount of time prior to diagnosis further suggest its usefulness as a screening tool of plasma DNA methylation markers. In fact, there is increasing evidence that plasma DNA methylation of certain genes allows for over 90% sensitivity for breast cancer detection. One important benefit of blood markers for more effective screening is its use as an alternative or additional option to MRI and mammography, especially in cases where these screening tools have shown less sensitivity, and to reduce cumulative radiation.

DNA Methylation Markers and Tertiary Prevention and Role in Prognosis

Despite abundant information on DNA methylation in tissue samples at diagnosis, research of the correlation between DNA methylation patterns on diagnosis and subsequent prognosis and overall survival is scarce. Results of all recent studies that initiated on correlations between DNA methylation and breast cancer have converged toward cumulatively demonstrating the importance of methylation biomarkers present in tissue, plasma, and serum samples for secondary and tertiary prevention, as well as for prognosis of disease behavior and therapy outcome for the patient.

Further studies, especially cohort studies, are needed to accurately clarify the prognostic contribution of DNA methylation biomarkers, particularly in samples harvested at baseline. Continued extensive research is a necessary means to demonstrate the usefulness for screening and prognosis in general practice of complementing standard clinical markers measured at diagnosis (stage, grade, tumor size, molecular subtype) with assessment of methylation biomarkers.

To conclude, growing information on all aspects of the correlation between incidence of breast cancer and DNA methylation markers has not been fully clarified. Prospective research is required to eliminate temporality-related uncertainties resulting from the retrospective character of most studies thus far, which has made it difficult to determine whether aberrant methylation is a cause of or a consequence of cancer or its treatment. Future research also needs to ascertain, by repeated measurement, the potential for environmental factors to alter levels of DNA methylation markers, as well as the capacity of such modifications to influence the risk itself.

Finally, the panel of studied gene targets should be diversified.

MALE BREAST CANCER SUSCEPTIBILITY FACTORS

Epidemiology

Male breast cancer accounts for less than 1% of all breast cancers and only 0.2% of all cancers in males (ACS, 2013).

Pathology

Although rare, the glandular and adipose tissues of the breast in adult males can grow and proliferate as a result of a process similar to that occurring in females subject to high estrogen and progesterone levels, ending in disruption of the estrogen-to-androgen ratio (Johnson and Murad, 2009; Dickson, 2012). Growth of adipose tissue and a decrease of testosterone production thus inclining the estrogen:androgen ratio toward estrogen is the primary cause of breast cancer in men of age >65 (Niewoehner and Schorer, 2008).

In approximately 85% of cases, male breast cancer appears as a subareolar, unilateral thickening of the breast and is usually painless and may involve nipple retraction, ulceration, or discharge (Johansen Taber et al., 2010; Zygogianni et al., 2012).

Risk Factors

Major risk factors for male breast cancer include excess estrogen:androgen ratio, family disease history, inclusion in a particular ethnic group, occurrence of specific gene mutations, and environmental factors (Niewoehner and Schorer, 2008; Johansen Taber et al., 2010; Zygogianni et al., 2012; Ruddy and Winer, 2013). One of the most important causes of higher estrogen:androgen ratio underlying male breast cancer is the Klinefelter syndrome (XXY sex chromosomes), which is also characterized by more estrogen and progesterone receptors in the breast tissue (Aksglaede et al., 2013). Both of these features pose a very significant breast cancer risk (20−30 times normal) (Brinton, 2011).

Among other causes of excess estrogen:androgen ratio potentially leading to male breast cancer are low levels of androgen determined by such testicular anomalies as orchitis or cryptorchidism, elevated estrogen and androgen caused by congenital adrenal hyperplasia or Leydig cell tumor, therapy with exogenous estrogen, increased estradiol levels triggered by abnormal aromatase function or Sertoli cell tumor, abnormal levels of sex hormone binding globulin, hyperthyroidism, liver or renal disease, obesity, environmental antiandrogenic and proestrogenic factors (e.g., excessive heat), and carcinogenic compounds and radiation (Niewoehner and Schorer, 2008; Johansen Taber et al., 2010;

Zygogianni et al., 2012; Ruddy and Winer, 2013). Given their shared risk factors, gynecomastia may be considered a marker of breast cancer risk.

Recently, a new cause of gynecomastia has been added to the established one (high effect of estrogens or the low effect of androgens, i.e., use of estrogen receptor binding drugs e.g., digitalis, diazepam, and ketoconazole) and exogenous compounds (marijuana) (Niewoehner and Schorer, 2008; Swerdloff and Ng, 2011).

Another important risk factor for male breast cancer is mutation in the BRCA2 gene (accounting for 5%–10% likelihood) and, to a lesser extent, the BRCA1 gene (Ruddy and Winer, 2013). Because of a current lack of awareness of this disease in men, screening and breast examination for males is infrequent, which sharply diminishes the possibility for early detection. In over 50% of cases, tumors of the male breast are diagnosed at stage II or more, whereas this only happens in about 35% of cases in women (Johansen Taber et al., 2010; Zygogianni et al., 2012).

Cancer Aggressiveness Risk Factors

Accumulating evidence from clinical and epidemiological studies increasingly demonstrating the diversity of risk factors for cancer occurrence and for life-threatening cancer, as well as the complexity of their interplay, suggests a potential difference between pre-diagnostic risk factors for cancer occurrence and those for cancer death (Autier, 2012; Barnett et al., 2008), even in the same organ. This renders the significance of finding the so-called "cancer aggressiveness risk factor," consisting of individual-specific genetic, lifestyle, and/or environmental features or of measuring nontumor biomarkers to determine individuals who are more likely to develop aggressive, life-threatening cancers. From this perspective, it has been determined that even if highly instrumental in breast cancer risk, reproductive factors are weak for breast cancer mortality (Barnett et al., 2008). Though modest as breast cancer risk triggers in post-menopausal women, adiposity increases the risk for breast cancer death in women before menopause (Loi et al., 2005). The example of fertility may be added to these, which is generally a weak risk for breast cancer but an aggravating one for cancer death in women aged 40 and above and in those who give birth (Daling et al., 2002).

Impact of Cancer Aggressiveness Risk Factors for Patient Management and Health Policies

The identification of cancer aggressiveness risk factors is a most important tool for risk stratification and therefore proves useful for medical practice and health policies. Primary prevention would acquire the necessary base to target efforts in high-risk individuals by providing personalized counseling. Furthermore, given the basic purpose of screening to detect cancer early and thus prevent lethal disease outcomes, application of cancer aggressiveness risk factors would decrease harm from unnecessary screening in less aggressive cancer risk cases. By differentiating between subjects at higher risk of cancer death and those at mere higher risk of cancer occurrence, screening would thus become more cost-effective and improve participation due to better patient awareness.

At the same time, use of such tools would improve cancer patient stratification and referral, distinguishing between absence of life-threatening risk, where active surveillance is the adequate approach, and presence of life-threatening risk, requiring immediate treatment. A further benefit would impact decisions for therapeutic options, warning against cancer aggressiveness risk factors leading to likelihood of relapse despite an ostensibly favorable prognosis and endorsing more resolute management of such patients.

Lastly, discovery of such risk factors would greatly assist in clarification of biological mechanisms leading to poor prognosis for progression, relapse, and lethal cancer outcome. In the context of cancer overdiagnosis and resulting overtreatment with unnecessarily aggressive therapy, relevance of cancer aggressiveness risk factors for medical practice lies in their potential to prioritize referral to diagnosis and specialized care. By eliminating pseudocancers and borderline or in situ cancers from therapy, their use can increase cost-effectiveness of both screening and therapy and reduce associated harm.

Further research in this respect would prove highly beneficial for the design of screening policies, chemoprevention strategies, and making better-informed decisions on treatment options based on more accurate evaluation of relapse risks and would avoid unnecessary treatment.

INTRODUCTION

The challenge of caring for patients diagnosed with malignancies of the pancreas or ovaries remains daunting despite steady advances in risk assessment and treatment for these conditions. The prospect of curative treatment for both of these cancers is restricted to those patients who present with the earliest stages of disease; however, effective and practical methods of identifying these patients remain elusive. Clinical management of the majority of patients with pancreatic cancer (PC) or ovarian cancer (OC), for whom surgical resection is either not indicated or only indicated as a palliative measure, largely relies on systemic chemotherapy as the primary therapeutic option. Outcomes in the systemic treatment of PC and OC could be significantly improved with the use of biomarkers, aiding in the design of personalized treatment options offering the greatest chance of favorable responses. This chapter will provide an overview of recent and ongoing trends related to the use of biomarkers for diagnosis, prognosis and prediction of response to therapy in PC and OC with an emphasis on protein biomarkers measured in body fluids (Table 47.1). A discussion of currently used clinical biomarkers within each disease setting will be provided, followed by a review of the most promising recent findings related to novel biomarker development.

CURRENTLY USED CLINICAL BIOMARKERS

Cancer Antigen 19-9 in Pancreatic Cancer

The mucin-associated sialylated Lewis (a) antigen CA 19-9 is a biomarker of pancreatic duct adenocarcinoma (PDAC) with limited clinical utility in the screening setting. CA 19-9 has demonstrated modest effectiveness in screening of symptomatic individuals with a median sensitivity of 79% (range 70%–90%) and median specificity of 82% (range 68%–91%); however, it appears to be ineffective in screening of asymptomatic subjects (Goonetilleke and Siriwardena, 2007). The principal limitations include its frequent elevation in pancreatitis and obstructive jaundice that frequently cooccur with PC and a variety of other malignant and benign conditions. CA 19-9 is also severely limited in detecting many early stage malignancies and is unsuitable for use in the estimated 5%–10% of patients, who are carriers of the Lewis-negative genotype and develop tumors that do not express the antigen (Locker et al., 2006). The clinical usefulness of CA 19-9 is improved in patient cohorts enriched for pancreatobiliary disease (Pleskow et al., 1989).

Preoperative CA 19-9 levels offer modest prognostic value in localized and advanced PDAC, but are not accurately or reproducibly correlated with disease

---

TABLE 47.1   Overview of Diagnostic, Prognostic, and Predictive Biomarkers in Pancreatic and Ovarian Cancer

	Pancreatic Cancer	Ovarian Cancer
Diagnostic biomarkers	**Protein biomarker combinations**	**Protein biomarker combinations**
	Individual biomarkers CA 19-9 (symptomatic patients), OPN, TIMP-1, CEA, ICAM-1, osteoprotegerin, miRNAs, cell-free DNA (KRAS)	**Individual biomarkers** CA-125/HE4/LPA/mesothelin/PRSS8/tissue kallikreins/FOLR1/miRNAs/gene mutations
		FDA approved triage tools ROMA/ROCA/OVA1
Prognostic biomarkers	**Gene signatures**	**Gene signatures**
	Gene mutations *DPC4*	**Genetic markers** *RAB25, FGF1, ING-5*
	Protein biomarkers CA 19-9 (resectability, post-chemo), MUC1, MUC2, mesothelin, HuR, TgII, HES-1, HEY-1	**Protein biomarkers** OPN, kallikreins, cyclin E, VEGF, bikunin, relaxin, high progesterone and estrogen receptors, galectins, $CD8^+/CD20^+$, vasohibin-1, cyclin E, Ki67, E-cadherin)
Predictive biomarkers	**Protein biomarkers** HuR, miRNAs, SPARC, Hent1	**Gene signatures**
	Genetic markers *BRCA1, BRCA2, PALB*	**Protein biomarkers** kallikrein, bikunin, ABCF2, YB-1, miRNAs, long noncoding RNAs, IL-37, galectins, ERCC1, TUBB3, PGP, PDGFR-beta VEGFR2

clinical manifestations (Brody et al., 2011). Several studies observed Cox proportional hazard ratios for CA 19-9 comparable to lymph node and margin status (Barton et al., 2009; Hartwig et al., 2011). However, preoperative CA 19-9 levels with a cutoff value of 130 U/mL offer some indication of whether PDAC is resectable (Maithel et al., 2008). Postoperative levels of CA 19-9 offer much more substantial information regarding prognosis, with low, normalized levels indicating improved overall survival and a failure to normalize associated with median survival of <1 year. Nevertheless, normalization of CA 19-9 levels may take 3–6 months, representing a significant window of uncertainty for patients and physicians.

CA 19-9 is weakly prognostic before treatment with chemotherapy or radiotherapy and considerably more informative as a marker of response. Similar to observations regarding postoperative CA 19-9 in resectable PDAC, normalization of biomarker levels or failure to normalize is significantly associated with improved or diminished survival, respectively. The predictive performance of CA 19-9 is greatly limited by the variability among and within individuals diagnosed with PDAC. CA 19-9 levels for an individual patient may fluctuate considerably over time, resulting in an inaccurate impression of treatment response or disease progression that leads to considerable patient anxiety.

Cancer Antigen-125 in Ovarian Cancer

CA-125 is the most widely used OC biomarker to date. It is a high-molecular-weight membrane glycoprotein, encoded by the MUC16 gene. The precise function of CA-125 in normal physiology/development of malignancy has yet to be identified. The cutoff normal value of 35 KU/L has been determined from the distribution of healthy individuals to include 99% of the population.

The initial finding of CA-125 levels >35 U/mL in ∼83% of patients with advanced epithelial OC and in only 1%–2% of the normal population led to investigation of its use as a biomarker for early detection of OC (Bast et al., 1983; Zurawski et al., 1988). However, there are weaknesses that make its use as an early detection biomarker for OC equivocal. It is absent in 20% of OC because of nonepithelial carcinoma and elevated in numerous malignant and benign conditions such as endometrial cancer, endocervical cancer, PC, breast cancer, lymphoma, lung cancer, peritonitis, endometriosis, liver cirrhosis, pancreatitis, and acute pelvic inflammatory disease. Factors such as race/ethnicity, age, hysterectomy, smoking history, and obesity may influence CA-125 level. Despite these well-recognized limitations, CA-125 remains the most widely studied serum biomarker for OC. It is currently FDA approved for disease monitoring in all patients diagnosed with epithelial

OC and it is used concurrently with transvaginal ultra-sonography (TVS) in women with hereditary breast OC syndrome every 6 months after the age of 30 or 5—10 years before the earlier presentation age of cancer in their family.

The best available protocol for early detection of OC to date, a combination of screening for elevated CA-125 and TVS in the presence of elevated CA-125, does not meet the stringent criteria for cost-effectiveness espoused by the US Preventive Services Task Force. As a result, no professional group currently recommends screening for OC in the general population (Grossman et al., 2018). Despite the stand-alone biomarker weaknesses, CA-125 has been used together with other biomarkers such as the circulating receptor of alpha-fetoprotein to improving the sensitivity of the former for stages I/II and III/IV from 58.1% to 76% and 79.6% to 88.2%, respectively (Tcherkassova et al., 2011).

In the PLCO cancer screening trial, 78,216 healthy women between the ages of 55 and 74 were randomly assigned either to undergo annual CA-125 testing plus TVS or to receive "usual care." The positive predictive value of screening was 1.0%—1.3% during a 4-year period. However, 72% of detected cases were stage III or IV, indicating that screening does not result in stage shift. The PLCO project team concluded that the CA-125/TVS screening approach does not reduce disease-specific mortality in comparison to usual care but increases invasive medical procedures and associated harms (Pinsky et al., 2016). In the UKCTOCS, 202,638 postmenopausal women between the ages of 50 and 74 at average risk for OC were randomly assigned to annual pelvic examination (control arm), TVS alone (TVS arm), or measurement of CA-125 plus TVS in cases of elevated CA-125 level (multimodality arm) (Jacobs et al., 2016). Compared to the TVS arm, the multimodality arm showed a significantly greater specificity (99.8% vs. 98.2%) and a higher positive predictive value (35.1% vs. 2.8%); sensitivity did not differ significantly between arms. Both TVS and multimodality arms demonstrated a higher proportion of stage I—II cancers. Despite the initial analysis, the 7—14 year follow-up showed a significant mortality reduction in the multimodality arm when prevalent cases were excluded (Jacobs et al., 2016).

Following technological advances of the modern era, the use of computerized algorithms has managed to enhance the sensitivity of CA-125. Risk of Ovarian Cancer Algorithm (ROCA) uses patient's age and CA-125 to stratify them into low, intermediate, and high risk for OC, enabling clinicians to proceed with further interventions. It has been shown that ROCA improves CA-125 sensitivity to 86% in preclinical detection (Skates, 2012).

CA-125 has also been evaluated as a prognostic biomarker in OC both postoperatively and during disease remission. Following cytoreduction, a steep decline

is an indication of optimal surgical outcomes and a failure to demonstrate such a response is associated with suboptimal cytoreduction and increased risk of relapse (Yoo et al., 2008; Zivanovic et al., 2009). Clinical post-treatment remission is defined by imaging and normalization of CA-125 levels. Persistently abnormal levels following treatment indicate a high risk of recurrence within 6 months and a high likelihood of disease-related death. CA-125 retains prognostic value even in those patients who achieve a clinical remission with levels below 35 U/mL. Elevated levels within this normal range are associated with reduced overall and progression-free survival (Juretzka et al., 2007), whereas serially increasing values within the normal range are associated with increased risk of recurrence (Karam and Karlan, 2010). Current utility of CA-125 predominantly resides in monitoring patients in clinical remission for CA-125 levels, which become elevated out of the normal range preceding clinical and/or radiological indications of recurrence by 2—4 months (Bridgewater et al., 1999; Rustin et al., 1996, 2001; Tuxen et al., 2000, 2002; Vergote et al., 2000). However, clinical management of asymptomatic patients with elevated CA-125 levels remains controversial and a significant source of anxiety for patients.
